I. STUDIES ON THE REVERSIBLE INACTIVATION OF PAPAIN AND CATHEPSIN.

By ARNULF PURR.

From the Cancer Research Laboratories, Graduate School of Medicine, University of Pennsylvania, Philadelphia, Pa.

(*Received October 4th, 1934.*)

The natural activation of cathepsin and papain by sulphydryl compounds acquired increased physiological interest when it became known [Purr, 1933] that the combination, vitamin C-Fe″, can activate not only arginase but also cathepsin. Later, Maschmann and Helmert [1934] found a similar activation of papain by the vitamin C-Fe″ complex.

The activation of these two proteinases by such widely dissimilar types of compounds made it of interest to investigate further the mechanism of these activations. The experiments here reported show much promise, contributing not only to our knowledge of the nature of intracellular proteolysis, but also to our understanding of the part played by vitamin C in the regulation of cellular metabolic processes.

Since the initial activities of papain and cathepsin vary considerably for different preparations, it was necessary to devise methods for obtaining entirely inactive enzyme preparations. For comparative studies in enzyme activation, it was essential that these inactive preparations should retain the property of being completely reactivated upon addition of the proper activator.

Reversible inactivators of papain.

I. *Alloxan inactivation and reactivation.* Papain extract was prepared from a commercial Merck papain powder by 6 hours' extraction with 10 parts of water. After centrifuging, 4 ml. of the clear fluid were allowed to stand for 30 minutes at 30° and p_H 7 with 40 mg. of cysteine hydrochloride dissolved in 4 ml. of water. To the thus fully activated enzyme solution were then added 80 mg. of alloxan in 4 ml. of water, and the reaction mixture was incubated for 1 hour at 30° and p_H 7. The volume was brought to 20 ml., and the papain activity determined on 10 ml.; H_2S was bubbled through the remaining 10 ml. for 1 hour at p_H 7, and the degree of reactivation determined. (If cysteine be used for reactivation, it is necessary to use a large excess, 50 mg., because of the presence of excess alloxan.) The measurement of enzymic activity was carried out by adding 5 ml. of 8 % gelatin, 2 ml. of M acetate buffer of p_H 5 and sufficient water to bring the volume up to 25 ml. 10 ml. of this were analysed at once for free amino-groups, and a second 10 ml. after 1 hour's incubation at 30°. The increase of free amino-groups, determined by the Van Slyke method, constitutes a measure of the enzymic activity, the results being expressed in ml. of 0·05N KOH.

For the determination of the initial activity before inactivation, 2 ml. of the papain extract, prepared as described above, were mixed with 5 ml. of 8 % gelatin, 2 ml. of *M* acetate buffer of p_H 5 and sufficient water to bring the total volume up to 25 ml. Amino-group determinations were carried out immediately and after 1 hour's incubation at 30° on 10 ml. portions of the mixture, exactly as previously described. For the determination of full activity before inactivation, 2 ml. of the original papain extract were fully activated by passing a stream of H_2S for 1 hour at 30°. The rest of the treatment was identical with that just described.

II. *Methylglyoxal inactivation and reactivation.* The experimental details of this experiment were identical with those described for alloxan, except that for inactivation 48 mg. of methylglyoxal in 5 ml. of water were used in place of the alloxan. The methylglyoxal was prepared by distillation of dihydroxyacetone with dilute sulphuric acid according to the method of Neuberg *et al.* [1917]. Since the same papain extract was used, the initial and full activities before inactivation are the same as those in the case of alloxan.

Table I. *Reversible inactivation of papain by alloxan and methylglyoxal.*

Reversible inactivator	Papain activity before inactivation: Initial activity	Papain activity before inactivation: Full activity	Papain activity after inactivation	Reactivation: Cysteine	Reactivation: H_2S
	0·80	3·54	—	—	—
Alloxan	—	—	0·0	3·50	3·65
Methylglyoxal	—	—	0·0	—	3·60

The results given in Table I (as NH_2 increase in ml. 0·05*N* KOH) show not only that alloxan and methylglyoxal completely remove the slight initial activity present in the papain preparation, but also that the enzyme, after inactivation by these compounds, may be completely reactivated, showing that the enzyme itself has not been damaged. In separate experiments with the nitroprusside test for SH groups, it was found that the inactivation is connected with a disappearance of the SH reaction. This finding demonstrates the dependence of papain activity on the presence of SH groups.

The inactivation of papain by alloxan and methylglyoxal differs sharply from that brought about by iodoacetic acid. The inhibition produced by the latter, which is irreversible, will be discussed later in more detail.

III. *The system "aerobic dehydrogenase-peroxidase."* The application of this system to the reversible inactivation of papain is suggested by the illuminating work of Thurlow [1925], who found that the system aerobic dehydrogenase-peroxidase catalyses the formation of H_2O_2 from molecular oxygen. An aerobic dehydrogenase, such as xanthine oxidase, is able, in the presence of hypoxanthine, to make molecular oxygen directly available as a hydrogen acceptor, and, in the presence of excess oxygen, to produce H_2O_2. As Thurlow found, the quantity of H_2O_2 formed is very small at the beginning of the experiment, but as soon as the greater part of the hypoxanthine is converted into xanthine, the quantity increases remarkably. Bach and Chodat [1903] have defined as an oxygenase a system which is able to convert molecular oxygen directly into H_2O_2. Thurlow showed that the system xanthine dehydrogenase-hypoxanthine falls within the classification of oxygenases.

In contrast to this are the anaerobic dehydrogenases, such as lactic dehydrogenase, which do not possess the ability to react directly with molecular oxygen

Only the addition of a small quantity of methylene blue enables the system to react with molecular oxygen. The methylene blue acts as an intermediate carrier (hydrogen acceptor) between oxygen and the dehydrogenase substrate.

Peroxidase is an enzyme which activates the oxygen in the H_2O_2 molecule. This active condition of the oxygen enables it to transfer its oxidation potential very easily to other substances, which themselves are oxidisable.

If such a system (aerobic dehydrogenase + substrate + peroxidase) is added to a papain preparation, and care is taken that the oxygen of the air comes into intimate contact with the solution, a complete inactivation of the papain is obtained. This inactivation occurs only when all the components mentioned are present, the separate components being without effect on the enzymic activity.

The procedure for the inactivation was as follows: 30 mg. of milk xanthine oxidase (prepared by the method of Dixon and Thurlow [1924]), 1 mg. of hypoxanthine and 10 mg. of milk peroxidase [Elliott, 1932] were dissolved in 2 ml. of water and added to 2 ml. of the papain extract previously described. 1 ml. of $M/10$ phosphate buffer of p_H 7 was added. Air was then bubbled through the solution for 3 hours, after which 5 ml. of 8 % gelatin, 2 ml. of M acetate buffer of p_H 5 and sufficient water to bring the total volume up to 25 ml. were added. Amino-determinations were carried out immediately, and after 1 hour's incubation at 30°, on 10 ml. portions. The results are shown in Table II as NH_2 increase in ml. of $0 \cdot 05 N$ KOH. A similar inactivated reaction mixture was treated with H_2S for 1 hour at p_H 7 and the degree of reactivation obtained measured as previously described. The determination of initial and full activity of the papain before inactivation was carried out as described under Table I.

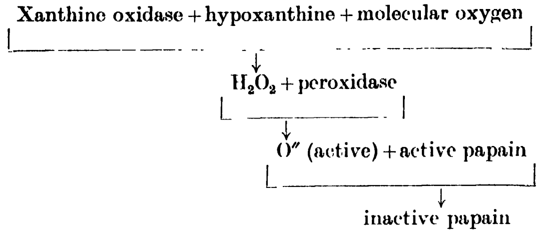
The following control experiments were carried out: (*a*) 2 ml. of papain extract were diluted with 2 ml. of water and 1 ml. of $M/10$ phosphate buffer of p_H 7; air was then bubbled through for 3 hours and the papain activity determined as described above; (*b*) same as (*a*) except that 1 mg. of hypoxanthine was added; (*c*) same as (*a*) except that 1 mg. of hypoxanthine and 30 mg. of milk xanthine oxidase were added; (*d*) same as (*a*) except that 30 mg. of milk xanthine oxidase and 10 mg. of milk peroxidase were added.

Table II. *Reversible inactivation of papain by respiration ferments.*

Reversible inactivator	Papain activity before inactivation: Initial activity	Papain activity before inactivation: Full activity	Papain activity after inactivation	Reactivation: Cysteine	Reactivation: H_2S
	0·90	3·50	—	—	—
D + Hy. + Per. + O_2	—	—	0·05	3·50	3·40
O_2 (3 hours)	—	—	0·90	—	—
Hy. + O_2	—	—	0·90	—	—
Hy. + D + O_2	—	—	0·85	—	—
D + Per. + O_2	—	—	0·90	—	—

D = aerobic dehydrogenase; Hy. = hypoxanthine; Per. = peroxidase.

As shown in Table II, the reversible inactivating effect on papain is obtained only by the simultaneous action of xanthine oxidase (aerobic dehydrogenase), hypoxanthine (substrate for the dehydrogenase), peroxidase and excess oxygen. From these findings, which for the first time demonstrate the dependence of intracellular proteolysis on the respiration ferments, it may be concluded that the following intermediary steps are responsible for the papain inactivation:



Xanthine oxidase + hypoxanthine + molecular oxygen
H_2O_2 + peroxidase
O″ (active) + active papain
inactive papain

IV. *Hydrogen peroxide.* Preliminary experiments on the reversible inactivation of papain with hydrogen peroxide gave satisfactory results. A method was therefore developed which permits the preparation of large quantities of inactive papain in a stable, pulverisable form.

To an aqueous solution of 5 g. of papain (Merck) in 100 ml. are added 3 ml. of 30 % H_2O_2, and the mixture is allowed to stand 1 hour at 30°. The enzyme is then precipitated by addition of 600 ml. of 95 % alcohol, centrifuged, and the residue washed twice with 95 % alcohol. After the final centrifuging, the residue is redissolved in 100 ml. of water (any insoluble matter is removed by centrifuging) and treated again with H_2O_2 and alcohol as described above. This procedure is repeated five times. The final precipitate is dried *in vacuo* over P_2O_5 and powdered.

For reactivation experiments, the inactive powder was extracted with 40 parts of water and centrifuged. 1 ml. of the liquid (comparable in activity with 2 ml. of crude papain extract before inactivation) was brought up to 5 ml. with water, mixed with 20 mg. of cysteine HCl in 2 ml. and allowed to activate for 30 minutes at p_H 7. The measurement of enzymic activity, as well as the determination of initial and full activity before inactivation, were carried out as previously described.

Table III. *Reversible inactivation of papain by hydrogen peroxide.*

Reversible inactivator	Papain activity before inactivation		Papain activity after inactivation	Reactivation	
	Initial activity	Full activity		Cysteine	H_2S
	0·80	3·30	—	—	—
H_2O_2	—	—	0·0	3·35	3·40

Table III shows that papain inactivated by hydrogen peroxide can be fully reactivated, just as is the case with the other inactivators described in this paper. The method described for the inactivation of papain by hydrogen peroxide possesses the advantage of being easily performed. The technique is therefore peculiarly adapted to the preparation of large amounts of papain, so that comparative activation studies on this enzyme are made much simpler.

Reversible inactivation of cathepsin.

I. *Alloxan.* Rat liver was used as the source of cathepsin. Liver from well-bled rats was finely ground in a micro-mincing machine (Leitz). The "brei" thus obtained was suspended in 10 parts of 90 % glycerol and used directly for the enzyme studies.

To obtain an estimate of the initial activity, 5 ml. of this suspension were treated with 5 ml. of 8 % gelatin (Kahlbaum), 1 ml. of N acetic acid and sufficient water to bring the volume up to 25 ml. (final $p_H = 4$). By means of the Van Slyke method, amino-nitrogen was estimated immediately, and again after 24 hours' incubation at 30°, on 10 ml. portions of the reaction mixture. As before, the increase in amino-nitrogen, expressed in ml. of $0{\cdot}05N$ KOH, indicates the cathepsin activity. A second portion of the glycerol suspension was fully activated by allowing 5 ml. to stand for 15 minutes at 30° and p_H 7 with 20 mg. of cysteine hydrochloride and 30 mg. of $FeSO_4, 7H_2O$ in 3 ml. of water. The determination of the full activity then followed exactly as described for the initial activity.

To demonstrate the inactivating effect of alloxan, 5 ml. of the glycerol suspension were fully activated by cysteine, then allowed to stand for 1 hour at 30° and p_H 7 with 30 mg. of alloxan, after which activity determinations were carried out as before. A second portion of the glycerol suspension was fully activated by cysteine, inactivated by alloxan and finally reactivated by passing H_2S for 1 hour at p_H 7. The results obtained are shown in Table IV.

II. *Methylglyoxal.* The experimental procedure was the same as that described for alloxan, except that 30 mg. of methylglyoxal were used in place of the alloxan. The results are shown in Table IV.

III. *Iodoacetic acid.* 5 ml. of glycerol suspension were fully activated by keeping with 26 mg. of cysteine hydrochloride in 2 ml. of water for 30 minutes at 30° and p_H 7. A second 5 ml. portion was first activated, then inactivated by allowing it to stand for 30 minutes with 15 mg. of neutralised iodoacetic acid. Attempts were made to reactivate similarly inactivated reaction mixtures by treatment with 3-fold quantities of cysteine hydrochloride (30 minutes at 30°) and with H_2S (1 hour). Activity determinations were made on all reaction mixtures by the usual procedure. The results are shown in Table IV.

Table IV. *Effect of alloxan, methylglyoxal and iodoacetic acid on cathepsin activity.*

Inactivator	Initial activity	Full activity	SH test* before inactivation	¼ hour inactivation		1 hour inactivation		Reactivation	
				Enzymic activity	SH test	Enzymic activity	SH test	H_2S	Cysteine
None	0·50	1·70	+ +	—	—	—	—	—	—
Alloxan	—	—	+ +	0·8	+	0·0	—	1·50	1·20
Methylglyoxal	—	—	—	—	—	0·0	—	1·60	—
Iodoacetic acid	—	—	+ +	0·0	+ +	0·0	+	0·0	0·0

* Nitroprusside colour reaction.

As shown in Table IV, alloxan and methylglyoxal differ from monoiodoacetic acid in their mode of action on cathepsin. Cathepsin inactivated by the latter cannot be reactivated by direct addition of cysteine or H_2S, in contrast to alloxan- or methylglyoxal-inactivated cathepsin. The same difference is shown by a study of the SH colour reaction (nitroprusside test). It was found that a parallelism exists between the disappearance of sulphydryl from the cathepsin (and also papain) complex and the reversible inactivation by alloxan, methylglyoxal, H_2O_2, or by the system aerobic dehydrogenase-substrate-peroxidase. In the case of iodoacetic acid inactivation, however, no relation exists between loss of catheptic activity and loss of SH. Even after the enzyme has been completely inactivated, a strong SH test is obtained, which, however, eventually disappears. This irreversible inactivation of papain and cathepsin by iodoacetic acid does not involve a destruction of the enzyme complex. If iodoacetic acid-inactivated cathepsin or papain is treated with 80 % alcohol, according to the procedure of Maschmann and Helmert [1933], the enzyme may be reactivated practically to its original activity with cysteine.

A series of experiments was carried out on the inactivation of cathepsin by iodoacetic acid, to determine the effect of varying the order of adding the various reagents. (*a*) 6 ml. of 1:10 glycerol extract of acetone-ether-dried pig liver were activated with 25 mg. of cysteine hydrochloride in 2 ml. of water by keeping for 30 minutes at 30° and p_H 7. The mixture was then treated with 25 mg. of iodoacetic acid in 2 ml. of water and again allowed to stand for 1 hour. (*b*) The same quantities of cysteine hydrochloride and iodoacetic acid were added simultaneously to 6 ml. of glycerol extract and kept for 1 hour at 30° and p_H 7. (*c*) The same quantities of cysteine hydrochloride and iodoacetic acid were mixed and kept for 1 hour at 30° and p_H 7. 6 ml. of fully activated glycerol extract were then added. (*d*) To 6 ml. of fully activated glycerol extract were added 5 ml. of 8 % gelatin and then 25 mg. of iodoacetic acid in 2 ml. of water; 1 ml. of *N* acetic acid and sufficient water were then added to bring the volume to 25 ml. (p_H 4). The mixture was incubated for 24 hours at 30°. The various reaction mixtures were then treated with H_2S or cysteine hydrochloride (6 × 26 mg.) for 1 hour and, after addition of the appropriate reagents, tested for possible enzyme reactivation.

It was found that the order of adding the various reagents is immaterial. In each case the enzyme was found to be completely inactivated, and no reactivation was obtained with either H_2S or cysteine. The same results were obtained with papain. It should be mentioned that the inhibition with iodoacetic acid appears not to be a time reaction, but is effective immediately, even when excess SH groups are present.

The comparison of the two inactivation effects, the one reversible (alloxan *etc.*) and the other irreversible (iodoacetic acid) gives rise to conjecture as to the active groupings in papain and cathepsin. The reversible inactivation seems to be connected with a destruction of the SH groups in the papain and cathepsin complexes, and is probably related to interference in the reaction of enzyme with activator. The irreversible inactivation, on the other hand, appears to be concerned not only with an action on the SH groups, but also on a second essential grouping, which seems to be even more important to the enzyme than the SH groups. According to Willstätter *et al.* [1922] an enzyme consists of a colloidal carrier and an active group. If this is correct, then it appears probable that the papain and cathepsin molecules are equipped with at least two active groups, one of which may safely be specified as the SH group.

IV. *Reversible inactivation of liver cathepsin by organic solvents.* The following method was adopted for the preparation of large quantities of inactive cathepsin, as required for comparative activation experiments on this enzyme. Fresh pig's liver was ground in a micro-mincer and suspended in 15 parts (by weight) of absolute acetone. After shaking continuously for 1 hour the suspension was filtered by suction. This procedure was repeated three times. The residue was then extracted three times with 15 parts of an acetone-ether mixture (1:1), each extraction requiring 1 hour. Finally the residue was extracted three times with 15 parts of ether. After drying, the residue was finely ground and passed through a sieve and then extracted for 12 hours with 10 parts by weight of 85 % glycerol. After filtration the clear liquid contained the inactive cathepsin.

If, as sometimes happens, the cathepsin is not yet entirely inactive, excess 95 % alcohol may be added to the glycerol extract until no further precipitation occurs. Ordinarily 10–15 volumes of alcohol are required. After 6 hours' standing, the precipitate is filtered or centrifuged off and dried with ether. A glycerol extract is then prepared from the dried powder as previously described. The enzyme is now completely inactive. Table V shows the initial and full activity of the enzyme at the various stages of the procedure just described.

Table V. *Reversible inactivation of cathepsin by organic solvents.*

		Activity before inactivation		Activity after inacti-vation	Reactivation	
Treatment	Organ	Initial	Full		H_2S	Cysteine
Glycerol suspension 1 : 10 (fresh liver)	Pig liver	1·0	2·40	—	—	—
Glycerol extract 1 : 10 from dried liver after treatment 7 × with acetone, 3 × acetone-ether (1 : 1) and 3 × ether	,,	—	—	0·6	1·60	1·90
Glycerol extract 1 : 10 after alcohol treatment of the above glycerol extract	,,	—	—	0·00	1·10	1·00
Glycerol suspension 1 : 10 from fresh liver	Rabbit liver	0·90	2·20	—	—	—
Glycerol extract 1 : 10 from dried liver after treatment 4 × with acetone, 3 × acetone-ether (1 : 1) and 3 × ether	,,	—	—	0·00	1·0	1·00

The final treatment with alcohol appears not to be necessary in the case of rabbit liver, where only a few minutes elapsed between the death of the animal and the first treatment of the liver mince with acetone.

CONCLUSIONS.

I. *Reversible inactivation of papain.*

1. A method is described for the reversible inactivation of papain by means of alloxan, methylglyoxal, hydrogen peroxide and with the system milk xanthine oxidase + hypoxanthine + milk peroxidase. From the observation that the reversible inactivation of papain proceeds parallel with the disappearance of the SH colour reaction with sodium nitroprusside it is concluded that the destruction of the SH groups in the papain complex (the same applies to the cathepsin complex) through the reagents mentioned is responsible for the reversible inactivation.
2. A relation between typical respiration ferments and intracellular proteolysis was shown by the reversible inactivation of papain by the system aerobic dehydrogenase + hypoxanthine + peroxidase.
3. A method is described for the preparation of large quantities of reversibly inactivated papain in stable form.

II. *Reversible inactivation of cathepsin.*

1. Cathepsin is also reversibly inactivated by alloxan or methylglyoxal. The loss of enzymic activity runs parallel with the loss of SH.

2. On the basis of the reversible and irreversible inactivations of papain and cathepsin the possibility is suggested that the two enzyme systems require at least two active groups for their activity, of which groups one can be said with certainty to be an SH group.

3. A method is described for the preparation of large quantities of inactive cathepsin.

The author wishes to express his thanks to Dr Ellice McDonald, Director, for his interest and support throughout this work.

II. THE ACTIVATION PHENOMENA OF PAPAIN AND CATHEPSIN.

By ARNULF PURR.

From the Cancer Research Laboratory, Graduate School of Medicine, University of Pennsylvania, Philadelphia, Pa.

(*Received October 4th, 1934.*)

THE discovery [Purr, 1933] of the activating effect of the vitamin C—Fe″ complex on arginase and cathepsin demonstrates that a product of plant cellular metabolism may, like sulphydryl compounds (*e.g.* glutathione), exercise a regulatory action on animal protein metabolism. Later investigations by Maschmann and Helmert [1934], as well as the present work, show that this activating effect of vitamin C—Fe″ is not limited to animal proteases, but extends also to papain. The latter is the protease of many plants and appears to be the complete counterpart of cathepsin, the protease of most animal organs and leucocytes. According to our present knowledge, a close relationship exists between the proteolytic enzyme systems of the plant and animal worlds.

The vitamin C—Fe″ complex is a physiological product which resembles HCN in its activating effect on papain and cathepsin. The discovery of this new activator complex has cast considerable doubt on the widely held idea that sulphydryl compounds function as specific activators of these proteinases. Purr and Weil [1934] have likewise found evidence that sulphydryl may not be a specific activator of arginase. The clarification of these questions is of considerable physiological significance because of the fact that the newly-found activator is a vitamin.

The present investigation deals with the activation phenomena of papain and cathepsin. It is a continuation of a series of studies which has as its goal the explanation of the relation between intracellular enzymes and vitamins. A further aim is to clarify our knowledge of the mechanism of enzyme activation, so that differences between normal and cancerous enzymic processes may more readily be detected. It appears quite probable that the proteinases of specific organs (*e.g.* liver) will differ in some essential points (perhaps in activation mechanism) from those of pathological neoplasms, which have been designated by Waldschmidt-Leitz *et al.* [1933] as unspecific organs with respect to their enzymic equipment.

Activation of papain.

For comparative activation studies, a papain preparation was used which had been reversibly inactivated with H_2O_2 according to a procedure described by Purr [1934]. The use of such an inactivated preparation makes the results obtained independent of the variations in initial activity which are characteristic of natural papain. 1 g. of inactive papain was extracted by standing overnight in the ice-box with 50 ml. of water. After filtration and addition of a drop of toluene the extract may be preserved for a long time in the ice-box.

The initial activity of this extract was determined as follows. 0·20 ml. of papain extract was treated with 20 mg. of $FeSO_4, 7H_2O$ in 1 ml. of H_2O, 5 ml.

of 8 % aqueous gelatin, 2 ml. of acetate buffer of p_H 5 and sufficient water to bring the total volume to 25 ml. 10 ml. were removed immediately and 10 ml. after an incubation period of 20 hours at 30° for analysis. The increase in free amino-groups was estimated by the Van Slyke method, the results being expressed in ml. of 0·05 N KOH.

By this procedure, the following activation experiments were carried out. (*a*) 0·20 ml. of papain extract was incubated for 15 minutes at p_H 7 with 20 mg. cysteine hydrochloride in 2 ml. of water and 20 mg. of $FeSO_4, 7H_2O$ in 1 ml. of water; (*b*) 0·20 ml. of papain extract was treated for 1 hour at 30° with 5 ml. of $M/5$ KCN at p_H 7; (*c*) 0·20 ml. of papain extract was incubated for 1 hour at 30° and p_H 7 with 7 mg. vitamin C in 2 ml. H_2O and 20 mg. $FeSO_4, 7H_2O$ in 1 ml. of H_2O; (*d*) same as (*c*) except that 20 mg. of pyruvic acid were substituted for the vitamin; (*e*) same as (*c*) except that 20 mg. of succinic acid were substituted for the vitamin.

The reaction mixtures were then carried through the same procedure as described for initial activity. The entire series was repeated (except for the HCN experiment) in the absence of iron salt. The results are shown in Table I.

Table I. *Reactivation of inactive papain.*

Reactivator	Activity (ml. 0·05 N KOH) Without Fe″	With Fe″	Time of incubation (hours)
None	0·00	0·00	20
Cysteine	4·85	5·00	20
HCN	3·10	—	20
Vitamin C	0·00	0·05	20
„	—	0·80	70
Pyruvic acid	0·00	0·05	20
Succinic acid	0·00	0·00	20

It is evident that neither vitamin C nor the vitamin C—Fe″ complex is able to reactivate the purified, reversibly inactivated papain used. A possible explanation for this finding, which is contrary to the results obtained by Maschmann and Helmert [1934], is suggested by the appreciable activation obtained on longer incubation (70 hours). It appeared likely that certain contaminating substances, which were removed by the purification and inactivation process, might be responsible for the variations in the results.

The experiment was therefore repeated using a 1:10 aqueous extract (6 hours' extraction) of commercial unpurified papain (Merck). The experimental details were similar to those described for Table I, except that 2 ml. of the papain extract were used. The results are shown in Table II.

Table II. *Activation of unpurified commercial papain.*

Activator	Activity in ml. 0·05 N KOH Without Fe″	With Fe″
None	0·70	0·71
Cysteine	5·10	5·20
HCN	5·65	—
Vitamin C	0·80	2·41
Pyruvic acid	2·10	2·20
Succinic acid	0·65	0·75

In agreement with Maschmann and Helmert's [1934] results, it was found that the vitamin C—Fe″ complex activates unpurified commercial papain. The pyruvic acid—Fe″ complex likewise produces a similar degree of activation. In the absence of iron salts, vitamin C produces no activation, while under the same circumstances pyruvic acid produces nearly as high an activation as with iron.

The failure of the vitamin C—Fe″, and the pyruvic acid—Fe″ complexes to activate purified inactive papain led to the conclusion that these combinations are able to activate papain only indirectly. Observations made during a search for a possible contaminating substance, which might play a part in the activations produced by the above-mentioned complexes, led to a study of proteins containing fixed SH groups, first described by Hopkins and Dixon [1922]. Proteins of this type, which occur in all plant and animal tissues, contain SH groups which are resistant to mild oxidation. Furthermore, the SH groups of these water-insoluble proteins cannot be removed by washing with water or dialysis through animal membranes, which indicates that these groups are an essential part of the structure of the protein molecule. Aqueous solutions of such proteins cannot be obtained by direct extraction. However, if the organs are freed from blood, minced and thoroughly washed with water, most of the SH proteins may then be extracted with excess secondary phosphate. It was found that these dissolved proteins are not attacked enzymically by activated papain. The extracts thus prepared give a positive nitroprusside test, which is intensified by addition of KCN, indicating the presence of fixed, reducible SS groups in addition to SH. The same conclusion was reached by Hopkins and Dixon [1922].

The following series of experiments was carried out to determine to what extent the addition of solutions of SH- and SS-proteins influences the activation of purified papain by vitamin C—Fe″, and whether these proteins may not be among the contaminating substances in commercial papain which cause the latter to respond differently to vitamin C—Fe″.

Preparation of fixed SH- and SS-proteins.

The organ, or preferably muscular tissue, of horse, ox, rabbit *etc.*, is freed from fat and nerve tissue and finely ground. 100 g. of the ground tissue are repeatedly kneaded with small portions of 0·25 % NaCl solution until the mass becomes greyish white. Most of the NaCl is removed by kneading with 2 volumes of distilled water. The mass is filtered with suction and the residue thoroughly kneaded with a small amount of $M/10$ Na_2HPO_4. More phosphate solution, up to a total volume of 150 ml., is then added. The mixture is shaken 2 or 3 hours and centrifuged. The supernatant fluid, which contains the desired proteins, may be preserved with toluene for several days in the ice-box.

Table III shows the effect of various activators on inactive papain in the presence and absence of fixed SH- and SS-proteins. The experimental details were identical with those described for Table I, except that in the cases indicated 7·0 ml. of the above-described fixed SH- and SS-protein solutions were added with the activator. The enzyme solution must not contain cathepsin. The time of incubation in each case was 20 hours.

It is evident from these results that purified inactive papain, which is not activated by vitamin C, pyruvic acid or succinic acid (or by their iron complexes), is nevertheless activated by these complexes in the presence of fixed SH- and SS-proteins. The magnitude of the activation is of the same order as that obtained with cysteine—Fe″. These findings demonstrate not only that the observed papain activation effects are dependent on the presence of accompanying substances, but also that these substances are to be sought for in the

Table III. *The effect of fixed SH- and SS-proteins on the activation phenomena of papain.*

Activator	Activity in ml. 0·05 N KOH	
	Without Fe″	With Fe″
None	0·00	0·00

Succinic acid + fixed SH- and SS-proteins	3·10	4·70
Fixed SH- and SS-proteins + cysteine + papain (without gelatin)	0·08	0·05

class of proteins which contain fixed SS groups. The activator systems (vitamin C—Fe″, pyruvic acid—Fe″ and succinic acid—Fe″), in the presence of the papain complex, convert these SS-proteins into the SH-form, which is then able to activate the enzyme. It is also evident from Table III that this conversion of SS- into SH-protein (as a step in the activation process) requires the presence of bivalent iron. This reduction of SS to SH can also be followed by means of the nitroprusside reaction, as, for example, in the system HCN + fixed SS-protein. The part played by the bivalent iron in this process is not yet clear. Possibly the relationship is to be sought in an activation, by the iron, of dehydrogenases which are always found in the fixed SH- and SS-protein solutions prepared as described. The activation of papain by the system succinic acid—fixed SH- and SS-protein—Fe″ supports this view. It will be of interest to attempt to establish a connection between papain activation and the flavins (vitamin B_2). Our knowledge of this field has been greatly extended by the recent work of György *et al.* [1934] and Wagner-Jauregg *et al.* [1934].

It frequently happens that the protein solutions prepared as previously described contain mostly fixed SH-protein and very little of the SS-form. This can be seen from the high activation of inactive papain which they produce. In these cases also the nitroprusside reaction is not intensified by HCN or other activators. This latter finding in particular is evidence supporting the assumption that the conversion of fixed SS-protein into the SH-form by the various activators (vitamin C, pyruvic acid and succinic acid in presence of bivalent iron) is responsible for the activating effect of the latter. Further evidence for this is presented in the next section of this paper, in which a series of papain activation experiments was carried out with a solution of fixed SS-protein prepared by treatment of the tissue extract with alloxan.

Conversion of fixed SH-protein into the SS-form by means of alloxan.

It has been pointed out [Purr, 1935] that alloxan converts SH groups into SS groups without appreciably affecting the structure of the protein molecule. On the basis of this finding the following method was evolved for converting fixed SH-proteins into the SS-form.

100 ml. of a muscle extract prepared as previously described were treated for 5 hours at 37° with 0·7 g. of alloxan. A trace of toluene was then added and the excess alloxan removed by dialysis through an animal membrane (fish bladder), the desired protein being non-dialysable. At the end of the dialysis

the protein solution was divided into 2 parts, one of which was used immediately in the activation experiments. The other part was centrifuged to remove a precipitate which had formed during the dialysis, and the liquid was dried in a vacuum-desiccator over P_2O_5. The fine powder thus obtained contains mostly fixed SS-proteins (little SH) and was used directly.

A series of activation studies was carried out on reversibly inactivated papain using the dialysate and the dry powder obtained from alloxan-treated muscle extract, with and without HCN, vitamin C, pyruvic acid and succinic acid. Duplicate experiments were run with the addition of 20 mg. of $FeSO_4, 7H_2O$.

(*a*) *Before alloxan treatment.* Control experiments were run with a solution of fixed SH- and SS-proteins before alloxan treatment. These experiments were identical with those recorded in Table III.

(*b*) *Dialysate after alloxan treatment.* These experiments were identical with those described in (*a*) except that 10 ml. portions of the alloxan-treated dialysate were used instead of the untreated solution of fixed SH and SS groups.

(*c*) *Dry powder from alloxan-treated dialysate.* These experiments were identical with those described in (*a*) except that 60 mg. of the dry powder obtained from the alloxan-treated dialysate were used instead of the untreated solution of fixed SH- and SS-proteins.

Table IV. *Effect of fixed SS-proteins on the activation phenomena of papain.*

	Activity before alloxan treatment		Activity after alloxan treatment

Succinic acid + fixed SH- and SS-proteins	3·65	4·10	2·40	2·30	0·65	0·50

The results, shown in Table IV, indicate that it is possible to convert fixed SH-protein into the SS-form. It is also clear that the activation of inactive papain, obtained with fixed SS-proteins in the presence of the vitamin C—Fe″ complex, is an indirect effect resulting from the formation of fixed SH groups. The vitamin C—Fe″ complex is able, in the presence of the papain complex, to convert fixed SS-protein into the corresponding SH-form. This follows from the fact that addition of vitamin C—Fe″ scarcely affects the papain activity obtained with a fresh, untreated solution of fixed SH- and SS-protein (containing much SH-protein and very little of the SS-form). The observed activation is due merely to SH groups present in the protein solution, since approximately the same degree of activation results in the absence of vitamin C—Fe″. When however a mixture of fixed SH- and SS-proteins (alloxan treatment) is used, the partial papain activation can be increased to full activation by addition of vitamin C—Fe″. This is true also when the latter is replaced by HCN. Full papain activation is obtained also with pyruvic acid—Fe″ and succinic acid—Fe″, provided the fresh (untreated) SH- and SS-protein solution is also added. However, for unknown reasons these two complexes lose their activating effects when alloxan-treated preparations of SH- and SS-proteins are used.

Distribution of fixed SH- and SS-proteins.

Fixed SH- and SS-proteins, which, on the basis of the above results, play a part in the activation of papain by vitamin C—Fe″, are widely distributed in plants and animal organs. As examples of animal tissue, ox muscle, rabbit muscle, rabbit liver and rat sarcoma (Philadelphia #1) were extracted by the previously described method for obtaining solutions of these proteins. The activating effects of these solutions (7 ml.) on inactive papain were then measured in the presence of iron or vitamin C—Fe″, the experimental details being identical with those previously described. As examples of the plant kingdom, barley meal and jack bean meal were studied. The quantities used were 100 mg. of meal, 0·2 ml. of inactive papain, 20 mg. of $FeSO_4, 7H_2O$ (in 1 ml. of water) and 7 mg. of vitamin C (in 1 ml. of water). The total volume was brought to 7 ml., and the mixture was then incubated for 30 minutes at 37° and p_H 7. The measurement of papain activity followed as usual. Similar experiments were carried out without the addition of vitamin.

Table V. *Distribution of fixed SH- and SS-proteins in plant and animal cells, and their relation to the vitamin C activation of papain.*

Activator	Activity without vitamin C (Fe″ present)	Activity with vitamin C (Fe″ present)	Time of incubation (hours)
None	0·00	0·00	20
Cysteine	5·00	—	20
Ox muscle	3·70	5·0	20
Rabbit muscle	3·10	4·80	20
Rabbit liver	3·80	4·90	20
Rat sarcoma	3·50	5·0	20
Barley meal	0·70	2·50	20
Barley meal and cysteine	5·00	—	20
Jack bean meal	1·00	2·10	20

Table V shows that fixed SH- and SS-proteins probably occur in most plant and animal cells. This is evident from the papain activations obtained in the presence or absence of vitamin C. As previously stated, the activation obtained with the protein solutions in the absence of vitamin is due only to the fixed SH-protein present. The increased activation which results on addition of vitamin C—Fe″ is due to the conversion of the SS-proteins into the SH-form by the vitamin C—Fe″ in the presence of the papain complex. HCN has a similar effect.

Experiments with SS-glutathione.

Hopkins and Dixon [1922] and Bernheim and Dixon [1928] found that fixed SH-proteins (bound to the cell residue) would reduce oxidised glutathione to the SH-form. It was of interest, therefore, to investigate the effects of SS-glutathione, fixed SH- and SS-protein suspension and vitamin C on papain activation.

A solution of oxidised glutathione was prepared by passing oxygen through a solution of 100 mg. of reduced glutathione in 10 ml. of water, in the presence of a trace of $FeSO_4, 7H_2O$. Twelve hours' oxygenation were usually sufficient to complete the reaction, the course of which was followed by means of the nitroprusside test, and by the iodimetric procedure of Woodward and Fry [1932].

To 10 mg. of oxidised glutathione in 1 ml. water were added 20 mg. of $FeSO_4, 7H_2O$ (in 1 ml. of H_2O) and 6 ml. of a 1:5 aqueous suspension of ox muscle, which had previously been minced and thoroughly washed with water. The mixture was incubated at p_H 7 and 37° for 1 hour, after which 0·2 ml. of inactive papain extract was added. The incubation was continued for an additional hour. The papain activity was then measured as previously described. Control experiments were carried out in a similar manner on oxidised glutathione alone and muscle suspension alone. In a second series, 10 mg. of oxidised glutathione were treated with 20 mg. of $FeSO_4, 7H_2O$, 7 mg. of vitamin C and 2 ml. of inactive papain, in a total volume of 6 ml. After 1 hour's incubation at p_H 7 and 37°, the papain activity was measured in the usual manner. A control was run without oxidised glutathione. The results are shown in Table VI. Time of incubation in all cases was 20 hours.

Table VI. *Relation of fixed SH-proteins and the vitamin C—Fe″ complex to glutathione metabolism.*

Activator	Activity (ml. 0·05N KOH)	
	Without Fe″	With Fe″
None	0·00	0·00
Cysteine	4·9	4·30
Oxidised glutathione	0·50	0·30
Ox muscle	3·5	3·40
Oxidised glutathione and ox muscle	4·6	4·90
Vitamin C	0·00	0·05
Vitamin C and oxidised glutathione	0·60	1·50

The reduction of SS-glutathione to the SH-form by fixed SH groups, which was first followed analytically by Hopkins [1926], has now been demonstrated enzymically by means of papain activation. Such a reduction process is probably related to intracellular proteolysis. A similar reduction of oxidised glutathione (or oxidised papain?) is obtained when oxidised glutathione and vitamin C—Fe″ are added to inactive papain. Since neither oxidised glutathione—Fe″ nor vitamin C—Fe″ is able to activate inactive papain, it appears likely, as in the case of fixed SS-proteins, that the vitamin C—Fe″ complex and the papain are jointly responsible for the reduction of the SS group. In the absence of papain no reduction can be observed. The activation of papain by vitamin C—Fe″ apparently depends on the presence of SS groups, either in the glutathione molecule or in fixed SS-protein.

Activation of cathepsin.

In these experiments, an inactive cathepsin preparation was used, which was made by acetone-ether extraction of minced rabbit liver [Purr, 1934]. The dry powder thus obtained was extracted for 12 hours with 10 parts of 90 % glycerol and then filtered. 5 ml. of the filtrate were kept for 30 minutes at p_H 7 and 30° with 6 ml. of a solution of fixed SH- and SS-proteins (prepared from ox muscle as previously described), 20 mg. of $FeSO_4, 7H_2O$ in 1 ml. of water and 7 mg. of vitamin C in 1 ml. of water. After incubation the enzymic activity was measured essentially as described for papain. 5 ml. of 8 % gelatin and 2 ml. of M sodium acetate buffer of p_H 4 were added. 10 ml. of the reaction mixture were analysed immediately for amino-nitrogen, and 10 ml. after 24 hours' incubation at 37° by the Van Slyke method, the results being expressed in ml. of 0·05N KOH. Controls were run in the absence of (*a*) vitamin C, (*b*) fixed SH- and SS-protein and (*c*) fixed SH- and SS-protein and vitamin C. A similar reaction was carried out using 20 mg. of pyruvic acid in place of the vitamin C.

Also the full activity was determined by keeping 5 ml. of cathepsin solution for ½ hour at p_H 7 and 30° with 20 mg. $FeSO_4, 7H_2O$ in 1 ml. of H_2O and 20 mg. of cysteine hydrochloride in 1 ml. of H_2O. The activity of the enzyme was measured in the usual way; time of action 24 hours.

Table VII. *The effect of fixed SH- and SS-proteins on the activation phenomena of cathepsin.*

Activators	Activity (ml. 0·05 *N* KOH) (with Fe″)
None	0·00
Cysteine	1·40
Vitamin C	0·6
Fixed SH- and SS-proteins	0·40
Vitamin C and fixed SH- and SS-proteins	1·50
Pyruvic acid	0·00
Pyruvic acid and fixed SH- and SS-proteins	0·25
Fixed SH- and SS-protein and gelatin (no cathepsin)	0·00
Fixed SH- and SS-protein and cysteine and cathepsin (no gelatin)	0·01

The results shown in Table VII indicate that, as far as they have been studied, the activation phenomena of cathepsin are quite similar to those of papain. Only in the case of pyruvic acid did the results differ. Here it was found that the system fixed SH- and SS-protein—pyruvic acid—Fe″ does not increase catheptic activity.

SUMMARY.

1. It has been shown that the activation of papain by the vitamin C—Fe″ complex is dependent upon the presence of contaminating substances. Among the latter were found fixed SS-proteins and SS-glutathione.

2. Evidence is produced to show that the activation of papain and cathepsin by the vitamin C—Fe″ complex or by HCN is an indirect effect. The real activators are sulphydryl compounds, which are formed from the SS compounds which accompany the enzyme complex (fixed SS-proteins and SS-glutathione), by the action of the activator system mentioned. In contrast to arginase activation, the activation of papain and cathepsin is probably produced only by sulphydryl compounds.

3. It is concluded that papain and cathepsin in the active state are fixed SH-proteins of definite constitution, while the reversibly inactivated forms of these enzymes appear to be SS-proteins.

The author is greatly indebted to Dr Ellice McDonald for his support and encouragement throughout this work.

III. THE CHEMISTRY OF MOULD TISSUE.

VI. FACTORS INFLUENCING THE AMOUNT AND NATURE OF THE FAT PRODUCED BY *ASPERGILLUS FISCHERI*[1].

BY EDWARD ALBERT PRILL, PETER RUDOLF WENCK
AND WILLIAM HAROLD PETERSON.

From the Departments of Agricultural Chemistry and Agricultural Bacteriology, University of Wisconsin, Madison.

(*Received October 22nd, 1934.*)

THE fat content of mould mycelium, as reported by various authors, ranges from 1 to 40 %, depending upon the species and upon the conditions of growth. Even within a single strain of a species certain characteristics of the fat, as well as its amount, have been reported to vary with the conditions of growth.

From what is known about the chemical composition of mould-fat it appears that glycerides together with free fatty acids constitute the major portion of it. In some cases the mould-fat contains a high percentage of free fatty acids [Pruess *et al.*, 1934]. Barber [1929] found that the nature of the fatty acids, both free and combined, produced by a *Penicillium* sp. remained practically unchanged whether this mould was grown on glucose, sucrose, xylose or glycerol. The more easily extracted fat of *A. sydowi*, exclusive of the phospholipins [Strong and Peterson, 1934] and that of *P. javanicum* [Ward and Jamieson, 1934] have both been shown to yield upon saponification glycerol and oleic, linoleic, palmitic, stearic and small amounts of *n*-tetracosanoic acids. The mould-fat contains variable percentages of phospholipins and sterol, the latter having been definitely shown to be ergosterol in the case of *A. fischeri* [Pruess *et al.*, 1932]. There also occurs a small amount of some other unsaponifiable material which has not yet been studied. A small amount of pigment is presumably also present, since the mould-fat is usually quite deeply coloured.

The mould-fat has been generally regarded as a reserve material [Perrier, 1905], although Kordes [1923], observing that the fat globules in the hyphae persisted even during inanition, believed that this fat should be considered as an "excretory" product. Belin [1926] demonstrated that the fat content of *A. niger* fell to a low value after prolonged inanition. He postulated that the fats of moulds and of other living organisms should be considered as consisting of an "élément constant" and an "élément variable." By the term "élément constant" he designated that minimum percentage of fatty material, assumed by him to be phospholipins, intimately associated with the protoplasm, which is indispensable for the life of the organism; and by the term "élément variable" he designated any additional amount of fat stored as a reserve material.

In the case of animal tissues, three possibilities have been postulated for the function of the phospholipins [Sinclair, 1934]: (1) that they are intermediate

---

[1] This work was supported in part by a grant from the Wisconsin Alumni Research Foundation.

products in fat metabolism; (2) that they act as oxygen transport agents within the cells; and (3) that they, and possibly also the cholesterol, are concerned in some more strictly physicochemical sense in the structural make-up and activity of the cell. It is possible that in the mould cells the phospholipins and also the sterol (ergosterol) might have functions similar to those postulated above.

The purpose of the present investigation was to determine the effects of the variations of certain factors on the amount and nature of the fat produced by *A. fischeri*, and also to determine any relationships which might exist among the percentages of total fat, phospholipins and sterol in the mycelium.

EXPERIMENTAL.

The mould was grown in 500 ml. pyrex Erlenmeyer flasks, six to eight flasks for each condition of growth, each flask containing 100 ml. of inorganic salt solution to which cerelose (commercial glucose) was added in the amount of 20 g. unless otherwise indicated. Except for certain indicated changes in the amount or nature of the nitrogen source in some of the experiments, the composition of the inorganic salt solution per flask was as follows:

NH_4NO_3	1·00 g.
KH_2PO_4	0·68 g.
$MgSO_4, 7H_2O$	0·50 g.
$FeCl_3, 6H_2O$	0·016 g.
$ZnSO_4, 7H_2O$	0·005 g.
Distilled water	100·0 ml.

To prevent the development of acidity, $CaCO_3$ was added to the media for all experiments except those concerned with the effects of acidity or alkalinity. Those components of the media which would react with each other if heated together, *e.g.* glucose and an alkaline substance, were sterilised separately.

Except for the comparison of the different cultures, in which case soil suspensions of these cultures were used as inocula, an aqueous suspension of the spores from a malt-agar slant of a single spore culture of *A. fischeri* was used as the inoculum in each series of experiments.

At the end of the growth period the mould was killed by autoclaving at 120° for 10 minutes. The mould pads were removed, washed with water, air dried at 37° for 2 days, weighed and ground to pass a 40-mesh sieve. The amounts of unutilised glucose remaining in the media were determined by the Shaffer and Hartmann [1920–21] method.

For the analyses 10 g. samples of the dry mould were weighed out, usually in duplicates if the amounts of material permitted. The samples were extracted with hot absolute alcohol in continuous extractors for at least 12 hours. It was found that this solvent extracted the fat from the mould more completely than did chloroform, ether or light petroleum. Moreover, it was also found that comparatively negligible amounts of additional fatty acids were obtainable upon more drastic treatment of the alcohol-extracted residue with alkali or acid. Since the alcohol also extracted some materials other than fat, the alcohol was distilled from the extracts, and the mixtures of fat and other extracted matter were dried in a vacuum-desiccator over $CaCl_2$ and then treated with hot chloroform, which dissolved only the fat. The chloroform-insoluble material was usually a light yellow water-insoluble powder, which comprised 10–30 % of the total alcoholic extract and 2–4 % of the mould pad. In some cases, which will be mentioned later, the chloroform-insoluble material was of a different nature, *i.e.* it was gummy and appeared to contain a large amount of carbohydrate. In these latter cases this fraction comprised the major portions of the alcoholic extracts and in an extreme case it formed 36 % of the mould pad.

The chloroform solution of the fat was in each case made up to a volume of 50 ml. For the determination of the amount of total fat a 20 ml. portion of this solution was evaporated in a tared 50 ml. Erlenmeyer flask, dried in a vacuum-oven at 60° for 2 hours and weighed. An aliquot of this same portion of fat was used for the determination of phosphorus by the Fiske and Subbarow [1925] colorimetric method after ignition with $Mg(NO_3)_2$. In some cases another aliquot of this fat was used for the nitrogen determination [Chiles, 1928].

The $CHCl_3$ was completely removed by distillation from the other 30 ml. portion of the solution and the fat was saponified by boiling for 1½ hours with 50 ml. of 5 % alcoholic KOH. After removal of the greater portion of the alcohol by distillation and addition of 50 ml. of cold water, the unsaponifiable matter was extracted by shaking with three successive 50 ml. portions of ether, the liquids being allowed to stand in the separating funnel until the two layers were distinct and free from emulsions. The combined ether solution of the unsaponifiable matter was washed once with 1 % KOH and twice with water, these washings being added to the aqueous soap solution. The aqueous soap solution was made strongly acid with HCl, and the fatty acids were extracted with ether. After washing this extract with water, distilling off the ether and drying the crude fatty acids in a vacuum-desiccator over $CaCl_2$, light petroleum was used to redissolve the true fatty acids. The small amount of more deeply coloured residue insoluble in light petroleum amounted to 3 % or less of the original fat. After distilling off the solvents and transferring to tared 50 ml. Erlenmeyer flasks, both the unsaponifiable matter and the fatty acids were dried in a vacuum-oven at 60° for 2 hours. This method of drying did not affect the iodine numbers of the fatty acids. The weight obtained for the fatty acids corresponds to that of the non-volatile fatty acids. These were in all cases light yellow in colour and appeared to be solid up to about 30°.

Aliquots of the fatty acids were taken for the determination of the iodine numbers and neutral equivalents. All the iodine numbers were determined by the Rosenmund and Kuhnhenn [1923] method, which, while reported to give somewhat lower values than the Wijs method, is less affected by experimental conditions and gives values which are consistent amongst themselves [Barbour, 1934; Yasuda, 1931]. The neutral equivalents, as determined by titration of an alcoholic solution of the fatty acids with $N/10$ NaOH to the phenolphthalein end-point, were all around 280, with maximum deviations of 5. Because these deviations are not much greater than the experimental error, the individual neutral equivalents are not included in the Tables.

The amount of sterol in the unsaponifiable matter was determined by a colorimetric method based on the Liebermann-Burchard reaction. This method will be described in a later publication.

Comparison of cultures.

Nine different cultures of *A. fischeri* Wehmer, eight of which were recently developed from single spores [Greene, 1933], were grown at 30° on a medium containing 10 % glucose. A series of old soil suspensions (A) and another series of more recently prepared soil suspensions (B) of these cultures were used as inocula. Practically all the glucose was utilised at the end of the 10-day growth period. The yields of mould pad per g. of glucose utilised varied only slightly from the average value of 0·27 g. In Table I the single spore cultures (S.S.C.) and the parent stock culture are arranged in the approximate order of the decreasing fat contents of the mycelia which they produced.

Table I. *Comparison of cultures.*

It is seen that the variations in the amount and nature of the fats produced by the different cultures were quite appreciable and were fairly parallel in the two series. The pads produced by S.S.C. No. 13 were the highest in fat content, while those produced by S.S.C. No. 20 and by the stock culture were the lowest. In those cases where the fat content of the mould was low the fatty acids made up comparatively low percentages of the fat (about 55 % in the extreme cases) and the unsaponifiable matter tended to make up increased percentages; but the sum of these two components left considerable percentages of the fat unaccounted for, which might have been due to the presence of some other water-soluble components. The iodine numbers of the fatty acids produced by the different cultures showed fairly regular variations in both series and were highest in the cases of S.S.C. No. 20, S.S.C. No. 10 and the stock culture.

For the subsequent experiments the culture designated as S.S.C. No. 13 was used exclusively. It was believed that by using an inoculum as homogeneous as possible, *i.e.* all its components having the same characteristics, the observed variations in the amount and nature of the fat would be a true picture of the effects due to the variations in the conditions of growth; whereas, by using an inoculum, such as the stock culture, consisting of a mixture of components having different characteristics, the observed variations in the fat would be due partly to the altered proportions in which the different components would co-exist under the changed conditions of growth.

Effect of initial concentration of glucose.

The data for this series are summarised in Table II. The initial concentrations of glucose were varied by adding from 1 to 70 g. of cerelose to 100 ml. of the salt solution. The progressively increasing initial concentrations of glucose in

the medium caused certain quite regularly progressing variations in the amount and nature of the fat produced by the mould. The limited amount of nitrogen source compared with the large amount of carbon source in the media high in glucose was doubtless an important factor in producing some of these changes.

The fat content of the mould increased quite distinctly, which is in accord with previous reports [Belin, 1926]. In the case of yeasts also a high fat content is reported to be favoured by a high concentration of fermentable sugar and a low concentration of nitrogen in the medium [Smedley-MacLean, 1922]. Although the yields of mycelium per g. of glucose utilised decreased from 0·38 to 0·23 g., the yields of fat per g. of glucose utilised still showed an increase from 0·0395 to 0·083 g. These changes can be correlated because the conversion of carbohydrate into fat requires energy, hence greater portions of the glucose would have to be more or less completely oxidised in order to furnish the necessary energy for the synthesis of the greater amounts of fat. The "efficiency of the conversion of energy" [Terroine and Bonnet, 1927], which is equivalent to the value of the ratio,

energy content of the mould pad/decrease in energy content of the medium,

would doubtless have shown a much smaller decrease than did the yields in terms of the weight of mould pad per g. of glucose utilised.

The fatty acids obtained after saponification comprised increasing percentages of the original fat, while the unsaponifiable matter comprised decreasing percentages. Also the sum of these two components accounted for the fat more completely when the fat content was high. These facts, together with the decreasing percentages of phosphorus in the fat, indicate that the increment of fat consisted almost entirely of glycerides.

Based upon the mycelium, the percentages of unsaponifiable matter varied slightly around an average value of 1·2 %. The sterol usually comprised from 65 to 75 % of the unsaponifiable matter, except in the first two members of the series where the percentages were lower. Based upon the mycelium, the percentages of lipin-phosphorus were unusually high for the first two members (0·23 and 0·14) and decreased through the series, down to 0·05. Except for the first two members, the ratio of lipin-phosphorus to fat-free mycelium tended to remain fairly constant in this series.

The iodine numbers of the fatty acids decreased. The unusually high iodine numbers for the first three members of the series might be due to the more unsaturated character of the mould-phospholipins, which in these cases appear to make up appreciable percentages of the fat.

Effect of ammonium nitrate concentration.

The data for this series of experiments are summarised in Table III. The mould was allowed to grow at 30° for 10 days.

Table III. *Effect of ammonium nitrate concentration.*

NH_4NO_3 %	Glucose utilised %	Mycelium per g. glucose utilised g.	Fat %	Percentages of fat					Iodine no. of fatty acids
				Fatty acids	Unsap. matter	Sterol	P	N	
0·2	44	0·45	22·3	81·0	3·6	2·2	0·23	0·18	90
0·5	68	0·37	20·8	78·8	3·9	2·6	0·27	0·26	91
1·0	79	0·33	17·9	79·5	5·6	3·4	0·34	0·39	88
2·0	92	0·35	15·8	81·2	6·7	3·3	0·22	0·37	84
5·0	73	0·25	15·2	78·8	6·7	3·4	0·16	0·33	83
10·0	47	0·20	14·1	80·0	5·0	Traces	0·23	0·45	83

It is seen that the utilisation of the glucose was most complete in the medium containing 2 % NH_4NO_3. It should also be mentioned that the chloroform-insoluble portions of the alcoholic extracts (not shown in Table III) were the greatest in those cases where the mould had been grown on a medium having either an extremely high or extremely low concentration of NH_4NO_3 and where the utilisation of the glucose had been least complete. In these cases this fraction was gummy and appeared to contain a large amount of carbohydrate. This fraction made up 28 % of the mould pad produced on the 10 % NH_4NO_3 medium.

With the increasing initial NH_4NO_3 concentration of the medium the yields of mould pad per g. of glucose utilised decreased, the fat content of the mycelium decreased, and certain characteristics of the fat changed progressively. The unsaponifiable matter formed an increasing percentage of the original fat while the fatty acids made up a fairly constant percentage (about 80). The iodine numbers of the fatty acids decreased.

The percentages of sterol and of lipin-phosphorus were highest in the mycelium produced on the usual 1 % NH_4NO_3 medium, both on the basis of the mycelium and on the basis of the fat.

The mould pads produced on the 10 % NH_4NO_3 medium, and to a lesser extent those produced on the 5 % NH_4NO_3 medium, were slimy and lacked turgidity. The abnormal growth is probably reflected in the very low sterol content produced on the 10 % NH_4NO_3 medium and in the unusually high values of the ratio, lipin-N/lipin-P, for the mould grown on the higher NH_4NO_3 concentrations.

Effect of acidity or alkalinity.

Ammonium salts of mineral acids have a tendency to produce acidity in the medium because of the liberation of mineral acid when the nitrogen of the ammonium radical is utilised. In the case of NH_4NO_3 this does not necessarily apply, because the mould can utilise both ammonium- and nitrate-nitrogen but not necessarily at the same rate. Likewise, the use of the nitrates of the alkali metals would be expected to decrease the acidity or produce alkalinity in the medium.

To determine the effects of the acidity or alkalinity which is produced in the medium by virtue of the nitrogen source, the mould was grown on media in which the NH_4NO_3 was in some cases replaced by equivalent amounts of various other nitrogen sources. Parallel experiments in which either $CaCO_3$ or potassium acetate was added to some of these media were also performed. The mould was in all cases allowed to grow at 30° for 12 days. The data for these experiments are summarised in Table IV.

Table IV. *Effect of acidity or alkalinity developed in the media by virtue of the nitrogen source.*

					Percentages of fat				
N source	Neutralising agent per flask g.	Glucose utilised %	Mycelium per g. glucose utilised g.	Fat %	Fatty acids	Unsap. matter	Sterol	P	Iodine no. of fatty acids

The growth of the mould on the unneutralised $(NH_4)_2SO_4$ and NH_4Cl media apparently produced such a high degree of acidity that further growth was inhibited. The glucose was very incompletely utilised and the yields of mycelium per g. of glucose utilised were very low. The alcoholic extracts contained large amounts of chloroform-insoluble material similar to that previously described, and in the case of the mycelium produced on the NH_4Cl medium this amounted to 36 % of the mould pad. The mould pads produced on these media had low fat contents. Based on the mycelium, the percentages of sterol and unsaponifiable matter were as high as those observed in other cases: hence, these components amounted to appreciable percentages of the fat. The percentages of lipin-phosphorus were unusually low. The iodine numbers of the fatty acids were comparatively high.

The addition of $CaCO_3$ to these two media caused the production of good yields of mould pad per g. of glucose utilised and high fat contents of the mycelia. The addition of a small amount of potassium acetate partially neutralised the H_2SO_4 which was liberated during growth. The potassium acetate acts as a neutralising agent because of its own slightly alkaline reaction and probably also because of the production of the more alkaline $KHCO_3$ upon utilisation of the acetate radical as an additional carbon source. In this case the utilisation of the glucose was more complete, the yield of mould pad was fair, but the fat content was only slightly increased. The nature of this fat was intermediate between those of the fats produced by the mould on the $(NH_4)_2SO_4$ media with and without $CaCO_3$.

The growth of the mould on the unneutralised NH_4NO_3 medium was fairly normal; however, the addition of $CaCO_3$ or increasing amounts of potassium acetate caused an increase in fat content of the mycelium.

Urea, $NaNO_3$ and $Ca(NO_3)_2$ also served as suitable nitrogen sources and favoured the production of mycelia with high fat contents. The mould pads produced on the $Ca(NO_3)_2$ medium contained an abnormally high percentage of mineral matter (16 % ash). If corrections were made for the excessive mineral content of these pads (5 % is a more usual ash content), the fat content would appear as a higher percentage than that indicated in the table. The addition of $CaCO_3$ to the urea media proved unfavourable to growth, probably because of the development of excessive alkalinity. The iodine numbers of the fatty acids in the two last-mentioned cases were unusually low.

For the investigation of the effect of the initial p_H of the medium, the usual medium was modified by the substitution of an equivalent amount of urea in place of the NH_4NO_3, and H_2SO_4 or KOH was added to adjust the initial p_H to the values indicated in Table V. The mould was allowed to grow at 37° for 12 days.

Table V. *Effect of initial* p_H.

N reagent added per flask ml.	Initial p_H	Mycelium per g. glucose utilised g.	Fat %	Percentages of fat: Fatty acids	Unsap. matter	Sterol	P	N	Iodine no. of fatty acids
H_2SO_4 2	2	0·200	19·2	64·5	15·7	10·3	0·66	0·24	85
H_2SO_4 0·5	3	0·217	17·0	66·5	14·6	11·3	0·63	0·37	87
0	4·6	0·223	19·5	59·0	12·9	8·6	0·66	0·46	88
KOH 2	6	0·275	23·9	78·5	6·7	4·6	0·46	0·23	89
KOH 6	8	0·270	37·0	76·5	2·9	1·8	0·23	0·11	77

Probably because of the hydrolysis of urea to $(NH_4)_2CO_3$, either by mould enzymes or by ordinary chemical reactions, and because of the low buffer capacities of the media, a final p_H of about 7·5 was observed in all media except the one which had an initial p_H of 8. The growth of the mould on this last medium was unique in that the p_H decreased from 8 to 7, only 67 % of the glucose was utilised (whereas all the glucose was utilised in the other media), and the mycelium had a marked tendency to pile up against the walls of the flasks. This mycelium contained an unusually high percentage (37) of fat. Also, the iodine number of the fatty acids was lower in this case than in the others.

The addition of H_2SO_4 to the urea medium caused a slight decrease in the yields of mycelium, hardly any changes in the percentages of fat or of lipin-phosphorus, but a marked increase in the percentages of sterol and total unsaponifiable matter. The addition of KOH to the urea medium caused an increase in the yields of mycelium and an increase in the percentages of fat, but a decrease in the percentages of sterol, total unsaponifiable matter and lipin-phosphorus, both on the basis of the mycelium and on the basis of the fat.

Pontillon [1930; 1932–33] made a study of the effects of various nitrogen sources and the concomitant changes in the degree of acidity of the media upon the amount and nature of the fatty constituents of *A. niger*. It is difficult to correlate his results and ours; however, it appears that, in regard to the nature of the fat produced, *A. fischeri*, while showing considerable variations, does not tend to exhibit some of the rather extreme variations which, as his data imply, occur in the case of *A. niger*.

Effect of temperature.

The data for these experiments are summarised in Table VI. The mould was allowed to grow at the indicated temperatures until all the glucose was utilised.

Table VI. *Effect of temperature.*

Temp. ° C.	Period of incubation days	Mycelium per g. glucose utilised g.	Fat %	Percentages of fat					Iodine no. of fatty acids
				Fatty acid	Unsap. matter	Sterol	P	N	
20	16	0·331	24·4	79·0	5·9	3·4	0·46	0·20	93
30	12	0·305	25·7	81·5	5·8	4·1	0·39	0·20	82
37	12	0·273	20·0	80·0	8·5	6·8	0·41	0·22	88

It appears that a temperature of 37° is somewhat less favourable for fat production than are the lower temperatures. The percentage of sterol (based on the mycelium) increased greatly while that of the lipin-phosphorus decreased slightly as the temperature of growth was increased.

It has been reported [Pearson and Raper, 1927; Terroine *et al.*, 1927] that in the case of two moulds, *A. niger* and *Rh. nigricans*, and also in the case of the timothy bacillus, the iodine numbers of the fatty acids obtained from these organisms decreased as the temperature at which they were grown increased. Our data do not lend much support to the supposition that this tendency is a general one; for although the iodine number of the fatty acids produced by the mould at 20° was somewhat higher, those of the fatty acids obtained from the mould grown at 30° and 37° were in an order the reverse of that which would have been expected.

Effect of increased aeration.

The data for this experiment are summarised in Table VII. This experiment was performed twice, (A) with the usual 500 ml. Erlenmeyer flasks, and (B) with 3 l. Currie flasks containing 750 ml. of medium. The medium contained 15 % glucose in both cases. For increased aeration a continuous current of sterile air was introduced just above the surface of the pads. The flasks containing the controls were plugged with cotton wool in the usual manner. The mould was in all cases allowed to grow at 25° for 10 days.

Table VII. *Effect of increased aeration.*

		Fat %	Percentages of fat					Iodine no. of fatty acids
			Fatty acid	Unsap. matter	Sterol	P	N	
A	Aerated	23·8	79·0	3·8	2·2	0·24	0·12	83
	Control	24·6	75·5	4·3	2·3	0·26	0·10	83
B	Aerated	27·0	79·0	3·5	2·4	0·21	0·09	82
	Control	29·8	75·5	3·4	2·0	0·23	0·11	79

With increased aeration the growth of the mould was more rapid and the glucose was practically all utilised at the end of the 10-day period. In the controls there were considerable amounts of unutilised glucose, but the yields of mycelial pads per unit of glucose utilised did not differ greatly from those produced with increased aeration. No changes in the amount or nature of fat that can be considered significant were found to be produced by increased aeration.

Effect of inanition.

The mould for this series of experiments was grown at 30°. The first sample of six flasks was taken for analysis after 10 days' growth at which time 77 % of the glucose had been utilised. The other pads were allowed to remain on the medium for longer periods of time. The data for this series are summarised in Table VIII and the changes in the amounts of some of the mycelial constituents per flask are shown graphically in Fig. 1.

Table VIII. *Effect of inanition.*

Period of incubation days	Mycelium per g. glucose utilised g.	Fat %	Percentages of fat: Fatty acids	Unsap. matter	Sterol	P	Iodine no. of fatty acids
10	0·320	23·3	65·0	5·0	2·8	0·45	83
20	0·245	16·2	70·7	9·2	5·6	0·57	82
30	0·212	13·9	69·6	12·4	8·6	0·41	81
40	0·177	11·6	65·0	18·5	12·4	0·11	79
50	0·165	11·5	60·6	19·1	13·5	0·10	78
68	0·074	12·1	65·5	14·7	9·8	Traces	82

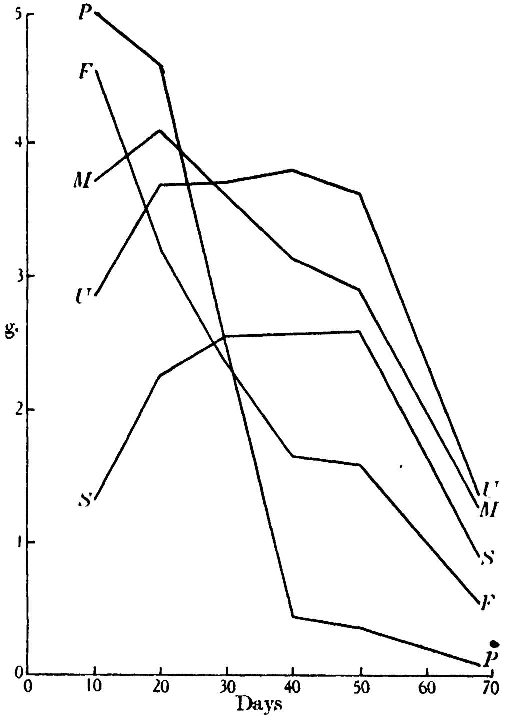

Fig. 1. Effect of inanition on some mycelial constituents, expressed as g. per 100 ml. of medium. M = mycelium *minus* fat; F = fat × 4; U = unsaponifiable matter × 50; S = sterol × 50; P = lipin-P × 1000.

Between the 10th and 20th days the absolute amount of fat began to decrease. The fat decreased more rapidly than did the sum of the other mycelial constituents until about the 40th day, after which both decreased at almost the same rate; consequently, the percentage of fat in the mould pad decreased from 23·3 to 11·6 and then remained fairly constant. Belin [1926] reported that on prolonged inanition the fat content of *A. niger* fell to a low final value corresponding to 1·37 % fatty acids on the basis of the final weight of the mycelium.

While a decrease in the absolute amount of fat was in progress, the amount of unsaponifiable matter, including the sterol, still increased slightly and then remained fairly constant for a long period before it also finally decreased. Until about the 50th day, the sterol and other unsaponifiable matter amounted to increasing percentages both of the fat and of the mould pad.

The fatty acids remained a fairly constant percentage of the fat. The iodine numbers of the fatty acids showed only a very slight tendency to decrease and the neutral equivalents varied only slightly around 280, just as was observed in the previous series of experiments. If these fatty acids are a mixture consisting of appreciable amounts of both saturated and more or less unsaturated individuals, the almost constant iodine number of this mixture would indicate that the unsaturated fatty acids are not preferentially utilised. It has also been reported [Pearson and Raper, 1927; Terroine and Belin, 1927] that the iodine number of the fatty acids obtained from *A. niger* is not greatly influenced by the period of incubation of the mould.

The amount of lipin-phosphorus decreased very rapidly between the 20th and 40th days. In view of the hypothesis that the phospholipins serve as intermediates in fat metabolism, it might be assumed that the phospholipin would be utilised more readily than the other fatty constituents. However, it is also possible that the observed decrease in lipin-phosphorus might have been due to an enzymic cleavage of the phosphate linkage rather than a complete utilisation of the phospholipin molecules.

DISCUSSION.

In the series of experiments dealing with the initial concentration of glucose, the yields of mycelium and of fat per g. of glucose utilised varied in opposite directions, and this was partly explained by the energy required for the conversion of carbohydrate into fat. In the other series studied the variations in the yields of both mycelium and fat were in the same direction, which indicates that in these cases the effect due to the above-mentioned principle was completely overshadowed by the effects due to other factors.

The percentages of sterol and other unsaponifiable matter, when based on the mycelium, were usually less variable than were the percentages of total fat: consequently, these components generally made up comparatively greater percentages of the fat in those cases where the fat contents of the mycelia were low. Also the undetermined water-soluble components left unaccounted for by the sum of the percentages of fatty acids and unsaponifiable matter amounted to comparatively greater percentages of the fat in these cases.

The amount of lipin-phosphorus was taken as an approximate measure of the amount of phospholipins. In those cases where the lipin-nitrogen was also determined, except for a few apparently abnormal cases, the value of the ratio N/P usually indicated between one and two atoms of nitrogen to one of phosphorus.

At a given temperature of growth and with media that did not become strongly acidic, the percentages of phospholipin (based on the mycelium) and of total fat tended to vary in opposite directions as the initial concentration of glucose, the concentration of NH_4NO_3 (up to 1 %) or the initial p_H was varied.

With a given initial concentration of glucose in the media, the percentages of sterol (based on the mycelium) and of total fat tended to vary in opposite directions as the degree of acidity, the concentration of NH_4NO_3 (up to 1 %) or the temperature of growth was varied.

It was observed that within a certain limited range of growth conditions—a temperature of 25° to 30°, a fairly neutral medium (presence of $CaCO_3$) and an initial concentration of glucose between 5 and 30 %—the values of the ratio, sterol/lipin-P, were usually within the range of 9 to 11. Under most other conditions of growth the value of this ratio was higher. If the free rather than the total sterol had been determined, an even more direct relationship might have been obtained. It has been suggested [Sinclair, 1934] that in animal tissues the sterol and phospholipin might be concerned in the regulation of some physicochemical property of the cells, and it has also been supposed that these two substances have antagonistic actions. Parallelisms between the percentages of cholesterol and phospholipins in different healthy organs of animals have been reported by numerous authors. In mould grown under a limited range of conditions there appears to be a parallelism between the percentages of sterol and phospholipin. In the mould grown under more extreme conditions different amounts and proportions of these two substances might be necessary for the adjustment of the mould cells to the external conditions.

The neutral equivalents of the fatty acids were in all cases very near to 280 (maximum deviation of 5). Although the neutral equivalent of a mixture of fatty acids is usually considered as the effective average molecular weight of the components, the almost constant value observed for the neutral equivalents of the fatty acids produced by *A. fischeri* under such diverse conditions suggests that there was a very great preponderance of those fatty acids which contain 18 carbon atoms.

SUMMARY.

1. Several single spore cultures of *A. fischeri* were compared in regard to the amount and nature of the fats produced in the mycelia. Appreciable differences were noted.

2. A study was made of the effects of the initial concentration of glucose, concentration of NH_4NO_3, acidity, alkalinity, temperature, increased aeration and period of incubation upon the amount and nature of the fat produced by a single spore culture of *A. fischeri*.

3. The production of mycelia with high fat contents was favoured by neutral or slightly alkaline media, a high initial concentration of glucose and a low concentration of NH_4NO_3.

4. The production of increased percentages of sterol in the mycelium was favoured by a fairly high initial concentration of glucose, 1 % NH_4NO_3 or an initially acid medium containing an equivalent amount of urea, a higher temperature (37°) and a long period of incubation.

5. The production of increased percentages of phospholipin in the mycelium, as judged by the percentages of lipin-phosphorus, was favoured by a low initial concentration of glucose, 1 % NH_4NO_3, and an initially slightly acid medium.

6. During inanition the greater part of the fat (exclusive of unsaponifiable matter) was utilised by the mould.

7. The iodine numbers of the fatty acids obtained from the total fat of the mould were higher when the mould was grown on a low concentration of glucose, on a medium which became strongly acid or at a lower temperature.

8. The neutral equivalents of these fatty acids were in all cases very near to 280.

IV. FLAVIN CONTENT OF ANIMAL TISSUES UNDER DIFFERENT CONDITIONS.

By ABRAM J. CHARITE and NICOLAY W. KHAUSTOV.

From the Laboratory of Animal Biochemistry, Academy of Sciences, Leningrad.

(*Received September 28th, 1934.*)

A NUMBER of communications during recent years by Warburg and Christian [1932, 1, 2] show that besides the iron-containing enzyme of a haemin nature there exists another enzyme capable of transporting oxygen under aerobic conditions and of dehydrogenation under anaerobic conditions. The scheme of its action is as follows:

1. Leuco-enzyme + oxygen = yellow enzyme + hydrogen peroxide (under aerobic conditions).
2. Leuco-enzyme + methylene blue = yellow enzyme + leucomethylene blue (under anaerobic conditions).

The power of flavins to oxidise by means of dehydrogenation has also been confirmed by Wagner-Jauregg *et al.* [1934] and by Adler and Euler [1934]. Freed from its colloidal carrier the yellow oxidation enzyme is identical with the flavin discovered and described in the same year by Kuhn *et al.* [1933, 1, 2] and simultaneously by Ellinger and Koschara [1933]. These same authors have shown in their investigations that the flavins are quite similar to vitamin B_2 in their action on the organism, and this makes these compounds the more important. Notwithstanding the great biological significance of the flavins, there do not exist sufficiently precise methods for their determination in animal tissues and organs. György *et al.* [1934] have drawn up a table of the flavin content of tissues according to their degree of action as carriers of vitamin B_2. Euler and Adler [1934] have compared the intensities of the colour of aqueous extracts from different tissues with a standard scale of solutions of flavins in different concentrations. The data obtained by Euler agree well with the data obtained by György *et al.* These methods however do not supply absolute values of the flavin content, but give only approximations.

We believe the method of Warburg and Christian [1933] to give more exact determinations. These authors consider it possible to calculate the concentration of flavins by the intensity of the absorption spectra of methanol extracts. This method of determination is however hardly available for most laboratories as it requires complicated equipment; we have therefore modified it by substituting colorimetry for spectrophotometry.

Method of determination.

Our method of determination is as follows. A definite amount of the organ is powdered and repeatedly washed in water until the water remains clear. The tissue is then extracted with 10 parts of a mixture of 3 vols. methanol with 1 vol. water for 36–48 hours at 28–36°. The extract is centrifuged and the upper transparent layer, containing all the flavins of the tissue under examination, is decanted into a separating funnel and treated with an equal volume of chloroform. The other pigments associated with the flavins pass into the chloroform; treatment with chloroform also clarifies the methanol layer. The lower chloroform layer, usually uncoloured (if the flavins of the kidneys, heart and liver are being examined), is drawn off, and the methanol layer is used for the determinations. The yellow flavin solution in methanol, having a green fluorescence, is compared in a colorimeter with a standard solution of potassium chromate containing 0·1 mg. $KCrO_4$ in 1 ml. This solution corresponds in colour to 1 ml. of an extract containing 2·37γ of flavin as shown below. Colorimetric determinations are possible for two reasons: (1) methanol extracts of the liver, kidneys, heart, brain or lungs do not contain any other pigments, as has been demonstrated by the absorption spectra of extracts of these organs; (2) at these concentrations the solution behaves according to Beer's law that the intensity of the colour is proportional to the concentration of the substance. In Table I is given an example of a determination of the flavin in the cortical substance of the kidney. 9·4 g. of the tissues were treated as above described. The volume of the methanol extract after treatment with chloroform was 70 ml. The solution was yellow-green in colour. The absorption spectrum was determined in the usual manner according to Warburg [1933].

SPECTROPHOTOMETRIC DATA.

Table I. *Measurements of the absorption of light by a methanol extract of the cortical substance of the kidneys.*

λ $m\mu$	I_0	I_1	$\frac{I_0}{I_1}$	λ $m\mu$	I_0	I_1	$\frac{I_0}{I_1}$
510	27·5	25·5	1·08	450	3·6	1·95	1·85
500	21·5	18·2	1·18	448	2·95	1·55	1·91
490	15·7	11·9	1·32	445	2·8	1·5	1·86
430	12·4	8·3	1·47	440	2·1	1·2	1·75
470	8·5	5·2	1·64	430	1·127	0·7	1·61
460	5·9	3·3	1·78	420	0·7	0·5	1·5
455	3·5	1·85	1·88	415	0·35	0·25	1·4

As the table shows, maximum absorption occurs at a wave-length of 448$m\mu$ in the visible spectrum. This fully agrees with the data obtained by Warburg and Christian [1933] for lactic acid bacilli and yeast. The flavin concentration calculated by the formula of the above authors was 0·2406 mg. in the 70 ml. extract or 25·6γ per g. of kidney cortex.

The methanol extract was then measured by the colorimetric method. The standard solution, as has been mentioned above, contains 0·1 mg. $KCrO_4$ in 1 ml. Comparison showed that the intensity of the colour of 1 ml. of the extract corresponded to the colour of 0·145 mg. $KCrO_4$ in 1 ml. But 1 ml. of extract contains 0·2406/70 mg. or 3·44γ of flavin. Hence 0·1 mg. $KCrO_4$ in 1 ml. will correspond in colour to 3·44/1·45 or 2·37γ flavin in 1 ml. This method is suitable for making determinations of flavins in those tissues and organs where the aqueous methanol extract does not contain other pigments, colouring the solution yellow. The liver, kidney (cortical substance), heart and brain belong to such tissues. Other tissues such as the spleen and, especially, blood contain a number of other pigments which influence the colorimetric determinations. Spectrophotometric analysis of the extract of the blood of the white rat for example clearly demonstrates the presence of three maxima, probably corresponding to the haemins (419$m\mu$, 474$m\mu$ and 575$m\mu$). It is evident therefore that colorimetric determination of flavins in blood cannot be based on the yellow colour of aqueous methanol extracts.

Flavin contents of various organs.

Using this method, so convenient for its rapidity and precision, we determined to have the flavin contents of the organs and tissues of several animal species. In Table II the flavin contents of the organs and tissues of a cat and a rabbit are given.

Table II. *The flavin contents in γ per g. of tissues and organs of a rabbit and a cat.*

Species	Liver	Kidney	Kidney cortex	Kidney medulla	Heart	Lung	Brain	Muscle
Rabbit	7·17	14·5	—	—	6·15	9·90	3·07	—
Cat	24·5	6·56	25·2	0	7·82	—	—	—

Our data on the distribution of flavins in the tissues and organs agree with the data of Euler and Adler [1934].

Effect of avitaminoses-A and -C.

We then carried out a series of experiments to determine the effect of avitaminosis on the flavin content of the animal body. Abderhalden's earlier work [1921] on the influence of avitaminosis in lowering the respiration of tissues served as the starting point for our experiments. The flavins form an oxidation-reduction system existing in every cell. We therefore considered it interesting to establish how much avitaminoses-A and -C influence the flavin contents of the livers of calves, rats and guinea-pigs. Determinations of the flavin contents of the liver and kidneys only were made, since these organs are richest in flavins. Table III summarises the results of our experiments.

Table III. *The flavin content in γ per g. of liver and kidneys of animals suffering from avitaminoses.*

Species	Normal	Avitaminosis-A	Avitaminosis-C
Calf (liver)	35·6	28·4	—
Rat (liver)	—	16·9	—
,,	-	28·4	--
,,	30·0	27·5	—
Guinea-pig			
Liver	20·8	—	22·0
,,	13·7	--	19·9
,,	11·9	—	--
Kidney	15·6	—	14·9
,,	—	–	19·2

A small decrease in the flavin content appears to occur in the liver of animals suffering from avitaminosis-A; avitaminosis-C however does not give a clear result; an increase in the flavin content occurred in the liver and a decrease in the kidneys.

Effect of rich protein diet.

The work of Tcherkess [1934] indicates that the lesions of pellagra are often caused by a faulty balance of proteins in the diet and sometimes by excessive protein in the diet of experimental animals. A high content of protein in the food exercises also a large specific dynamic effect. Wishing to establish to what extent these phenomena react on the course of oxidation-reduction processes, we made a number of experiments to determine the influence of a rich protein diet on the flavin content of the liver of white rats. The rats were sub-divided into two groups of eight animals in each, a control and an experimental group. The control group received the usual laboratory diet while the experimental group was fed on a diet rich in protein. The diet of this experimental group consisted of:

60 parts caseinogen (treated with alcohol);
40 parts starch (rice);
10 parts dry yeast;
1 part irradiated yeast;
4·8 parts Mendel-Osborne salt mixture.

The rats were kept for 28 days on such a diet. Table IV gives the flavin content in the liver of the experimental and control rats.

Table IV. *The effect of a rich protein diet on the flavin content γ per g. of liver of white rats.*

No.	1	2	3	4	5	6	7	8
Control	—	19·3	18·2	20·7	13·2	21·0	21·5	19·6
Experimental	20·3	20·4	19·2	18·5	22·9	21·6	19·3	20·3

The quantity of flavins in the liver does not apparently change significantly under the influence of a rich protein diet.

SUMMARY.

1. A method of determining flavins in some tissues and organs is described.
2. Data of the flavin contents of the tissues and organs of a cat and a rabbit are given.
3. In avitaminosis-A there is observed a slight decrease in the flavin content of the livers of white rats and calves.
4. The influence of avitaminosis-C is not clear.
5. A rich protein diet also has no definite effect on the flavin content.

V. THE SPREADING OF COMPLEX PROTEINS.

By EVERT GORTER, HANS VAN ORMONDT
AND THOMAS MARINUS MEIJER.

*From the Laboratory of the Children's Hospital of the
University of Leiden, Holland.*

(*Received October 4th, 1934.*)

SPREADING of proteins can be obtained by bringing a small amount of concentrated aqueous solution of the protein on to the surface of a Langmuir-Adam tray. In our experiments 0·5 % protein solutions and a micro-pipette containing 0·005 ml. are used. The pipette is held horizontally, so that the point is close to the water surface, and the content is slowly blown out. If conditions are favourable for spreading, measurements can be made after a very short time (1–2 minutes).

In order to determine the area occupied by a protein under different pressures, a glass slide is moved towards the floating barrier until this barrier moves away, thus indicating a small rise of the surface pressure.

The floating barrier can now be brought back into equilibrium by torsion of a spring mounted on a balance. The amount of torsion is read on a scale, which is calibrated in dynes per cm. of the floating barrier. The area is measured for different pressures and by extrapolating from these numbers, the area for zero pressure can be found. This part of the technique is identical with that described by Adam [1930] in his studies of the spreading of different substances.

It has been possible to show [Gorter, 1926; Gorter and Grendel, 1926; 1928; 1929; Gorter and Seeder, 1932; Gorter *et al.*, 1932, 1934] that spreading of a protein in a very thin layer (6–7·5 Å. thick) occurs under different conditions. From the experiments of Hughes and Rideal [1932], who used a somewhat different technique, this same thickness can be calculated.

The measured spreading (extrapolated to zero pressure and calculated in sq.m./mg. of spreading substance) is plotted against the p_H of the solution in the tray on which the substance is spread.

The buffers used in the tray were, amongst others, $M/300$ solutions of acetate-acetic acid covering the range p_H 3·6–5·6.

Spreading ovalbumin at a range of these p_H values, a maximum is found at p_H 4·6 (the isoelectric point) and very low minima of spreading on both sides of the isoelectric point, provided the solutions contain very few and only univalent ions.

By increasing the amount of electrolytes in the tray, the minimum spreading on both sides of the isoelectric point can be made to increase.

Multivalent negative ions appear to have a great influence on the minimum on the acid side (p_H 3·0), multivalent positive ions on that on the alkaline side (p_H 6·0) of the isoelectric point. Large amounts of univalent ions (± 40 millimol per litre) small amounts of bivalent ions (± 1 millimol per litre) or very small amounts of trivalent ions (± 1/40 millimol per litre) all produce similar effects: if they are positive they change the minimum spreading on the alkaline side into a maximum, if they are negative, they cause the disappearance of the minimum on the acid side.

Not only inorganic ions but also organic ions like glutathione on the acid side, or spermine on the alkaline side, produce the same effect, when added to the solution in the Langmuir tray. Moreover, a difference is seen between the members of a lyotropic series. Thus Li has a smaller influence than K, and more is needed of Cl to produce the same effect than of CNS [Gorter, 1934].

The explanation of these phenomena is that a protein like ovalbumin does not spread well in an ionised state, whereas the undissociated protein and its non-ionised salts do spread. Addition of ions to the water in the tray favours the spreading by discharging the protein ion.

These results have been obtained with different proteins: ovalbumin, pepsin and trypsin have been most completely studied.

It is the purpose of this paper to give the results of investigations of differences in spreading on different solutions in the tray between a simple protein and a complex protein artificially prepared therefrom.

In these complex proteins basic or acidic substances are combined with acid or basic groups of the protein.

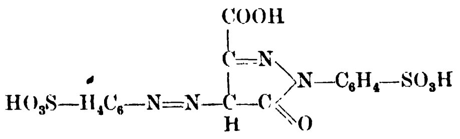
The spreading of complex proteins.

Many proteins are complex in so far as they contain a simple protein molecule to which a prosthetic group is attached, which is important for the behaviour of the molecule as a whole.

In order to elucidate the spreading of this group of proteins, we have prepared complex proteins by adding different substances to ovalbumin and to pepsin.

The first protein is very well suited for this study; it contains a great many free amino- and carboxyl groups and therefore the introduction of another molecule attached to these groups will be most likely to influence the mode of spreading at varying p_H.

Pepsin has a pronounced minimum on the alkaline side of the isoelectric point (p_H 2·85) and therefore is very appropriate for studying the influence of positive ions. Ovalbumin can be combined with tartrazin (I).



$$\begin{array}{l} \qquad\qquad\qquad\qquad\quad \mathrm{COOH} \\ \qquad\qquad\qquad\qquad\quad \mathrm{C{=}N} \\ \qquad\qquad\qquad\qquad\quad\ | \qquad \rangle \mathrm{N{-}C_6H_4{-}SO_3H} \\ \mathrm{HO_3S{-}H_4C_6{-}N{=}N{-}C{-}C} \\ \qquad\qquad\qquad\qquad\quad \mathrm{H} \qquad\ \ \mathrm{O} \end{array}$$

(I).

It is obvious that the latter, being a strong acid, must combine with the free NH_2 groups of the protein.

If we study the spreading of this complex protein, we see no change at the isoelectric point and on the alkaline side of this point, whereas the minimum on the acid side at p_H 2·7–3·0 disappears completely (Fig. 2).

Examination of the amount of tartrazin that must be added to an ovalbumin solution shows that 5·6mM tartrazin is sufficient for an ovalbumin solution containing 5 mg./ml., this being 1/7mM (mol. wt. 35,000). From these numbers we may calculate that ovalbumin contains 39 free NH_2 groups per molecule which combine with tartrazin to form a product showing maximum spreading at p_H 3·0.

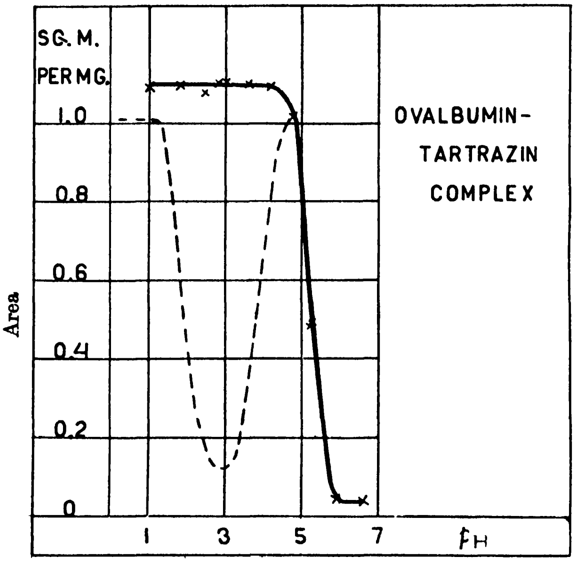


Fig. 1. The dotted curve shows the spreading of ovalbumin to which no tartrazin has been added. The continuous curve shows the area (in sq. m. per mg.) of the protein when spread on different solutions in the tray, the p_H of which is indicated on the abscissa. This ovalbumin-tartrazin complex contains 5 mg. ovalbumin per ml. and is 16*mM* with respect to tartrazin, an excess of which is present.

Measurements shown in this and other figures are made after 1–2 minutes unless otherwise stated.

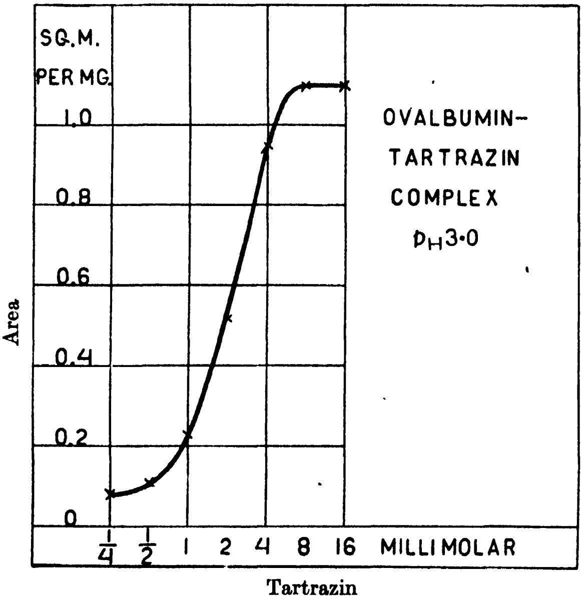

Fig. 2 Showing amount of tartrazin in millimols per litre that must be added to a 0·5 % ovalbumin solution in order to obtain spreading. The areas are indicated on the ordinate in sq. m. per mg.

If a less than 5·6*mM* solution of tartrazin is added to the same ovalbumin solution, some of the NH_2 groups only are bound and intermediate values for the spreading are obtained (Fig. 2).

The explanation must be that the protein now behaves as an acid and no longer as a zwitterion.

The reverse can be shown when a complex is prepared by adding to pepsin a substance like spermidine (II).

$$H_2N(CH_2)_3NH(CH_2)_4NH_2 \qquad \text{(II)}$$

This combines with the free COOH groups and now the curve of the spreading at varying p_H has the form shown in Fig. 3.

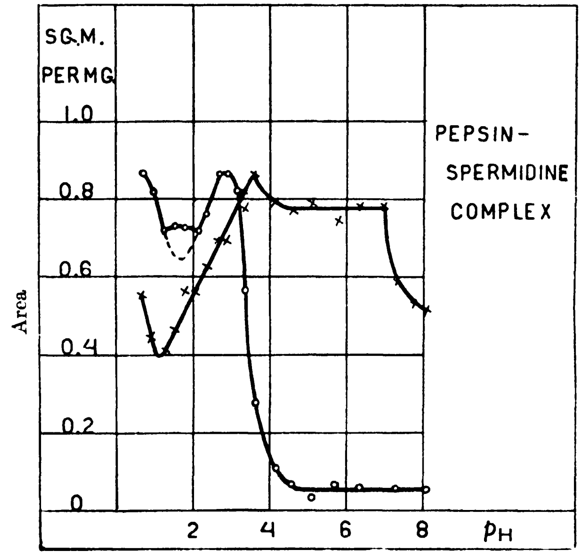

Fig. 3. The curve o—o—o gives the area for the spreading of pepsin (Northrop) on solutions of varying p_H. The dotted line between p_H 1·2 and 2·1 is the curve given by pepsin, to which no acetic acid is added as in this experiment (see experimental part).

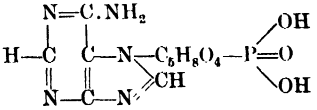
The curve ×—×—× gives the spreading of a pepsin-spermidine complex on solutions of varying p_H.

This is to be explained by the transformation of the protein into a multivalent amine.

Here however on the acid side of the isoelectric point a different spreading is also observed with spermidine-pepsin. This may be due to the fact that pepsin is already a complex protein (see below).

We have also studied the influence of nucleic acid on the spreading of ovalbumin,



$$\begin{array}{l} \mathrm{N{=}C.NH_2} \qquad\qquad\quad \mathrm{OH} \\ \mathrm{H{-}C\ \ C{-}N{-}C_5H_8O_4{-}P{=}O} \\ \mathrm{N{-}C{-}N{=}CH} \qquad\qquad \mathrm{OH} \end{array} \qquad \text{(III)}$$

and we were unable to discover any definite change of the spreading at varying p_H as is shown in Fig. 4.

This fact is readily explained by the amphoteric character of nucleic acid itself[1]. At p_H 3·0 on the acid side of the isoelectric point combination of the phosphoric acid groups with the NH_2 groups of the protein is to be expected. But this does not influence the spreading, because the other end of the molecule has a free NH_2 group which simply replaces the original free NH_2 group of the protein. On the alkaline side at p_H 6·0, the same reasoning holds good. The free NH_2 group of the nucleic acid then enters into relation with the free COOH group of the protein, but now the acid character is not modified, the COOH groups being simply replaced by the free acid groups of the phosphoric acid. The same reasoning can explain the absence of different behaviour in spreading experiments with the azoprotein prepared by coupling ovalbumin with the compound

---

[1] We give the formula of ¼ part of nucleic acid (III) to show this.

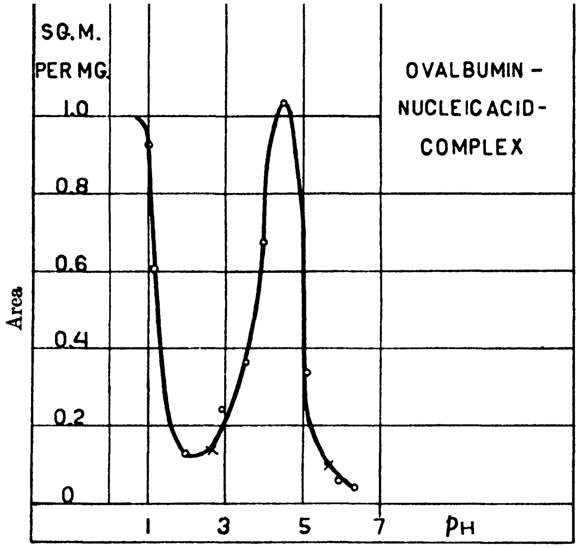


Fig. 4. Nucleic acid in 16*mM* solution is added to ovalbumin. There are only minor differences from the ovalbumin-curve (*cf.* Fig. 1). Points o and × represent different preparations.

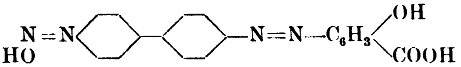

$$\underset{\mathrm{HO}}{\mathrm{N{=}N}}{-}\mathrm{C_6H_4{-}C_6H_4{-}N{=}N{-}C_6H_3}\begin{matrix}\mathrm{OH}\\ \mathrm{COOH}\end{matrix}$$

If now we compare the behaviour of this group of complex proteins with that of trypsin, pepsin and insulin, it is possible to state that in the latter proteins only few NH_2 or COOH groups are present.

Pepsin gives the same type of curve as shown by tartrazin-ovalbumin [Gorter and van Ormondt, 1935]; this is in agreement with the small number of free NH_2 groups (5 per molecule of 34,500) found by Northrop [1930] for this protein. Moreover, the curve of acetylpepsin[1] is somewhat modified, the minimum on the acid side of the isoelectric point being less distinct than that of ordinary pepsin (Fig. 5).

The behaviour might be explained by the assumption that pepsin is formed by the combination of a protein with a fairly strong multivalent acid neutralising most of the NH_2 groups of the protein molecule.

The reverse observation can be made with trypsin [Gorter and van Ormondt, 1935] which behaves like a spermidine-protein complex. It is reasonable to suppose that trypsin is a complex protein consisting of a combination of a protein and a multivalent base.

---

[1] Kindly supplied by Dr J. H. Northrop.

Insulin [Gorter and van Ormondt, 1933] gives a curve that would indicate that some of the NH_2 groups are not available for reaction with H ions on the acid side of the isoelectric point, because its minimum is not pronounced as in ovalbumin. It has the form of the curve obtained with a tartrazin-ovalbumin complex formed by admixture of less than 5·6*mM* tartrazin solution with a 0·5 % ovalbumin solution.

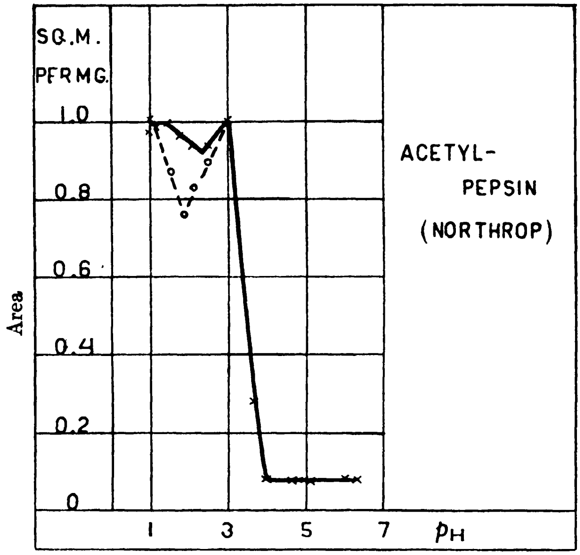

Fig. 5. The spreading of acetylpepsin. The dotted line gives the spreading of pure pepsin and the continuous line that of acetylpepsin solutions of varying p_H.

It is interesting to add to the above-mentioned fact a series of observations showing that not only does ovalbumin combined with tartrazin behave differently from ordinary ovalbumin, but that the same result can be obtained by spreading ordinary ovalbumin at a p_H 3·0 on a tray containing tartrazin.

Here the maximum spreading is obtained within a short time after the ovalbumin has been blown out on the surface of the water in the tray containing tartrazin in a 1/80*mM* solution at p_H 2·7 (Fig. 6), and the same observation holds good at p_H 5·6 when spermidine is added to the water in the tray on which ordinary pepsin is spread, and the spermidine content is *mM* at p_H 5·6 or 7·45 (Fig. 7).

Fig. 8 gives for comparison the amount of spermidine to be added to 0·5 % ovalbumin solution in order to obtain a product that shows maximum spreading at p_H 5·6.

This effect is no longer observable with the tartrazin-ovalbumin or spermidine-pepsin complex owing to the fact that the NH_2 groups or COOH groups can no longer react.

This influence of substances such as tartrazin on the acid side is exactly comparable with the influence of bivalent negative ions (*e.g.* $SO_4^{=}$ or glutathione) whereas spermidine (Figs. 9 and 10) has the same action as bivalent positive ions (*e.g.* Mg, Sr or agmatine). We can obtain maximum spreading of ovalbumin

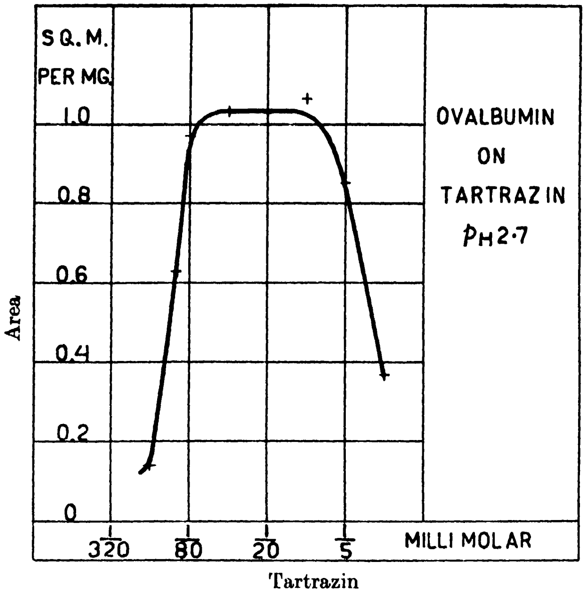

Fig. 6. Showing dependence of maximum spreading of ovalbumin on tartrazin at constant p_H upon the concentration of tartrazin.

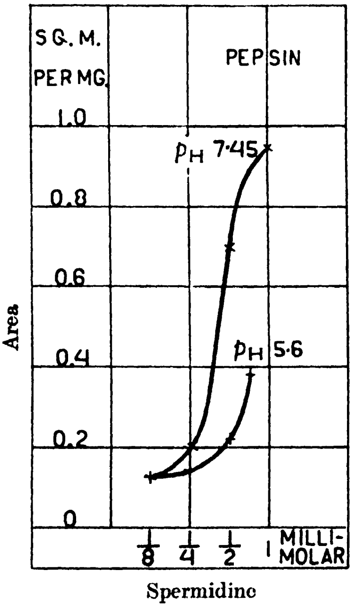

Fig. 7.

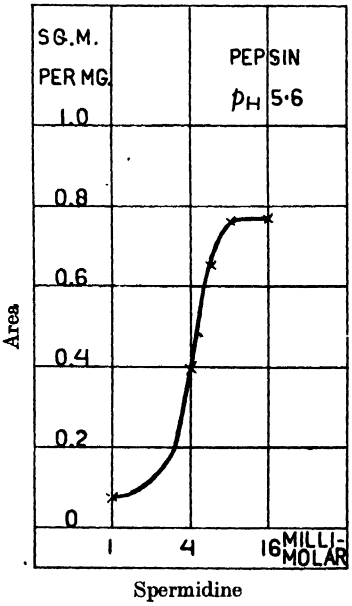

Fig. 8.

Fig. 7. Effect of concentration of spermidine in tray solution upon spreading of pepsin.

Fig. 8. Effect of concentration of spermidine in pepsin solution upon spreading of latter on acetate buffer solution, 0·033 M.

at p_H 3·0 by addition of the negative ions and at p_H 6·0 by adding the positive ions.

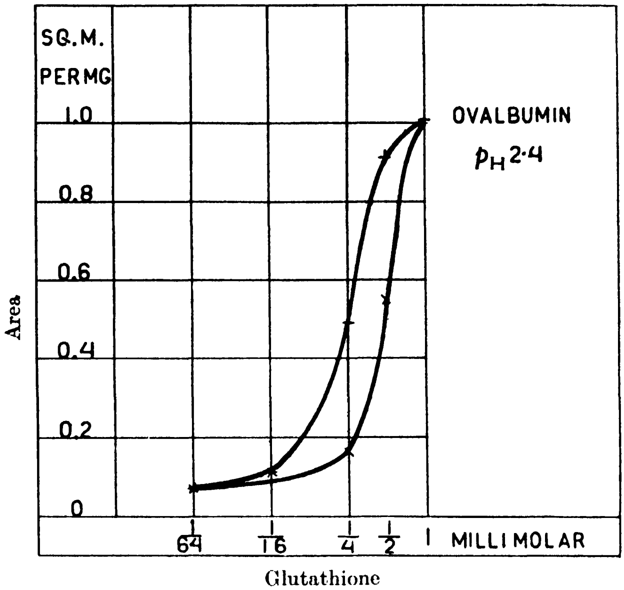

Fig. 9. Spreading of ovalbumin on solutions of glutathione of varying concentration. Left-hand curve after 6 minutes; right-hand curve after 12 minutes.

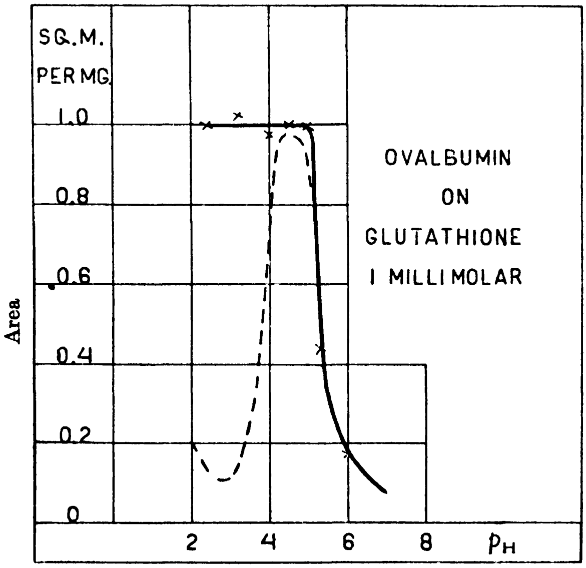

Fig. 10. Continuous curve shows spreading of ovalbumin on glutathione solutions of varying p_H; dotted curve shows the spreading on water at similar p_H.

The above experiments may indicate that at the water surface compounds of the protein and these different substances are formed.

Preparation of ovalbumin.

The ovalbumin used in these experiments was prepared in the following way.

The white of 20 fresh eggs, usually about 600 ml., was beaten and mixed with an equal volume of saturated ammonium sulphate to precipitate ovoglobulin. After standing 24 hours in the ice-box, the ovoglobulin was removed by centrifuging and to the remaining solution was added, slowly with careful stirring, saturated ammonium sulphate until the liquid became distinctly turbid. The slight precipitate was dissolved by slowly adding just sufficient distilled water. To the clear solution was then added, very slowly with careful stirring, 10 % acetic acid until again a slight precipitate was formed. Then some more saturated ammonium sulphate was added to induce rapid crystallisation. After standing 1 or 2 days in the ice-box a large amount of ovalbumin had crystallised. It was centrifuged and dissolved in distilled water. The solution was again treated with ammonium sulphate and acetic acid in the manner described above, and in all six recrystallisations were usually carried out in about a fortnight.

The solution was then dialysed in the ice-box against distilled water, using a cellophane membrane, until no more sulphate could be detected in the outer liquid. The concentration of the pure solution was determined either by ter Meulen's micro-nitrogen method or Bang's gravimetric method.

Preparation of the azoprotein.

0·46 g. of benzidine was dissolved in 100 ml. of water containing 3 ml. of 1 : 1 hydrochloric acid and tetrazotised at 7–8° with an aqueous solution of 0·35 g. of sodium nitrite. The solution was poured into a chilled solution of 3 g. of sodium acetate in 500 ml. of water, and to this was added a solution of 0·36 g. of salicylic acid in 100 ml. of water. The mixture slowly became a chocolate-brown colour, especially after adding 20 ml. of N K_2CO_3. The intensely coloured solution now contained tetrazotised benzidine coupled on one side with salicylic acid, but with the other diazo-group free.

165 ml. of dialysed egg-albumin free from ammonium salts containing about 1 g. of protein were made alkaline with 15 ml. of N K_2CO_3. 130 ml. of the above diazo-solution were then run in followed by 8 ml. of N K_2CO_3.

The dye protein solution was next chilled overnight and acidified first with acetic acid and then with hydrochloric acid until acid to Congo red.

The crude salicylic acid-azo-benzidine-azo-egg-albumin was collected by centrifuging. The centrifugate was washed with acidified water and again centrifuged. This was repeated three times. The precipitate was dissolved in distilled water by adding a few drops of 2·5N NaOH. The p_H of the solution was 11·6; by addition of HCl it was reduced to 8·4.

Preparation of the tartrazin-ovalbumin complex.

Since tartrazin is an acid dye, according to the rule that acid dyes colour best in acid medium [Hammersten *et al.*, 1928], the tartrazin solution and the ovalbumin solution were mixed at p_H 4·0. 4 ml. of egg-albumin solution, containing 60 mg. per ml., were diluted with citrate buffer (McIlvaine) to 44 ml., and to this solution 20 ml. of 1 % tartrazin in 50 % alcohol were added. A yellow precipitate separated and was centrifuged. The precipitate was washed three times with citrate buffer solution (p_H 3·0). The precipitate could be dissolved in a buffer solution of p_H 11·0 (made from 0·1N NaOH and M/10 borax).

The percentage of tartrazin in the solution was determined colorimetrically and the amount of egg-albumin by the micro-Kjeldahl method. The nitrogen content of the solution was determined and from this the nitrogen value of the tartrazin was subtracted.

Ovalbumin with varying amounts of tartrazin, obtained by simply adding different amounts of tartrazin solution to an ovalbumin solution, were made up. The following were prepared: 10 ml. containing 6·2 mg. ovalbumin per ml. and 0·016, 0·008, 0·004, 0·002 and 0·001M tartrazin respectively. The p_H was about 5·7.

Ovalbumin with varying amounts of nucleic acid.

In a similar way solutions containing ovalbumin and adenylic acid or rather sodium nucleate were prepared.

The following were prepared: a solution containing 6·2 mg. ovalbumin per ml., which was 0·016 *M* with respect to adenylic acid; the other solutions contained the same amounts of ovalbumin but were 0·008, 0·004, 0·002 and 0·001 *M* with respect to adenylic acid.

Pepsin with spermidine.

A solution of pepsin [Northrop, 1930] in glycerol containing 30 mg. of crystalline pepsin per ml. was diluted five times, and 1 ml. quantities of this solution were mixed with varying amounts of 0·032 *M* spermidine and the equivalent amounts of acetic acid. Each mixture was made up to 2 ml. The following were the final concentrations of spermidine: 0·001, 0·002, 0·004, 0·008 and 0·016 *M*.

These experiments have been made possible by a grant from the Pilter Langeshuizen Fund.

VI. THE SPREADING OF MYOSIN.

BY EVERT GORTER AND HANS VAN ORMONDT.

From the Laboratory of the Children's Hospital of the University of Leiden, Holland.

(*Received October 4th, 1934.*)

WHEREAS most proteins so far studied show spreading at their isoelectric points or on strongly acid solutions (we have examined more or less thoroughly ovalbumin, zein, gliadin, insulin, pepsin, trypsin, ovoglobulin, ovomucoid, caseinogen, globin and haemoglobin) some proteins do not spread, when tested by our usual technique. Gelatin is a bad spreader and this is due to its too great solubility. Myosin and probably fibrinogen also do not spread because the particles of the sols have too little solubility.

Spreading of well-purified myosin is very difficult to obtain. At the isoelectric point (p_H 6·1) spreading is never observed, and even on a strongly acid solution p_H 1·0 sometimes no spreading can be detected.

In early experiments when the myosin was not sufficiently freed from myogen (or other contaminants) we obtained some spreading differing according to p_H. When the solutions were almost free from other proteins, we observed small films of protein floating on the surface, visible to the naked eye, and having a bluish tint. After more prolonged purification, this also was no longer observed.

Now it is possible to induce myosin solutions to spread by adding to the solution a trace of a proteolytic enzyme. Before degradation takes place into small particles which have no longer spreading properties (amino-acids never spread and neither do smaller peptides like the tetrapeptide of alanine and the tripeptide of leucine [Gorter *et al.*, 1934]) the myosin is transformed into a spreading substance; this process is highly dependent on the temperature of the solution and on the amount of the trypsin added, and it takes some time before the final effect of the action of the trypsin on the myosin is obtained, when the concentration of trypsin is rather low.

In Fig. 1 the results are given of measurements of the spreading of myosin solutions (6 mg./ml.) to which trypsin in one concentration 1/3250 was added. The temperature was kept constant (38°) and the results after various times were plotted.

It appears that before hydrolysis as indicated by the falling off of the curve occurs, the myosin is transformed into a group of spreading substances. Even during a certain length of time spreading remains maximum, although the enzymic process must be considered as being continuous.

Whereas the curve in Fig. 1 from 2 to 10 minutes appears linear, experiments with smaller amounts of trypsin indicate that this appearance is incorrect (Fig. 2).

Fig. 3 shows the influence of the concentration of trypsin on the spreading of myosin solutions of the same strength, time and temperature being constant (8 minutes and 38° temperature).

The next series of curves (Fig. 4) shows the results of measurements of spreading when different concentrations of trypsin are added to myosin (6 mg./ml.) after various periods of time at the same temperature. If the concentration is high (1/125), no maximum spreading is observed: the hydrolysis has proceeded too far before the first measurement can be made (2 minutes).

In the next series with a concentration of 1/350, hydrolysis begins just after 2 minutes, when the maximum has been reached. At 1/1000 the curve begins

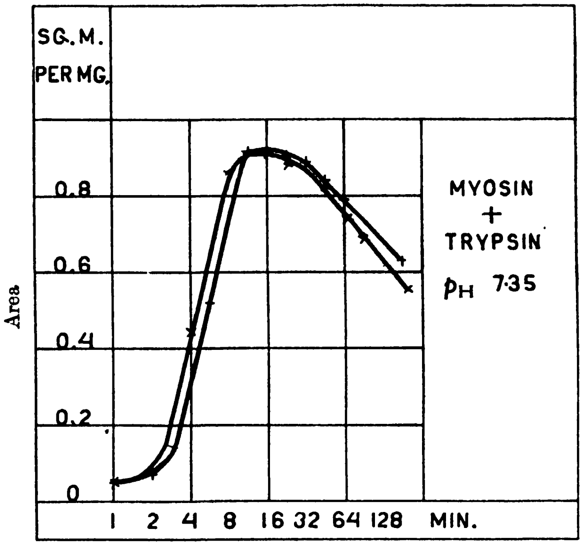

Fig. 1. Influence of time of action of trypsin (final concentration 1/3250) on spreading of myosin (6 mg./ml.). $T = 38°$. Tray solution 0·08 M phosphate.

— x — x — x — Myosin four times reprecipitated.

— + — + — + Myosin three times reprecipitated.

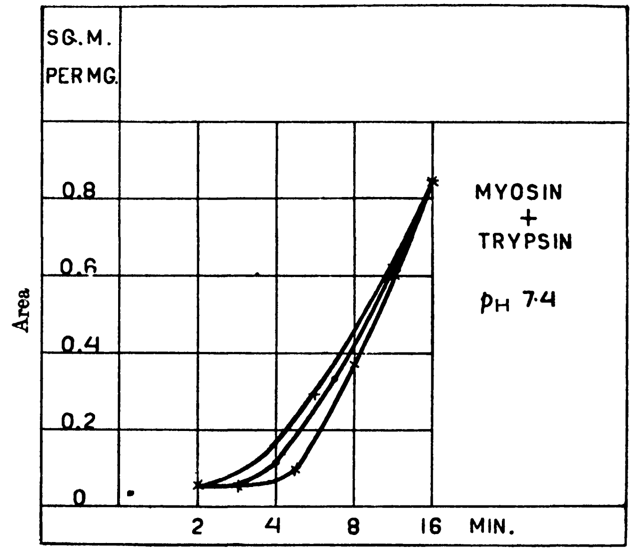

Fig. 2. Same as Fig. 1 save that trypsin concentration was 1/8000. $T = 40°$. Differences between the curve are due to experimental error.

to fall after 4 minutes and at 1/2200 both the beginning of the favourable influence on spreading and of the hydrolysis can be observed; the first process has already proceeded very far towards completion at the time of the first measurement. The typical form of curve showing a gradual rise to a plateau followed by a fall appears at dilutions of 1/8000 and higher.

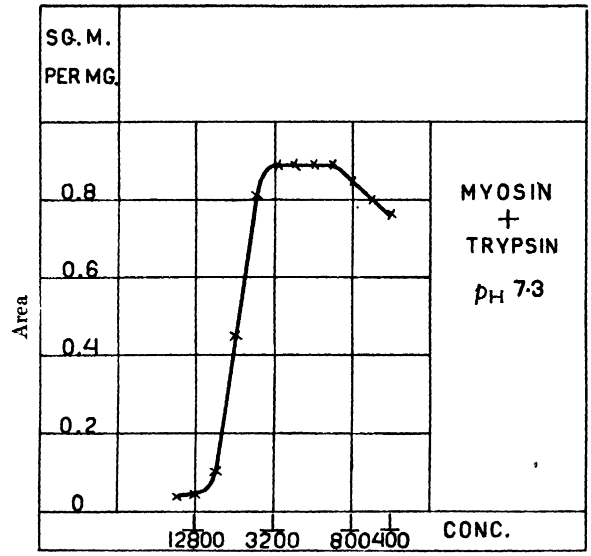

Fig. 3. Effect of varying concentration of trypsin on spreading of myosin. Time of action of trypsin 4 minutes. $T = 38°$.

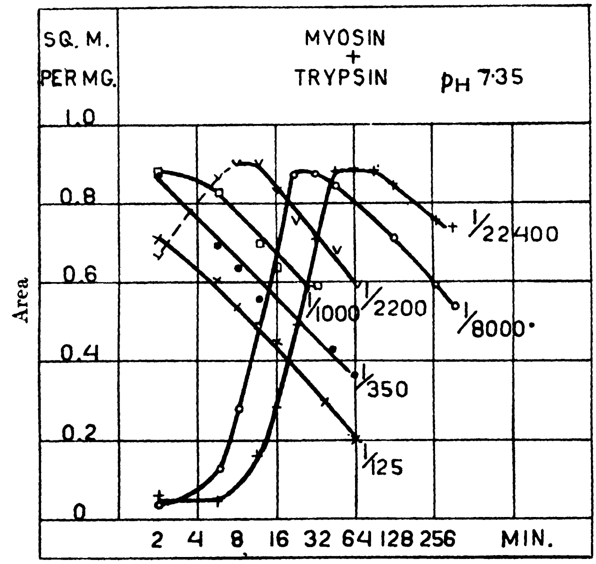

Fig. 4. Curves constructed similarly to those of Fig. 1 but with different concentrations of trypsin. Figures indicate relation between trypsin and myosin; *e.g.* 1/125 means 0·1 mg. trypsin and 12·5 mg. myosin in 2 ml. phosphate buffer.

In order to study the influence of temperature on the first part of the process, we have tried to get the same curve for different temperatures and different concentrations.

Fig. 5 shows that the same type of curve results when spreading is plotted against time. From these observations a linear relationship between temperature and the logarithm of the trypsin concentration can be deduced (Fig. 6) from which a temperature coefficient of 3·6 for 10° can be calculated.

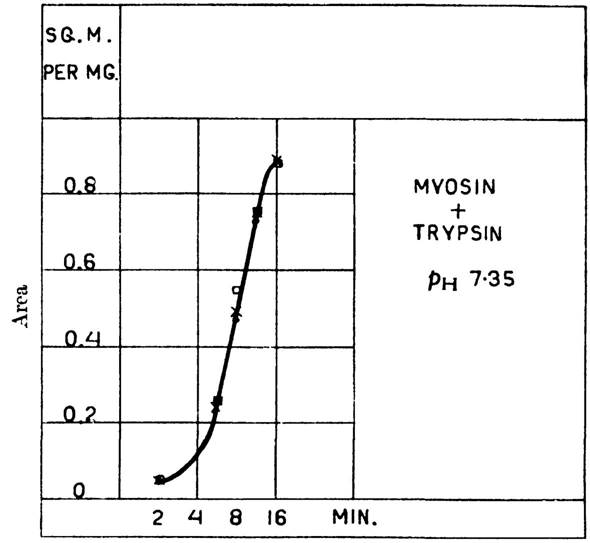

Fig. 5. Showing that the same area for the spreading of myosin after exposure for a given time to the action of trypsin can be obtained by varying both temperature and concentration of trypsin. If temperature is increased, the concentration must be lowered to get the same effect.

+—+—+ $T = 16°$, and trypsin/myosin = 1/350.
×--×—× $T = 24°$. „ „ = 1/1000.
●—●—● $T = 40°$. „ „ = 1/7900.
□—□—□ $T = 48°$. „ „ = 1/22,400.

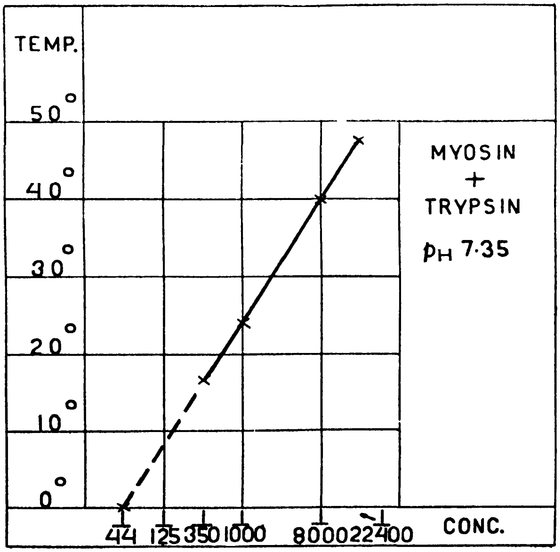

Fig. 6. Showing linear relationship between the logarithm of the concentration of trypsin and the temperature. Temperature coefficient = 3·6. The point at 0° is obtained by extrapolation.

The maximum spreading per mg. myosin under these conditions is 0·9 sq.m. It is somewhat less than the maximum spreading of most other proteins at the isoelectric point.

All the above-mentioned measurements were made on 0·08 M phosphate buffer solution, having p_H 7·3–7·4. It is possible to show that the product obtained by adding trypsin to myosin at the moment when it begins to show maximum spreading is not very much influenced by p_H at about this reaction. We have obtained the same figure when examining "spreading myosin" in the same phosphate solution at p_H 7·1, 7·4, 7·6 and 8·1. This result was obtained by arresting the reaction by cooling the mixture to 0°.

We have also found that a muscle extract, probably containing the proteolytic enzyme from muscle, can in much smaller dilutions produce the same effect on a myosin solution as does trypsin.

The foregoing results seem interesting in so far as they show that an enzyme can, by inducing a protein to increase its surface, prepare it for hydrolysis into smaller peptides and amino-acids.

They have perhaps a still greater importance in other respects, because they show that there exist proteins which do not spread under the conditions that permit a spreading of most other proteins (at p_H 1·0, at the isoelectric point or after addition of bivalent negative ions on the acid side or of positive ions on the alkaline side of the isoelectric point), but that partial hydrolysis into simpler compounds is necessary to produce this spreading.

It is worth while to emphasise that this behaviour is observed with a protein, which shows birefringence of flow under polarised light, which is a proof of the existence of long-shaped particles in a myosin solution.

Preparation of myosin.

The myosin used in these experiments was prepared in a way similar to that indicated by Edsall [1930].

A rabbit was narcotised by means of a 20 % solution of urethane, injected intraperitoneally. The animal was bled to death by opening the carotid artery. The muscles of the legs and back were taken, weighed and quickly put through a mincer. The minced muscle was brought into about three times its weight of a concentrated salt solution containing 1·2 M KCl, 0·05 M Na_2HPO_4 and 0·01 M KH_2PO_4. The mixture was kept at 0° and stirred vigorously for about 2 hours, during which time it became very viscous. It was strained through a linen cloth. The undissolved part was again mixed with salt solution (about a third of the quantity used the first time) and extracted at 0° during 2 hours. This was repeated until the solution no longer showed double refraction of flow and gave only a slight precipitate with salicylsulphonic acid. Usually three or four extractions sufficed.

The different solutions of muscle protein were combined and added slowly with careful stirring to twenty times their volume of ice-cold distilled water. The precipitate was centrifuged, redissolved in the smallest possible amount of the above-mentioned salt solution and the myosin reprecipitated by pouring into 20 vols. of ice-cold water. In this way the myosin was purified by three or four reprecipitations. The process of purification could be controlled by the spreading experiments: after some precipitations the product no longer spread, either immediately or after standing for an indefinite length of time.

The concentration of the solutions was estimated by means of micro-Kjeldahl determinations.

These experiments have been made possible by a grant from the Rockefeller Foundation.

VII. BRAIN RESPIRATION, A CHAIN OF REACTIONS, AS REVEALED BY EXPERIMENTS UPON THE CATATORULIN EFFECT.

BY RUDOLPH ALBERT PETERS, HÅKAN RYDIN[1]
AND ROBERT HENRY STEWART THOMPSON[2].

From the Department of Biochemistry, Oxford.

(*Received November 2nd, 1934.*)

PREVIOUS work has shown that vitamin B_1 acts *in vitro* in respiring enzyme systems from the avitaminous pigeon's brain to induce an increased oxygen uptake [Gavrilescu *et al.*, 1932] in lactate and pyruvate solutions under defined conditions. Pyruvate was formed in lactate solutions in absence of vitamin and disappeared in its presence, suggesting that it was a normal metabolite [Peters and Sinclair, 1933; Peters and Thompson, 1934, 1]. The average value for the quotient, extra O_2 uptake in presence of vitamin/pyruvic acid disappearing, represented 2 mols. of O_2 to 1 mol. of pyruvic acid used, but careful study of this ratio showed variations sufficiently wide to lead to the tentative conclusion that pyruvate disappearance was actually an indirect effect of the added vitamin. In this paper, more evidence is produced in the same sense. The action of the vitamin depends to a marked extent upon the method of preparing the tissue; it is apparently concerned with formation of some unidentified substrate which then interacts to produce increased O_2 uptake. Hence we must visualise the extra oxygen uptake observed as being the result of a chain of chemical events in the tissue.

We have continued to use the avitaminous pigeon's brain for this work; the behaviour of mammalian brain is of course more interesting from many points of view, but use of the pigeon's brain is advantageous in view of the exact knowledge of conditions of avitaminosis and above all of the ease of removal of the brain from the soft skull. It is doubtful whether the facts given below could have been elucidated without the use of the avitaminous brain, which illustrates the advantage of material of this type in illuminating obscure phases of metabolism.

Further details of technique.

Birds used have been in acute opisthotonus symptoms; they have usually been under vitamin B_1 test for 2–8 days, so that the symptoms have appeared for a second time. Depletion is thus more complete. Unless otherwise stated the tissue has been prepared upon a warm plate at 38°; division is done with a small, blunt bone spatula (to avoid cutting and metals). Duplicates are filled alternately; the tissue in the bottles, after re-weighing, is divided with a glass crusher. It is best to allow to stand 3 mins. before making the additions of the vitamin *etc.* Observations have been made in the differential apparatus. Tissue has been put into previously tared bottles. For the rapid simultaneous handling of a large number of duplicate samples from brain tissue, this method has proved more suitable than attempts to weigh exact amounts of tissue upon a balance. All bottles have been filled with oxygen, and duplicates evacuated in the order 1*a*, 2*a*, 3*a*, 4*a*, the first lot, then 1*b*, 2*b*, 3*b*, 4*b*, the second lot, *a* and *b* being duplicates, *etc.* Other details of the work have not been changed.

---

[1] Rockefeller Fellow.

[2] Senior Demy, Magdalen College.

Unless otherwise stated, sodium pyrophosphate (at p_H 7·3) has been used throughout, made up so that an addition of 0·1–0·2 ml. of Na pyrophosphate produced a final concentration of 0·01 *M*. Small variations in this concentration do not seem to matter. As has been shown previously [Peters and Sinclair, 1933], this compound enhances the catatorulin effect.

Effect of temperature of preparation upon the rate of respiration[1].

The difficulty of obtaining satisfactory duplicate values for respiring brain tissue "brei" has repeatedly forced itself upon our attention. It seemed also that some general factor of unknown nature influenced the level of respiration, apart from the action of the vitamin. In particular, there was a tendency for lower values in winter. This led us to study the effect of temperature of mincing upon the subsequent rate of respiration, with remarkable results. Some of these have been recorded elsewhere [Peters and Thompson, 1934, 2].

In these experiments, equal halves of the brain of a guillotined pigeon were removed with minimum injury; without delay the halves were minced respectively for 2 mins. upon a plate cooled in ice and upon a glass hot water funnel kept warm at 38° ± 2°. In most cases right and left cerebral hemispheres were compared. The results are given in Table I, and a particularly striking case which is diagrammatic of the effect is shown in Fig. 1.

For the normal brains in 13 out of 15 experiments (see a selection of these in Table I and Fig. 1), there was found to be a large difference between the respirations of the "warm" and "cooled" tissue in lactate solutions. This also occurred in pyruvate solutions with avitaminous brains. On the other hand the tissue in Ringer phosphate solution only (residual respiration) showed little difference. Respiration in succinate again was little affected. Among these three substrates (the only ones tried), the influence was confined to lactate and pyruvate. As in the catatorulin effect, succinate respiration is hardly influenced [*cf.* Gavrilescu *et al.*, 1932]. It might be expected that the tissue prepared "warm" would show damage to its respiration, owing to inactivation by enzymes of some essential constituent. The result is quite different. The greater respiration occurs in the tissue prepared "warm." Since there is little change in residual respiration, it is not merely an increase in tissue substrates. In older parlance, it would have been said that more lactate and pyruvate oxidases are present in the "warmed" than in the "cooled" specimen; but an increased O_2 uptake does not seem to be necessarily associated with increased disappearance of lactate [Meiklejohn, 1933]; hence it is more probable that some essential element of the carbohydrate respiration is retained in the "warmed" brain. It is to be noted that the effect is present with added pyrophosphate.

The difference in respiratory behaviour is accompanied by a visible difference in the state of the tissue; in the tissue kept "warm" the trace of blood present at the end of the period of mincing (2 mins.) is strongly reduced, whereas in that minced "cool" it is a bright red colour; it has also been our impression that the tissue kept "warm" has a slight yellowish tinge. The obvious suggestion that the effect was due to the state of the glutathione has been tested. Exp. 658 shows that the extra respiration is not restored to the "cooled" tissue by addition of glutathione.

---

[1] By use of the term respiration, we wish to imply that the oxygen uptake observed is a complex.

Table I. *Comparison of rates of respiration for tissue prepared under "warm" and "cool" conditions.*

Expressed as μl. O_2/g./hr. (wet weight). 2000 = Q_{O_2} 10.

511	Nil	Cool	655	600	394	364
	,,	Warm	830	615	525	424
	Lactate	Cool	1750	1455	1380	1260 (pp)
	,,	Warm	2255	1790	1708	1663
669	Lactate	Cool	2660	1870	1390	—
	,,	Warm	2870	2410	1790	—
	Succinate	Cool	4610	3900	2900	—
	,,	Warm	4200	3270	2470	—
670	Lactate	Cool	2270	1690	1300	1100
	,,	Warm	3100	2700	2190	1840
	Succinate	Cool	4610	3410	2420	1670
	,,	Warm	4030	3270	2440	1930

Note. The above experiments are illustrative only. 511 was made with addition of pyrophosphate (pp). In 669 and 670 the periods are 0–¼, ¼–¾ hours, *etc.* In 669 and 670 concentration of succinate = 0·07 *M* (25 mg. in 3·0 ml.). Nil = Ringer phosphate only.

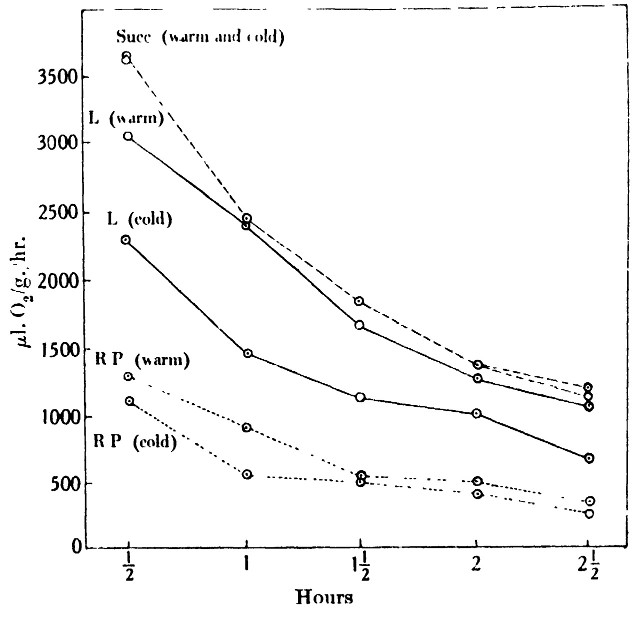

Fig. 1. Exp. 596. Basal medium Ringer phosphate, RP. Succ. = RP + Na succinate, 0·07 *M*. L = RP + Na lactate, 0·03 *M*. Pigeon's brain tissue minced "warm" and "cold". The difference in respiration rates is approximately the same for RP and Succ., but markedly different at first for L.

Exp. 658. The right and left lobes of a pigeon's brain (normal) were removed within 30 secs. of death and minced for 2 mins. upon warmed and cooled plates. Respiration μl./g./hr. Glutathione 0·009 *M*. Ringer-phosphate-pyrophosphate-lactate.

Period (hrs.) ...	¼–¾	¾–1¼	1¼–1¾
Cooled	1760	1470	1370
„ +G	1860	1560	1400
Warmed	2330	2000	1770
„ +G	2460	2160	1855

The slight effect here can be entirely explained upon the grounds of the O_2 uptake of the glutathione itself. Another possibility was tested, *viz.* that part of the effect might be due to drying of the "warmed" tissue and settling of moisture upon the "cooled," though this is really excluded by the succinate experiments; the water contents were found to be not significantly different. It is known [Kinnersley and Peters, 1929] that lactic acid production takes place with great rapidity in these brains, being complete in about 90 secs. At first it was thought that the effect was more marked in brains removed within 30 secs., but this could not be proved.

From the general relation of the catatorulin effect to pyruvate and lactate, it would be inferred that the vitamin would show greatest action upon tissue minced "warm." The experiments, of which one example of each is given in Table II, show that this is so. In one case even there was no effect of vitamin in the "cooled" tissue.

Table II. *Avitaminous brains. Temperature effects.*

μl./g./hr.

			Diff.	—	65	130	—
		Warm	Control	1905	1620	1320	1095
			V	2140	1955	1730	1540
			Diff.	235	335	410	445
518	Pyruvate	Cool	Control	670	490	370	340
			V	908	686	540	510
			Diff.	238	196	170	170
		Warm	Control	935	670	470	460
			V	1080	960	800	790
			Diff.	145	290	330	330

It is especially difficult to obtain good duplicate values with the "cooled" tissue, probably because of the uneven temperatures induced, even with the best efforts to crush immediately. It is clear that scrupulous attention to minute detail is necessary to get reliable control of these enzyme systems from brain. The temperature effect certainly explains some of our puzzling difficulties in the past.

In previous work, as an experimental hypothesis, we have postulated a substrate *X* with which the vitamin interacts. We have now reached the position that the vitamin effect depends in addition upon some unknown factor present in the "warmed" tissue; it therefore depends upon the method of preparation. If the tissue minced "warm" is transferred to the cooled plate, a change in colour takes place and the tissue becomes bright red. This is followed by a fall in the lactate respiration. Hence cooling and change in the level of oxidation together lower the respiration. On the other hand, if the "cooled" tissue is transferred after mincing to a warmed plate, change of colour indicating reduction occurs but there is no (or very little) return of the respiration rate in lactate or of increased vitamin effect, as we have found in four experiments of which Exp. 664, Table III, is one; compare with Exp. 651, Table II.

Table III.

Exp. 664. Avitaminous brain (cerebellum). Medium lactate-pyrophosphate (M) ± vitamin. Brain tissue removed within 1 min. and thoroughly minced upon cooled plate for 2 mins., colour bright red. Half transferred to warmed plate (38°), and reminced, colour dark purple. Respiration μl./g./hr.

Condition		¼–¾	¾–1¼	1¼–3¾
Cooled	M	1050	675	645
	M + V	1275	960	915
Cooled, then warmed	M	1190	865	795
	M + V	1355	1025	1000

In effect then a mild degree of cold destroys an essential factor, irreversibly. This may be by physical separation, which is rather the opinion of the Warburg school as to the difference in glycolysis *etc.* between sections and tissue pulp. A more attractive view is that there is irreversible oxidation of some essential co-enzyme, when the action of the dehydrogenases is depressed by the cool conditions.

Evidently determinations of Q_{O_2} in tissue "brei" must be influenced by these findings. In previous papers from this laboratory (except the last) the mincing was carried out at room temperature, and the values must be a mixture of the "cool" and "warm" values. The conclusions are not influenced, as they are based upon comparative work.

The catatorulin effect as a chain of reactions.

Until now the simple hypothesis that the vitamin acted upon a substance *X* with the direct result of increased oxygen uptake was tenable. A new experiment of different type disproves this simple view.

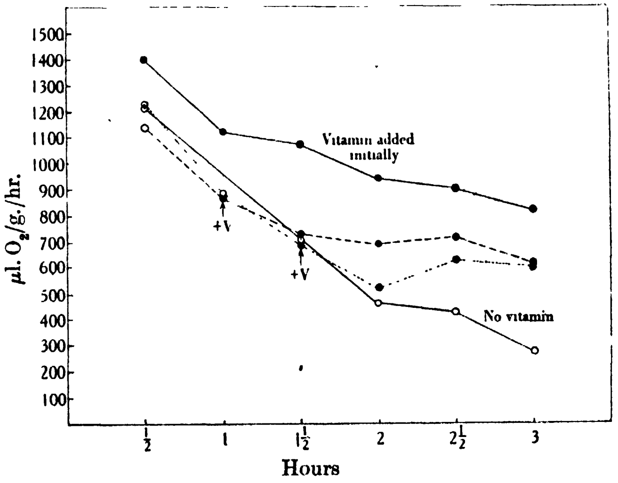

Fig. 2. Exp. 614. o No vitamin. • Vitamin present. Arrow indicates time of addition of vitamin. Avitaminous brain as usual.

Table IV.

Exp. 614. Vitamin added after commencing respiration.

Hours ...	0–½	½–1	1–1½	1½–2	2–2½	2½–3
A. Control	1215	—	710	460	430	270
B. Vitamin	1400	1120	1070	940	900	820
C. Vit. at 1 hr.	1140	870*	722	690	715	610
D. Vit. at 1½ hrs.	1225	885	690*	515	640	600

Note. All contained initially Ringer-phosphate-pyrophosphate and lactate. Vitamin was added to B before commencing the experiment, and to C and D at the times indicated by the asterisks. Dixon-Keilin apparatus used.

It has been realised for a long time in this laboratory that vitamin added at some interval after the start of respiration checks the fall in respiration but produces no rise. In unpublished work, Meiklejohn, Passmore and Peters found a tendency for the rate to be stabilised by added vitamin.

A more recent experiment shows this clearly.

In these tissue "brei" from the avitaminous bird, lactate, lactate + pyrophosphate, lactate + pyrophosphate + vitamin have increasing effects in mitigating the fall in respiration, as well as in increasing the initial rate when added initially.

Of the possible interpretations of these facts we were most attracted by the view that the "stabilised" respiration was due to the formation of some substance during the first 1–2 hours of respiration, which was subsequently oxidised. This was tested in the following way; avitaminous brain tissue was allowed to respire for periods up to $2\frac{1}{4}$ hours in Ringer-phosphate-pyrophosphate ± vitamin B_1, after which lactate was added. Exps. 644 (lactate) and 645 (pyruvate) given in Table V, and 645 (lactate) in Fig. 3 illustrate the results obtained. Delayed addition of lactate (or pyruvate) shows a comparatively small increase in respiration with tissue incubated without vitamin, but a large increase with tissue incubated in the presence of vitamin.

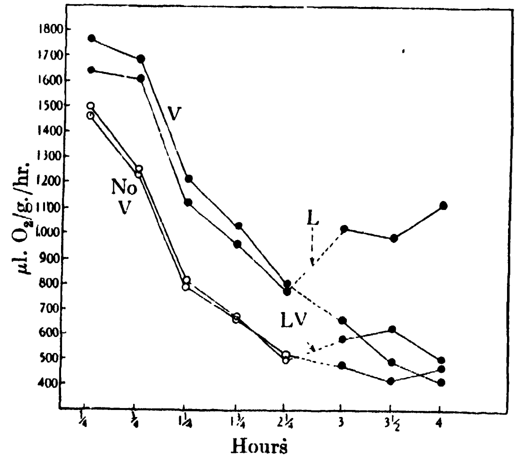

Fig. 3. *Delayed substrate experiment.* 0–2¼ hours' respiration in Ringer-phosphate with and without vitamin. At 2¼ hours, additions of L and LV made to two bottles, and of V to one of remaining bottles. Rise is large only when L is added to tissue previously treated with V. L = lactate. V = vitamin 2γ. ● Vitamin present. ○ No vitamin present. Tissue weights, 340–360 mg. Pyruvate and lactate both used, for pyruvate see Exp. 645, Table V.

Table V. *Delayed type experiments.*

Exps. 644 and 645. Avitaminous brain (cerebellum), prepared warm. Medium (M) Ringer-phosphate + sodium pyrophosphate (p_H 7·3). Vitamin 2γ in Ringer-phosphate-pyrophosphate. After shaking for 2¼ hours bottles were removed, additions made, bottles re-filled with oxygen, and replaced in bath. Time 5–10 mins. Readings commenced after a further 12 minutes' shaking. Solutions adjusted to make final volume 3·0 ml. Lactate added in 0·1 ml. to make 0·033 *M*.

	Diff.	258	284	660	—	Diff.	360	345	360

Note. To get satisfactory results, this experiment requires larger amounts of tissue than usual. It is better to use two brains, or, if unavailable, one cerebrum distributed in four bottles. In the latter and more usual case, duplicate estimations are not possible. The experiment was sometimes done in the Dixon-Keilin apparatus, but it is quite effective in the usual type of bottle. The differences in respiration are very large; the larger amounts of tissue complicate the issue with vitamin at the beginning owing to the larger amount of residual lactate present, but in most cases the rise is beyond experimental error.

This experiment has been repeated many times (25) with essentially the same results, though the rise is variable. Pyruvate can be substituted for lactate, and pyrophosphate when present in the incubation period enhances the effect.

In several of the experiments, the rise upon addition of lactate is proportional to the value for the respiration immediately before making the addition. In others the rise for the vitamin-treated samples is sufficiently large to exclude this interpretation. Hence something is present in the vitamin-treated sample which develops an oxygen uptake only when treated with substrate.

In the "delayed substrate" experiments the respiration increases upon adding lactate. Hence, the vitamin cannot be merely preventing the disintegration of the respiratory system [*cf.* Peters and Sinclair, 1933]. But there must be an accompanying inactivation of some essential co-enzyme, since the respiration after 2 hours never recovers to more than 1200–1400 μl., a value considerably less than the initial respiratory value.

A new hypothesis which embraces these further facts is as follows:

Stage 1 Stage 2
$X \longrightarrow Y$ + Pyruvate or lactate and O_2 = Products of oxidation and oxidative synthesis
$\uparrow$
Vit. B_1
Pyrophosphate

Stage 1 requires little if any extra O_2, and is therefore likely to be a "dehydrogenase" stage. Stage 2 needs the presence of the co-enzyme injured by oxidation. *X* must be regarded as a precursor of *Y*.

It is quite possible that *Y* is merely an active state of *X*, stabilised by vitamin B_1-pyrophosphate, or indeed that the vitamin merely prevents the relapse of *Y* into an inactive state.

If this hypothesis is correct, we should find marked differences in the responses to lactate of "warmed" and "cooled" tissue after the incubation period, without much effect previous to lactate addition. Exps. 660 and 661 in Table VI show that this is so (two similar experiments are not quoted). It is remarkable how much the delayed vitamin effect is increased in the "warmed" tissue. The initial vitamin effect in the "warmed" is accounted for by the presence of residual lactate.

Table VI. *Delayed addition of substrate; "warm" and "cooled" tissue.*

							Diff.		330	540	595	625

Note. Rpp = Ringer-phosphate-pyrophosphate medium. V = 2γ vitamin B_1. Lactate added at the arrow (0·1 ml. to make 0·033 *M*). In each of these experiments separate halves of the cerebrum were removed as quickly as possible with minimum injury and minced for 2 mins. respectively on "warmed" and "cooled" plates; colour of "warmed" tissue was purple and of "cooled" bright red. Addition of vitamin was made after weighing and subdivision of the tissue.

The nature of X[1] *and* Y. Upon the present hypothesis, a substance should behave as *Y* if it interacts immediately upon addition of lactate to produce a rise in respiration; it cannot be α-glycerophosphate, because this was shown to be independently additive in oxygen uptake experiments by Peters and Sinclair. The "delayed" experiment does not decide whether vitamin B_1 is essential for stage 2.

A substance will substitute for *X* if it causes a delayed increase in respiration when lactate + V are present, or increases the rise upon lactate + vitamin addition in the "delayed" experiment.

Several obvious brain constituents have been tested in the attempt to identify the unknowns. So far no effect of the required type has been seen with creatine, creatinine, inositol, galactose, xanthine or crude hexosediphosphate (candiolin). Several experiments with extracts of brain have given suggestive, but not decisive, results. Some *X* appeared to be present in a neutralised trichloroacetic extract of hen's or pigeon's brain.

---

[1] A possible alternative hypothesis. We have given what appears to be the simplest interpretation of our facts. It is just possible that the facts can be explained without recourse to the "indirect" oxidation view. If the vitamin in oxidising the residual lactate maintains the stability of the essential factor, we can then explain the delayed type of experiment as being merely the result of better protection of the essential factor from irreversible destruction. In this case, there would be no need to postulate the substance *X*.

DISCUSSION.

These experiments upon brain tissue depleted of vitamin B_1 demonstrate that oxidations (in the sense of oxygen uptake) with added lactate or pyruvate are secondary to a preparative stage, which is presumably one of H transfer. They seem fundamental, because the oxidation system of lactate is involved. As has been previously suspected, tissue respiration involves an organised chain of reactions, even in a "brei" of this nature.

We have been led by another path to the technique of Quastel and Wheatley [1932] upon which they base the conclusion that narcotics influence the oxidation of lactate rather than succinate. This conclusion is strikingly coincident with the independent finding of Gavrilescu *et al.* [1932], that the nervous symptoms in avitaminosis are related specifically to a lactate rather than a succinate lesion. The finding of Gavrilescu *et al.* can however be demonstrated upon freshly removed tissue. The technique of Quastel and Wheatley [1932] involves a preliminary autoxidation of the brain tissue for periods up to 3 hours, after which the substrate is added. It seems clear now that the subsequent reaction of the tissue to substrate will depend upon some action of vitamin B_1 (and possibly other factors) in the preparative stage.

Since the narcotic (or poison) is added during the preparative stage, the narcotic may well be influencing this preliminary stage, and no conclusions can really be drawn about the effect upon the oxidative stage. This is borne out by experiments upon the effect of fluoride and iodoacetate in the delayed substrate experiment in an accompanying paper [Peters *et al.*, 1935]. Hence the interpretation of Quastel and Wheatley might require modification to the extent that narcotics influence a constituent in the "coupled" oxidation of lactate[1]. That the "coupled" oxidation of lactate might be so influenced at a dehydrogenase stage by narcotics is satisfactory because it brings these effects into line with a generalisation of Keilin [1929] that narcotics in general interfere with the reduction of cytochrome by dehydrogenases.

Much has been made of the very real difference between the behaviours of tissue sections and "brei" in many types of experiment. The writers suggest that in sections the co-enzyme present especially in "warm" minced brain is better protected from irreversible oxidation by association with an active dehydrogenase system, which is more complete.

In regard to the specific application to vitamin B_1 problems, the possible interpretations discussed by Meiklejohn of his failure to correlate extra oxygen uptake of the vitamin with increased disappearance of lactate were three. Of these the most acceptable seems to be that vitamin catalyses the coupled oxidation in presence of lactate of some other substance. It is proved here that pyruvate can replace lactate; presumably the removal of "avitaminous" pyruvate is secondary to the action of vitamin B_1. Unfortunately, we cannot yet settle whether pyruvate or lactate is immediately concerned in the interaction. We must further point out that the proof that vitamin B_1 directly catalyses metabolism of some carbohydrate constituent is still lacking in absence of knowledge as to the exact nature of Y, though there is abundance of evidence as to the indirect connection with carbohydrate metabolites.

---

[1] It is possible that ignorance of these facts is the source of controversy between Bülow and Holmes and Quastel and colleagues; but see a recent paper by Quastel and Wheatley published while this paper was in course of preparation.

SUMMARY AND CONCLUSIONS.

1. As compared with tissue prepared "cold," pigeon's brain tissue prepared "warm" shows marked differences in oxygen uptake. A higher respiration is found in lactate and pyruvate solutions with the "warmed" tissue, whereas only slight differences occur in Ringer phosphate and succinate solutions.

2. The catatorulin effect of vitamin B_1 is most marked with tissue prepared "warm."

3. Vitamin B_1 interacts with some unknown substrate to produce a substance which increases the oxygen uptake in the presence of lactate or pyruvate. The catatorulin effect therefore depends upon a chain of tissue reactions.

4. Sodium pyrophosphate influences the interaction with the unknown substrate.

5. The following hypothesis for the oxidation system is suggested:

Stage 1 Stage 2
$X \longrightarrow Y$ + Pyruvate or lactate and oxygen = Products of oxidation and oxidative synthesis
↑
Vitamin B_1. Pyrophosphate
(depressed by fluoride
or iodoacetate)

We are indebted to the Medical Research Council for grants in aid of this work and to Messrs H. W. Kinnersley and J. R. O'Brien for their help in preparation of vitamin B_1.

VIII. THE RELATION OF PYRUVIC ACID IN BRAIN TO CERTAIN TISSUE POISONS.

By RUDOLPH ALBERT PETERS, HÅKAN RYDIN[1]
AND ROBERT HENRY STEWART THOMPSON[2].

From the Department of Biochemistry, Oxford.

(*Received November 3rd, 1934.*)

Some indication was obtained by Peters and Thompson [1934] that fluoride diminished the substantial amount of pyruvate formed by avitaminous brain, as well as the smaller amounts formed in normal brain respiration. On the other hand sodium iodoacetate led to increase of pyruvate even in normal brain: consideration of this for avitaminous brain was left until more data became available. This study was undertaken in the hope of deciding the point of action of vitamin B_1 and also of testing further the applicability of the Embden-Meyerhof scheme to brain systems. According to Meyerhof and Kiessling [1933], iodoacetate and fluoride inhibit different stages in the fermentation cycle; fluoride inhibits the appearance of pyruvic acid from phosphoglycerate and iodoacetate the disappearance of the former; the action of each gives rise to inhibition of lactic acid formation.

Oxygen uptake.

Table I (*a*) summarises the experiments which we have made upon respiration in the presence of the two poisons. The results are given as averages. It is to be understood that in each series of experiments the control and poison have been tested in duplicate upon the same brain. The results for fluoride confirm and extend those of Peters and Sinclair [1933]; the concentration used (0·024 M) is taken from their work. With iodoacetic acid the most suitable concentration was found to be 0·00054 M (0·1 mg. per ml.); this is the amount found to inhibit the action of glyoxalase in tissue sections [Dickens, 1933].

In orientating experiments upon normal brain, 0·0009 M seemed maximum, 0·00018 M gave less effect. With avitaminous brain in four experiments, 0·00018–0·00027 M gave approximately the same effect, 0·000095 M gave sometimes less.

The following can be concluded from Table 1 (*a*). Both poisons reduce the oxygen uptake in lactate solutions; the percentage of respiration so inhibited increases during the period studied, but the absolute amounts inhibited in μl./g./hr. remain surprisingly constant, if we exclude the first period. For avitaminous brain the inhibition amounts to 500 μl./g./hr. in every case except that of fluoride and pyruvate, where the average was 150. This curious difference with pyruvate is probably related to the observation of Meiklejohn *et al.* [1932] that there is a tendency for respiration of avitaminous brain to be lower in pyruvate solutions. The effect is not constant, because in two further experiments carried out recently by the latest technique, in which the actions of fluoride and iodoacetic acid with pyruvate were tried on the same brain, one showed the difference and the other did not (Exps. 692, 693, Table I (*b*)). Some unknown variation in the state of the brains must influence the result. With this exception, the effects of the two poisons upon respiration are identical.

In this and other Tables L = lactate; P = pyruvate; IAA = iodoacetic acid; F = fluoride; V = vitamin B_1.

Note. It is to be understood that in all cases medium consisted of Ringer phosphate-pyrophosphate with addition of lactate 0·03 M or pyruvate 0·02 M. LP = L 0·03 M, P 0·01 M.

The catatorulin effect (Table I (*c*)) is present but reduced to somewhat the same extent in each case; Exps. 612, 613 (Table I (*d*)) show that the poisons reinforce each other's action; both together eliminate the vitamin action.

Effect upon preformed pyruvate.

Avitaminous brain was allowed to form pyruvate by respiration for 2 hours in oxygen and lactate solution, at the end of which time additions of vitamin and tissue poisons were made. Pyruvate was estimated in most cases as bisulphite-binding substances [Clift and Cook, 1932] at the end of a further 1¼ hours. This was occasionally checked by Case's method.

The details of the experiment were as follows. Avitaminous cerebrum, minced warm, was distributed in five bottles containing Ringer phosphate and lactate 0·03 M. Pyruvate was formed by allowing respiration in O_2 for 2 hours from time of putting in the bath, the oxygen uptake being recorded for the last half hour, in order to check the values. At the end of this time, one bottle was removed as control and treated with 0·9 ml. trichloroacetic acid (25 %). The remaining four bottles were removed from the bath, one kept as control, one treated with vitamin (0·1 ml. containing 2γ), another the poison in 0·2 ml. and the last poison and vitamin; the bottles were quickly re-evacuated, filled with oxygen and returned to the bath. This operation need not occupy more than 7 minutes. Respiration was allowed to continue for 1 hr. 12 mins. after returning to the bath, the rate being calculated for the periods 12–42 mins. and 42–72 mins. No pyrophosphate was used in order to minimise the effects of the preparative stage (see preceding paper). At the end of 42 mins. the remaining bottles were removed from the bath and treated with trichloroacetic acid. Other details were as described by Peters and Thompson [1934].

It was thought better in this experiment to depart from the usual practice of using duplicate bottles for each point, and to use instead larger amounts of tissue from the cerebrum only, which is well known to be more homogeneous. Attempts to weigh exact amounts of brain "brei" introduce in themselves the qualitative errors of uneven cooling during the interval required for such weighing. We have therefore followed the usual practice of distributing the tissue by eye. This has not always been successful. We have therefore corrected for the tissue weights in the following way.

Variations in tissue weight for amounts of tissue over 100 mg. were found by Meiklejohn not to affect the oxygen uptake over 3-hour periods in the case of the cerebrum. This is contrary to the calculations of Passmore *et al.* [1933], who were able to correct for small amounts of tissue by the application of a formula. The difference between these two sets of results is not yet clear. The following diagram (Fig. 1) shows that oxygen uptake is independent of the amount of tissue for amounts between 140 and 250 mg. but the amount of pyruvic acid varies with tissue weight.

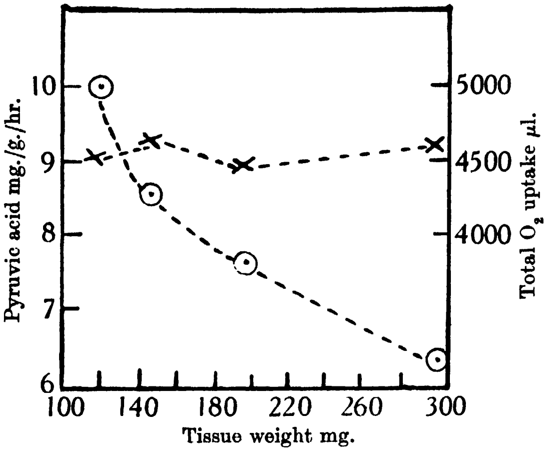

Fig. 1. ⊙ Pyruvic acid formed per tissue wt. × O_2 uptake per tissue wt.

Note. **In 682 and 683, L+V, L+V+IAA, also same wt.**

This is incidental evidence of the lack of correlation between O_2 uptake and pyruvic acid formation. The results given in Table II have been corrected for initial pyruvate (at end of 2 hours) to a basis of 160 mg. using the curve given in the figure. The conclusions which emerge from the averages are not however dependent upon this; in several cases tissue weights have been sufficiently close to require no correction. These are marked in heavy type.

Table II confirms the finding of Table I, that the O_2 uptake is reduced equally within the wide limits of error by the two poisons. The effect upon the pyruvate is strikingly different. It is decreased by fluoride and not affected by iodoacetate. In confirmation of Peters and Thompson, vitamin reduces the amount of pyruvate present. We must suppose that removal of pyruvic acid is already at a minimum in the avitaminous tissue in absence of vitamin so that no further accumulation takes place in presence of iodoacetate. So far as the origin and disappearance of pyruvic acid are concerned, the results are in good agreement with Meyerhof and Kiessling [1933]. As with the oxygen uptake, they do not give ground for the belief that the action of the vitamin is more concerned with iodoacetate than with fluoride, since no stress can be laid upon the variable results with pyruvate and fluoride. It must be noticed that in presence of vitamin, fluoride does not decrease significantly the amount of pyruvate formed.

Glutathione and added pyruvate.

Relatively more is known about the action of iodoacetic acid than about that of fluoride. We have therefore tried to analyse this further. The following is selected from the literature as to the action of iodoacetic acid.

1. Inhibition of lactic acid formation in muscle [Lundsgaard, 1930] and other tissues [Fisher, 1931].

2. Reduction of tissue respiration in muscle, which is partly restored by lactate addition [Meyerhof and Boyland, 1931]. Lactate improves contraction of muscle supplied with oxygen and poisoned with iodoacetate, and phosphagen synthesis [Mawson, 1932; 1933]; rather similar effects occur with nerve [Chang and Gerard, 1933].

3. Low concentrations interfere with the catabolism of glycogen (A), Meyerhof and Kiessling [1933], and with the action of glyoxalase in tissue sections (B) [Dickens, 1933; Quastel and Wheatley, 1932. *Cf.* Dudley, 1931].

4. Higher concentrations prevent the interaction of α-glycerophosphate and pyruvic acid (C). They also inhibit the action of glyoxalase in some brei preparations, the inhibition being believed to be due to the removal of glutathione [Dickens, 1933].

Hence at least three enzyme systems A, B, C, must be poisoned. Our present effect might be due to B or C. If to B alone it should be restored by adding glutathione.

In a series of seven experiments the effect of glutathione with and without vitamin upon pyruvate was studied in presence of iodoacetate. In order to ensure the presence of adequate pyruvate, a small amount of this was added to the medium, which also contained pyrophosphate to enhance vitamin effects. Some of the O_2 uptakes are summarised in Table I. In Table III, 1, 2, 3 are given only the figures relating to glutathione and the values for pyruvate.

In order to observe the action properly, the tissue should be kept in contact with the reagents for a standard time before adding the glutathione. In practice the tissue was allowed to stand for 3 minutes after division with the crusher, iodoacetate was then added, after an interval of 2 minutes glutathione and after a further interval vitamin.

Note. In Exp. 600, the pyruvic acid was estimated by the isolation of the 2 : 4-dinitrophenylhydrazone, in all other experiments by bisulphite-iodine titrations.

The increases seen in MIAA 601, 604 and 607 are probably not experimental errors, but due to the formation of pyruvate by the tissue (compare Table II).

In these experiments addition of glutathione restored the vitamin effect to some 30–50 %. Part too of the pyruvate seems to be removed again upon addition of glutathione, but this cannot be certainly concluded owing to the large experimental error. The dubiety of this result makes interpretation difficult. Iodoacetate is known to interact slowly, and it is not known how far glutathione will diffuse into these tissue systems, though in general it is freely diffusible. We think it probable that the glutathione is merely combining with the excess of iodoacetate, thereby preventing further action; if the effect were to restore a missing catalytic effect of glutathione we should have expected the recovery with the added substance to be more nearly maximum. Hence we do not think that glutathione is directly concerned with the vitamin effect; in this we have the support of earlier experiments with glutathione alone. So far judgment from the respiration experiments of Peters and Sinclair [1933] excludes interaction with α-glycerophosphate. Hence both A and C seem also excluded and we are left with the inhibition of some unknown metabolic link.

O = Ringer-phosphate; V = O + vitamin; pp = pyrophosphate. Pyruvate (P) approx. in Exps. 646, 0·02 *M*; in Exps. 641, 642, 0·007 *M*.

Delayed substrate experiments (Table IV).

There is a component of the preparative stage blocked by the action of the poisons. In experiments made by the delayed substrate technique (see preceding paper), poison in the preparative stage inhibits subsequent rise of oxygen uptake upon addition of lactate. The vitamin effect is eliminated. Poison added at the same time as substrate only acts slowly and does not inhibit the initial rise. We interpret this to mean that the poison acts upon the conversion of X into Y, but not the interaction of Y with substrate[1]. The later reduction of respiration of the tissue treated with lactate and poison at the same time is consistent with this view; it would be expected that after respiration for an hour with substrate, there would be a component of the respiration supplied by further formation of Y. The application of these results to the method of Quastel and Wheatley suggests that narcotics as well as iodoacetic acid will probably be acting upon the preparative stage.

It is to be noted that even after 2 hours of falling residual respiration, the capacity for forming pyruvic acid is not substantially diminished. Table V shows the few experiments made upon this question with avitaminous cerebrum. They suffice to indicate the rapid increase of pyruvate upon addition of lactate and again show the reduction in presence of vitamin. It will be recalled that there are reasons for thinking that pyruvate does not arise directly from lactate [Peters and Thompson, 1934].

Table V. *Formation of pyruvate in delayed substrate experiment.*

Bisulphite-binding substances present after respiration for periods indicated. ml. $N/100$ I/g. tissue (avitaminous cerebrum).

RP = Ringer phosphate only. At arrow (end of 2 hours) addition of L or LV or nil made as indicated and respiration continued for additional periods.

DISCUSSION.

Catatorulin effect. The catatorulin effect is inhibited by action upon the preparatory stages equally by the two poisons, irrespective of the effect upon pyruvate. This reinforces the view that the action of vitamin upon pyruvate is secondary. It seems to be a generalisation that poisons influencing catatorulin action affect phosphorylation stages. This is even true for phloridzin [Lundsgaard, 1933]. With 3 mg./ml. in three experiments the "vitamin effect" was almost eliminated. There is no evidence that any of these poisons is specific for vitamin B_1. Iodoacetate destroys vitamin B_1 activity upon warming at p_H 7·3 in Ringer phosphate for 12 mins., but a short period of standing at room temperature hardly influences it.

Embden-Meyerhof scheme. This is followed to the extent that fluoride and iodoacetate influence appearance and disappearance of pyruvate as in the scheme. According to Johnson (in press)[1], the scheme cannot be applied so far as α-glycerophosphate is concerned.

---

[1] See hypothesis in the previous paper.

Lactic acid. Chang and Gerard [1933] have found that with lactate present the fall in respiration of frog nerve is not so marked at first as subsequently in iodoacetate solutions. The figures of Table I bear this out for pigeon's brain. It is well explained by the hypothesis here advanced if iodoacetate poisons production of *Y*.

SUMMARY.

1. The actions of some poisons upon the avitaminous pigeon's brain tissue have been further investigated. Fluoride and iodoacetate reduce O_2 uptake equally. Each largely reduces the catatorulin effect (extra O_2 uptake in presence of added vitamin B_1): both together eliminate this.

2. The effect upon pyruvate formation by avitaminous brain is different; iodoacetate leads to increased accumulation and fluoride the reverse. So far only as pyruvate is concerned, this is consistent with the finding of Meyerhof and Kiessling for muscle extracts.

3. Glutathione only produces partial restoration of the vitamin effect in presence of iodoacetate.

4. Disappearance of pyruvate in presence of vitamin B_1 is an indirect result of some other change. These poisons influence a preparatory stage for oxidation.

IX. STUDIES ON THE VITREOUS BODY. I.

By WILLIAM STEWART DUKE-ELDER,
EDWARD BLAIR ROBERTSON AND HUGH DAVSON.

*From the Department of Physiology and Biochemistry,
University College, London.*

(*Received November 2nd, 1934.*)

The aim of the studies detailed below was to elucidate the phenomenon of the rise of intra-ocular pressure associated with chronic glaucoma (*glaucoma simplex*).

The facts of the shallow anterior chamber, the pushing forward of the lens and iris, the thinning of the choroid and the compression of the retina, combined with the freedom of the iris in numerous cases of the disease, lead to the conclusion that a swelling of the vitreous body is most probably the determining factor. The view of Heesch [1926, 1] that the increase in pressure might be due to negative osmosis across the scleral membrane is contradicted by the fact of the compression of the sclera to less than its normal thickness. Furthermore any theory postulating that the increased pressure is due to the failure of elimination of fluid from the anterior chamber is unable to account for one of the most obvious symptoms of the disease, *viz.* the shallow anterior chamber.

The vitreous body is a true gel showing an ultra-microscopic fibrillar structure [Baurmann, 1923; 1926; 1932; Heesch, 1926, 2; Duke-Elder, 1929; Goedbloed, 1934] with the characteristic vapour pressure isotherm of a gel formed from a lyophilic colloid [Duke-Elder, 1930], and typical elastic properties [Robertson and Duke-Elder, 1933]. It contains a protein called "residual protein" [Duke-Elder, 1930] in a concentration of 0·025 % which is responsible for its gel nature.

The combined isolated proteins of the vitreous body show degrees of swelling depending on the p_H of the swelling medium rising from a minimum at about p_H 4·5 to a maximum at about p_H 8·0 [Duke-Elder, 1930]. Large variations in the volume of the vitreous body are achieved by placing it in solutions of different p_H [Baurmann, 1924; Duke-Elder, 1930], but owing to the crudeness of the technique employed any deductions drawn from these experiments must be treated with caution. It is true that Redslob and Reiss [1928] found considerable variations in the total volume of an intact eye in a modified dilatometer on varying the p_H. Two maxima at p_H 8·1 and 8·7 were obtained. Since however the sclera is known to increase in volume with varying p_H these results do not allow of any conclusions as to the behaviour of the vitreous body to be made. On the other hand, Löbeck [1929], using the isolated vitreous body, failed to record any increase in volume on the alkaline side of normal p_H.

So far there is no conclusive evidence that the vitreous body, *in vivo*, is capable of increasing its volume on altering the p_H of its surrounding medium. Glaucoma however is not associated with any detectable abnormality in the p_H of the blood [see *e.g.* Schmerl, 1928], so that experiments on the variation of this factor are only of interest to the extent that they show that the vitreous body is capable of modification of its volume in response to a changed environment.

A factor in the swelling of proteins often more potent than the p_H is the presence of specific ions, *e.g.* I^- or CNS^-, or the so-called hydrotropic substances of Neuberg [1916]. The recent work of Katz [1933] on the swelling of starch and gelatin has shown that substances such as the sodium and potassium salts of long-chain fatty acids, and in general dipolar substances with both hydrophilic and hydrophobic groups in their molecules, will increase the rate of swelling to an enormous extent. Since the increased swelling so produced is due to adsorption on to the micelles of the colloid, it is obvious that these substances may be effective in low concentrations, and hence it is not impossible that they are effective in the causation of glaucoma. The occurrence of abnormal quantities of substances of a soapy nature in the eye in advanced glaucoma and similar degenerative conditions of the eye lends support to this view. It may be remarked here that Baurmann and Thiessen [1922] noted that KCNS delayed the occurrence of "age-changes" in the vitreous body, and Goedbloed [1934] observed ultra-microscopic changes in it after treatment with KCNS solutions for 24 hours which he interpreted as due to increased hydration of the micelles.

In this paper the results of experiments are described which are designed to show whether substances such as sodium oleate and sodium laurate in aqueous solution may affect the volume of the vitreous body. A full discussion of the possibilities that a gel, in such a state of dilution as is the vitreous body, may exhibit an increase in volume or hydration even under the most favourable conditions, will be left to a succeeding communication when it is hoped that the results of experiments on other swollen gels, at present under way, will have given us sufficient information to allow of a more than tentative decision to be made.

EXPERIMENTAL.

The apparatus of Schmidt [1931], used for the determination of the water-uptake of powders, was modified to suit the peculiarities of the vitreous body (see Fig. 1). The tap, T_1, allows connections to be made between the reservoir, R, and the capillary, C; between R and the chamber, P; between P and C, and between R, P and C. The vitreous body is placed in the chamber, P, which is separated from the fluid in the rest of the apparatus by a sintered glass disc, S, and which has a mark on it showing the level of the tap, T_1. Any uptake of water is measured by the movement of the meniscus in the capillary. The procedure is to fill the reservoir with the given solution and make connection, with T_2 open, to P and C until fluid flows through T_2 when the latter is closed and connection is made between R and C alone until the latter is half filled. T_1 is then half-turned so that no connections are made, and the vitreous body of an ox is placed in P to just above the mark. When the tap T_1 is turned to make connection between P and C the meniscus will move along the capillary to the right due to the slight excess of hydrostatic pressure in P. To counteract this the whole apparatus is tilted slightly as the tap is turned so that the meniscus stops after it has moved a few inches. The tilting must not be so steep that the meniscus starts to move backwards, otherwise water will enter P and the experiment must be started again. Solutions of 0·9 % NaCl buffered with phosphate to p_H 7·8 and 8·0, and solutions of 1 % sodium oleate and laurate were used.

Results.

In all cases no water-uptake was observed in 24 hours.

As will be appreciated, the apparatus described determines whether the gel takes up water, but not whether a volume increase occurs, although the one process is always associated with the other. Küntzel [1929] has divided the swelling process into two parts, one due to water-uptake and the other due to the mutual repulsion of charged micelles. Neville and Theis [1930] have shown that a maximum of swelling need not necessarily correspond with a maximum of water-uptake. In view of the possible independence of the two processes at certain stages of swelling it was thought that there was just a chance that the vitreous body might alter its volume by a re-orientation of the charged micelles, produced by the adsorption of a polar compound, without necessarily taking up water. To put this to the test, the apparatus shown in Fig. 2 was devised.

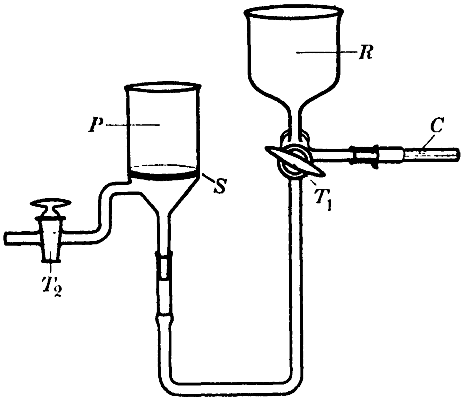

Fig. 1.

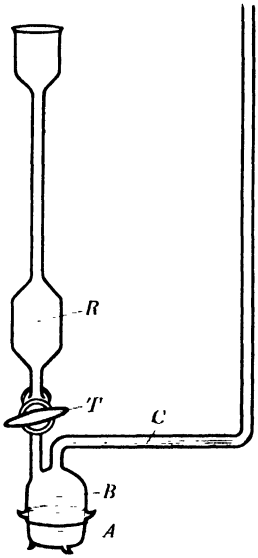

Fig. 2.

The hollow hemisphere, A, fits into the dome, B, by a ground joint. B is connected to a capillary, C, and a reservoir, R. A is filled with vitreous and fitted into B. R is filled with a saturated solution of sodium laurate in amyl alcohol dried with sodium sulphate. The whole is allowed to equilibrate in a thermostat at 25° (constant to 0·002°). When thermal equilibrium has been established the tap T is turned and the solution is allowed to fill up B and run along the capillary tube. The tap is turned off and the position of the meniscus fixed on the cross-wires of a telescope. Any increase in the volume of the vitreous would be registered by a movement of the meniscus to the right. A control was run using pure dry amyl alcohol.

Repeated experiments failed to show an increase of volume; in general a slight contraction in both control and test experiments was observed.

Discussion.

The absence of any water-uptake near p_H 8 in the first experiment is in agreement with the findings of Löbeck; the experiments with soaps show that under more extreme conditions than that of changed p_H the vitreous body does not increase in volume within 24 hours.

These results however can hardly be treated as absolutely demonstrating that the vitreous body is incapable of increasing in volume in *glaucoma simplex*,

as the increase in intra-ocular pressure associated with this disease is slow, frequently taking years to reach its maximum value. Furthermore, there seems to be a definite difference in the behaviour of the vitreous body according as it is *in vitro* or *in vivo*. For example, in the latter state it is capable of withstanding unbalanced stresses of quite a high order, whereas *in vitro* the slightest unbalanced stress tends towards liquefaction. Considerations such as these make it difficult, in the present state of our knowledge, to reason from the behaviour of the vitreous body *in vitro* as to its probable behaviour *in vivo*.

We have pleasure in recording our indebtedness to Profs. J. C. Drummond and H. Freundlich for their sustained interest and criticism, and to the Medical Research Council for defraying the expenses of this research and for personal grants to two of us (E. B. R. and H. D.).

X. THE CHROMOGEN OF MELANURIA.

By LOUIS LINNELL and HENRY STANLEY RAPER.

From the Department of Physiology, University of Manchester.

(*Received November 12th, 1934.*)

THE course of a melanotic sarcoma is sometimes marked by the excretion in the urine of a chromogen which readily oxidises on exposure to air to the black pigment, melanin. It has been shown by Raper [1927] that in the formation of melanin from tyrosine or 3 : 4-dihydroxyphenylalanine one intermediate product is 5 : 6-dihydroxyindole: a colourless material which rapidly oxidises to melanin in the air. It seemed possible that the chromogen might be this same indole derivative, or some closely related substance, and this view has been rendered more probable by the work of Bloch and Schaaf [1925] who showed that the production of melanin in the skin is due to the action of an enzyme, dopa-oxidase, on 3 : 4-dihydroxyphenylalanine. It has also been shown that tyrosinase is present in the skin of certain black rabbits [Onslow, 1915; Pugh, 1933] and in melanotic tumours [Gessard, 1903; De Coulon, 1920]. Clearly, if it could be demonstrated that the chromogen of melanuria is related to 5 : 6-dihydroxyindole, this would be good evidence for the view that in the higher animals melanin formation is due to the same series of changes that occur in the lower animals and plants, in which tyrosinase reacts with a suitable substrate such as tyrosine, 3 : 4-dihydroxyphenylalanine, or tyramine, 3 : 4-dihydroxyphenylethylamine.

Eppinger [1910] examined the urine from a case of melanotic sarcoma and concluded that two melanogens were present: one soluble, the other insoluble, in ether. He was able to isolate an ether-insoluble crystalline substance which appeared to be the amide of an ethereal sulphate of *N*-methylhydroxypyrrolidinecarboxylic acid. The product showed some of the properties associated with a melanogen and was considered by Eppinger to be the ether-insoluble chromogen, although in the light of recent work it seems most unlikely that a substance of the constitution suggested could be a precursor of melanin. The ether-soluble chromogenic material was further studied by Feigl and Querner [1917] who separated it into three fractions by precipitation with light petroleum and cadmium chloride. In this connection it may be noted that Thannhauser and Weiss [1922] isolated from melanotic urine an ether-soluble catechol derivative which they suggested was catecholacetic acid.

The view that tryptophan was the parent substance of the melanogen was advanced by Eppinger on his discovery that the administration of this amino-acid to the patient caused the excretion of the chromogen, as estimated by the Thormählen reaction, to rise considerably.

Our own experiments which are described below were planned to determine whether the administration to animals of the indole derivatives produced by the action of tyrosinase on tyrosine would lead to a condition of melanuria such as is encountered in melanotic sarcoma, and if this were so, whether the melanogens in the two cases had similar properties. We have also synthesised the ethereal disulphate of 5 : 6-dihydroxyindole in order to compare its reactions with those of the melanogen, since it seemed possible that this substance might be excreted in the urine if the dihydroxyindole either arose as a metabolic product or was administered directly.

EXPERIMENTAL.

I. *The melanogen from human urine.*

Through the courtesy of Dr G. A. Harrison, of St Bartholomew's Hospital, London, who kindly furnished the melanotic urine and crude melanogen precipitate, we were able to study the chromogen excreted in human melanuria.

On exposure to air the urine slowly blackened from the surface downwards and eventually a deposit of melanin appeared. The blackening could be prevented by keeping the urine in an oxygen-free atmosphere or by the addition of a small quantity of sulphurous acid. The urine exhibited all the characteristic melanogen reactions, of which the following are the more important.

The hydrochloric acid reaction. On heating the urine with concentrated hydrochloric acid it rapidly becomes dark brown or black.

The ferric chloride reaction. The addition of a few drops of ferric chloride solution causes the urine to turn grey.

The ferricyanide reaction. Dilute solutions of ferric chloride and of potassium ferricyanide are mixed and acidified with hydrochloric acid. On the addition of a few drops of urine there is a copious formation of Prussian blue. This reaction is given to some extent by normal urine.

The Ehrlich reaction. To 1 ml. urine are added 2–3 drops of a 5 % solution of *p*-dimethylaminobenzaldehyde in alcohol and 5 ml. alcohol. On the addition of 0·5 ml. concentrated hydrochloric acid a violet colour appears either in the cold or on warming. The addition of a few drops of very dilute sodium nitrite solution changes the colour to deep purple.

The Thormählen reaction. To 1 ml. urine are added a few drops of a dilute solution of sodium nitroprusside, followed by a little caustic soda. A violet-red colour is immediately produced. The addition of excess acetic acid now changes the colour to pure blue.

Both the Ehrlich and the Thormählen reactions are very delicate, although the former is considerably the more sensitive of the two. It is to be noted that both these reactions are characteristic of indole and some of its derivatives.

The urine was precipitated with lead acetate in the presence of acetic acid in order to remove phosphates and sulphates. The melanogen was then completely precipitated from the filtrate by the addition of ammoniacal lead acetate. The yield of dried melanogen precipitate was about 70 g. from 10 litres urine. It was yellowish white in colour and did not darken on keeping. 5 g. of this precipitate were ground up with 100 ml. distilled water, and a current of carbon dioxide was passed through the suspension with frequent shaking. After two hours the suspension was filtered and the precipitate washed. The filtrate was pale yellow in colour and gave intense Ehrlich and Thormählen reactions. The precipitate was again ground up with 100 ml. water and treated with carbon dioxide, the filtration and decomposition with carbon dioxide being repeated until the filtrate gave only very weak Ehrlich and Thormählen reactions.

The mixed filtrates were saturated with hydrogen sulphide to remove lead from solution, and after filtration, the liquid was concentrated to small bulk by evaporation under reduced pressure in a stream of hydrogen. The syrup so obtained was brought to dryness in a vacuum-desiccator. A brown resin remained: yield: 1·03 g. A repeat experiment gave a yield of 1·14 g.

The resin was rubbed up with methyl alcohol, in which it partially dissolved. The methyl alcoholic solution was filtered and brought to dryness in a vacuum-desiccator. This gave residue "A." The insoluble material was washed with methyl alcohol and dried in a vacuum-desiccator, giving residue "B."

The lead precipitate remaining from the carbon dioxide treatment was re-suspended in water and decomposed with hydrogen sulphide. After filtration, the liquid was concentrated to small bulk by evaporation under reduced pressure in a stream of hydrogen and finally brought to dryness in a vacuum-desiccator, giving residue "C."

Residue "A" was a brown semi-solid resin which would not crystallise; yield: 0·66 g; repeat: 0·88 g. It was further purified by redissolving in methyl alcohol, cooling the solution on ice, filtering from a small quantity of residue and again evaporating to dryness. The substance gave intense Thormählen and Ehrlich reactions and blackened when warmed with hydrochloric acid. On the addition of ether it was precipitated from methyl alcoholic solution in the form of very hygroscopic white flocks which rapidly changed to a black oil. Tollens's naphthoresorcinol test indicated the presence of a trace of glycuronate.

The material contained sulphur, nitrogen and a trace of halogen, but no phosphorus. On analysis by the method of Benedict, as modified by Denis (*i.e.* ignition with copper nitrate) the total sulphur content was found to be 2·29 %. The amount of sulphur present in the form of ethereal sulphate was found to be 1·68 %; repeat estimation: 1·60 %.

An attempt was made to effect a further purification of the melanogen by precipitating it as its mercury compound. Previous investigators have used Hopkins's reagent, 10 % mercuric sulphate in 10 % sulphuric acid, for this purpose. In view of the instability of the chromogen towards mineral acid it was thought that the sulphuric acid in Hopkins's reagent might have a deleterious effect. For this reason, mercuric acetate was used in place of mercuric sulphate.

0·52 g. material "A" was dissolved in 20 ml. distilled water and completely precipitated by the addition of a 2 % solution of mercuric acetate in 2½ % acetic acid (20 ml. of reagent required). The yellowish white precipitate was filtered off on paper pulp, washed, suspended in water and decomposed with hydrogen sulphide. After filtration, the liquid was concentrated to small bulk by distillation under reduced pressure in a stream of hydrogen and finally taken to dryness in a vacuum-desiccator. This gave residue "D." The filtrate remaining after the removal of the precipitate was saturated with hydrogen sulphide and, after filtration from mercuric sulphide, brought to dryness as before, giving residue "E."

The substance "D" was a dark brown solid which easily powdered on being rubbed; yield: 0·18 g. The powdered material showed no crystalline form: it was very hygroscopic and readily soluble in water, giving a brown solution which gave a fair Ehrlich reaction, good ferric chloride and hydrochloric acid reactions, but no Thormählen reaction. The solution was very acid to litmus. The solid was also soluble in methyl and ethyl alcohols, but not in ether, benzene, light petroleum, acetone or chloroform. The amount of sulphur present in the form of ethereal sulphate was found to be 2·86 %. The dark colour of the product, the weakness of the Ehrlich and absence of the Thormählen reactions suggested that a considerable decomposition of the melanogen occurred in the mercuric acetate precipitation process, and for this the acidity of the solution was, perhaps, responsible.

The residue "E" was a pale yellow viscid syrup which could not be crystallised; yield: 0·24 g. Amount of sulphur present as ethereal sulphate: 0·99 %.

Since the Ehrlich and Thormählen reactions were absent and the ferric chloride reaction weak, it was concluded that the substance was not a melanogen.

The material "B" was a pale pink powdery solid which was not hygroscopic; yield: 0·37 g.; repeat: 0·26 g. It was readily soluble in water and in dilute acids and alkalis, insoluble in methyl and ethyl alcohols, benzene, light petroleum and acetone. The substance was purified by dissolving in hot dilute ethyl alcohol, filtering rapidly and cooling. An emulsion formed which eventually solidified into flocks. The product was almost white in colour, entirely amorphous in appearance, gave a weak Ehrlich, but no Thormählen reaction, and no coloration with neutral or acidified ferric chloride. The pale pink coloration of the solid was probably due to a trace of melanogen and this would account for the positive Ehrlich reaction (which is more sensitive than the other melanogen tests). In aqueous solution it was acid to litmus but not to Congo red. On heating, it charred with a peculiar odour, melted and finally burnt completely away. It contained sulphur and nitrogen but no phosphorus. From the ready solubility in water it followed that the substance could not be cystine: whilst the absence of a reaction with sodium nitroprusside after boiling with caustic soda proved that it was no derivative of cysteine. Since it gave no coloration with ferric chloride it could not be a melanogenic substance. The presence of a sulphate group, ethereal or otherwise, could not be detected, so it was concluded that the sulphur existed as so-called "neutral sulphur." The only compounds containing neutral sulphur which have hitherto been found in urine and which resemble the substance "B" are antoxyproteic, oxyproteic, alloxyproteic and uroferric acids. Their principal reactions have been described by Bondzyński and Panek [1902] and by Bondzyński *et al.* [1905]. On applying these reactions to "B," it was clear that it was not a proteic acid. Its further examination was deferred.

The substance "C" was a yellowish white amorphous material; yield: 0·07 g. It was almost insoluble in water, but dissolved in dilute caustic soda, from which it was precipitated by sulphuric acid. Its suspension in water was faintly acid to litmus and did not decolorise bromine water. No nitrogen was detected, but traces of sulphur and halogen were present. The presence of a trace of melanogen probably accounted for the appearance of weak Thormählen, Ehrlich and ferric chloride reactions. As the material was evidently not a chromogen it was not further investigated.

II. *The production of melanuria by the administration of 5 : 6-dihydroxyindole.*

The method of Raper [1927] was used for the preparation of a solution of 5 : 6-dihydroxyindole from tyrosine by the action of tyrosinase. The solution obtained on the oxidation of 2 g. tyrosine was concentrated to about 10 ml. by evaporation under reduced pressure in a current of hydrogen, filtered from unchanged tyrosine, and its neutrality ensured towards Congo red. The liquid was then immediately injected subcutaneously into a rabbit. The urine excreted thereafter for about 30 hours had the typical properties of a melanotic urine: after the lapse of this period the excretion of a normal urine was resumed.

The colour of the "melanotic" rabbit urine was normal when fresh, but on standing, the urine blackened from the surface downwards. It gave a good hydrochloric acid reaction and very strong ferric chloride, Thormählen and Ehrlich reactions. On the other hand, there was no alteration in appearance on the addition of caustic soda, even on boiling. This immediately proved that no 5 : 6-dihydroxyindole was excreted unchanged, for this substance is very sensitive to alkali and, even very dilute solutions of it blacken when caustic soda is added. The urine also gave a good positive reaction on applying Tollens's test for glycuronates; normal rabbit urine gave this reaction but not so well.

The separation process previously used with the human melanotic urine was applied, with a small modification, to the rabbit urine. To the fresh urine was added sufficient dilute acetic acid to give an acid reaction to litmus, followed by an excess of 20 % lead acetate. The acid lead precipitate was filtered off and washed, and the filtrate and washings were mixed and rendered alkaline by the addition of dilute ammonia, whereupon a yellow precipitate was thrown down. This was filtered off and washed. A sample of each precipitate was suspended in water, decomposed with hydrogen sulphide, the solution filtered and a current of air passed to remove hydrogen sulphide.

The solution from the basic lead precipitate gave strong Thormählen, Ehrlich and ferric chloride reactions, whilst neither the solution from the acid lead precipitate nor the filtrate remaining from the two precipitations gave these reactions. Evidently the basic lead precipitate contained the whole of the chromogen. It was dried in a vacuum-desiccator to obtain it in a stable condition. By the injection into rabbits of the 5 : 6-dihydroxyindole prepared by the action of tyrosinase on 12 g. tyrosine, a total yield of 19·33 g. dry melanogen precipitate was secured from a bulk of 1188 ml. urine.

5 g. dried precipitate were ground up with 150 ml. distilled water, and the suspension was saturated with carbon dioxide and mechanically shaken for 4 hours. The suspension was then filtered, the precipitate resuspended in water and the saturation with carbon dioxide repeated until the filtrates ceased to give the melanogen reactions. Lead was removed from the mixed filtrates by the passage of hydrogen sulphide in the presence of ammonia. After filtration, the solution was evaporated to small bulk under reduced pressure in a stream of hydrogen and finally brought to dryness in a vacuum-desiccator. The product obtained was a brown resin which was completely soluble in absolute methyl alcohol and gave all the melanogen reactions; yield: 0·91 g. It thus corresponded to the substance "A" from human melanotic urine. No substance equivalent to "B" was found.

The material was redissolved in 20 ml. distilled water, and 30 ml. mercuric acetate reagent were added. The precipitate was filtered off, washed, suspended in water, mixed with a little baryta paste and saturated with hydrogen sulphide. When absorption of the gas ceased, the liquid was filtered from mercuric sulphide. It was found that the presence of barium in the solution complicated the further treatment of the product, so ammonium carbonate was added to precipitate the barium and the liquid refiltered. The filtrate was evaporated to dryness in the usual way. The residue (corresponding to "D" from human melanotic urine) smelt strongly of ammonium acetate. This was driven off by re-dissolving in 250 ml. water and repeating the evaporation to dryness. The product was a hard, pale brown, amorphous solid; yield: 0·19 g. Its solution in methyl alcohol deposited fern-shaped crystals of ammonium chloride. To remove this impurity, 0·11 g. of the material was dissolved in water with an equal weight of potassium carbonate and the solution allowed to evaporate in a vacuum-desiccator. The dry residue was extracted with absolute methyl alcohol (in which potassium carbonate and chloride are insoluble) and the solution brought to dryness in a desiccator. The resulting potassium salts formed a pale brown, very hygroscopic, amorphous solid, soluble in absolute methyl alcohol, but not in ether, light petroleum or benzene; yield: 0·11 g. It gave intense Ehrlich, Thormählen, and ferric chloride reactions and also Ehrlich's diazo-reaction. The material was analysed quantitatively for sulphur. (Found: total sulphur, 2·48 %; sulphur in form of ethereal sulphate, 1·96 %.) It was apparently stable towards alkalis, but on warming with hydrochloric acid it blackened with formation of melanin.

Substances corresponding to the products "C" and "E" from human melanotic urine were also obtained; yields: 0·03 g. and 0·72 g. respectively. As these substances gave the melanogen reactions very weakly or not at all they were not examined any further.

III. *The administration of 5 : 6-dihydroxyindole-2-carboxylic acid.*

Having produced a typical melanotic urine by the injection of 5 : 6-dihydroxyindole into rabbits, it was of interest to see if the injection of a closely related compound, 5 : 6-dihydroxyindole-2-carboxylic acid, would lead to a similar result. This acid is a colourless material which readily oxidises to melanin on exposure to air, and Raper [1927] has shown that it arises in the tyrosinase-tyrosine reaction under certain conditions. A solution of 5 : 6-dihydroxyindole-2-carboxylic acid was prepared according to the method described by Raper and concentrated to about 10 ml. by evaporation under reduced pressure in a stream of carbon dioxide. After filtration from unchanged tyrosine, the liquid was injected subcutaneously into a rabbit. It was noted that the solution showed some marked differences in its behaviour from a solution of 5 : 6-dihydroxyindole. While the Ehrlich, ferric chloride, and hydrochloric acid reactions were given in the usual way, the Thormählen reaction was negative and on the addition of alkali the colour of the solution changed to brown but did not become black. The substance was precipitated by basic lead acetate and by Hopkins's reagent. Following the administration of the carboxylic acid the rabbit excreted a urine which was not a typical melanotic urine, though it resembled one in certain respects. The urine darkened on exposure to air and gave the Ehrlich, ferric chloride and hydrochloric acid reactions. On warming with caustic soda, however, the colour changed to brown—melanotic urine is stable to alkali—whilst the Thormählen reaction was negative. The chromogenic substance could be completely precipitated from the urine by basic lead acetate and by Hopkins's reagent. On decomposing the lead or mercury precipitate with hydrogen sulphide, the solution obtained gave the same reactions as the original urine. These properties strongly suggest that the 5 : 6-dihydroxyindole-2-carboxylic acid was excreted unchanged. In any case, it is obvious that the substance is not produced in human melanuria and is unlikely to be the precursor of the melanogen.

IV. *The separation process applied to normal rabbit urine.*

In order that an indication might be gained of the extent to which the chromogenic substances were separated from other constituents of urine by the precipitation process used in the foregoing experiments, normal rabbit urine was worked up by the same method. 8·29 g. basic lead acetate precipitate were prepared from 400 ml. urine and treated with carbon dioxide as previously described. Corresponding to the substance "A" a very hygroscopic pale brown amorphous solid was obtained, containing sulphur and nitrogen; yield: 1·53 g. The Thormählen, Ehrlich and ferric chloride reactions were negative, but the ferricyanide reaction was strongly positive. A solution of 1·38 g. of this material on precipitation with the mercuric acetate reagent gave products corresponding to "D" and "E"; yields: 0·10 g., 1·25 g., respectively. The former substance was a brown gummy residue completely soluble in water and absolute methyl alcohol, insoluble in ether and benzene, and containing nitrogen and sulphur.

The Ehrlich, Thormählen, ferric chloride and biuret reactions and tests for the presence of tryptophan, indoxyl, allantoin, and ethereal sulphates were all negative. Ehrlich's diazo-reaction succeeded, whilst on applying Tollens's test for glycuronate the substance gave a positive, though weak, reaction.

The product corresponding to "E" was a hygroscopic syrup containing nitrogen and sulphur and giving a weak ferric chloride reaction, Ehrlich's diazo-reaction and Tollens's test for glycuronates. It was not an ethereal sulphate. Only a minute amount of material corresponding to the substance "B" from human melanotic urine was isolated, and although 0·09 g. of a substance corresponding to "C" was obtained, it was a yellow resin which did not resemble in any way the product in the human case.

These experiments show that a substance is excreted in normal rabbit urine which cannot be separated from the melanogen by any of the processes applied by Eppinger and later workers, for in its solubility and precipitation reactions it behaves in the same way as the chromogenic material. Whether this substance is excreted in human urine has not yet been tested, but the possibility must be borne in mind.

V. *Preparation of the ethereal sulphate of 2 : 6-dihydroxyindole.*

This was carried out by a method similar to that used by Jolles and Schwenk [1915] for making indoxyl-potassium sulphate. 2 g. tyrosine in 4 l. water were oxidised by means of tyrosinase at p_H 6·5 as described previously [Raper, 1927]. When the maximum red colour had developed, 1 ml. of 10 % acetic acid was added and the solution filtered. The filtrate was evacuated in large filter flasks and well shaken to remove dissolved gases. It was then kept under hydrogen until the red colour had disappeared, this indicating the formation of 5 : 6-dihydroxyindole. After adding a few ml. of sulphurous acid and a little capryl alcohol dissolved in ethyl alcohol the solution was concentrated by distillation under reduced pressure in an atmosphere of hydrogen. During this concentration a second similar batch of material was prepared and this was evaporated in the same flask as the first. When the liquid had been reduced in volume to about 300 ml., unchanged tyrosine (1·37 g.) which had separated out was filtered off. The filtrate was concentrated further to about 20 ml. and again filtered. The filtrate was taken to dryness and the residue extracted with 30 ml. of warm pyridine. Only a small portion dissolved. This pyridine solution containing 5 : 6-dihydroxyindole was added slowly to a mixture of 30 ml. pyridine and 4 ml. chlorosulphonic acid containing 20 ml. of chloroform. It was allowed to stand at room temperature for 2 days. An equal volume of water was now added and the liquid distilled under reduced pressure to remove chloroform and pyridine. 11·5 g. caustic potash dissolved in a minimum volume of water were added and the potassium sulphate which separated was filtered off. The filtrate was at once saturated with carbon dioxide and the residual pyridine removed by distillation *in vacuo*. To the pigmented solution, which now measured 35 ml., 40 ml. absolute alcohol were added. This precipitated some potassium sulphate and carbonate as well as pigment, which were filtered off and washed with 50 % alcohol. To the filtrate an equal volume of alcohol was added which removed principally potassium sulphate. The precipitate was extracted with boiling 95 % alcohol and the extract added to the filtrate. The two were now concentrated by distillation *in vacuo* and finally in a vacuum-desiccator. A little KCl separated and was filtered off. The filtrate now measured 10 ml. It gave all the melanogen reactions of melanotic urine except that with $FeCl_3$ in the cold. It did, however, darken on heating with $FeCl_3$ and HCl. The filtrate was now precipitated with 100 ml.

alcohol and the white crystalline precipitate dried *in vacuo*. It contained the substance giving the melanogen reactions as well as potassium chloride and sulphate. After several trials it was found that the inorganic potassium salts could be separated by converting them all into the sulphate and precipitating this with 70 % alcohol in which the 5 : 6-dihydroxyindole potassium sulphate was moderately soluble. The precipitate containing the melanogen was dissolved in water and a slight excess of silver sulphate added. The solution was left overnight and the silver chloride filtered off. The filtrate was made faintly alkaline with potassium carbonate to remove the excess of silver, filtered through pulp and concentrated to 60 ml. by distillation *in vacuo*. Absolute alcohol was added to make the concentration 70 % and the solution left for some hours to allow K_2SO_4 to separate. This was filtered off and the filtrate concentrated by distillation *in vacuo* and then in a vacuum-desiccator. A small amount of amorphous material was filtered off and the solution was then returned to the desiccator and taken to dryness. The residue was dissolved in 2 ml. water and allowed to evaporate slowly in a desiccator over sulphuric acid at the ordinary pressure. A white crystalline substance separated which gave the Ehrlich and Thormählen reactions but still contained a little K_2CO_3. This was removed by redissolving in water, adding the mother-liquor and diluting to 20 ml. The solution was boiled and 5 % sulphuric acid added until it was exactly neutral to litmus. After cooling, 3 vols. of alcohol were added and after standing the K_2SO_4 was filtered off. The filtrate was taken to dryness *in vacuo*. The residue was dissolved in 1 ml. hot water, and 5 ml. hot alcohol were added. On cooling rosettes of needles separated out which were dried *in vacuo*. They weighed 63 mg. Analysis showed that they were the expected dipotassium sulphate of 5 : 6-dihydroxyindole. (Found by micro-analysis, N, 4·15; S, 16·00 %. $C_8H_5N(SO_4K)_2$ requires N, 3·6; S, 16·6 %.) A trace of the substance dissolved in a few ml. water gave strong Ehrlich and Thormählen reactions, but it did not darken with ferric chloride except when heated in strongly acid solution. The latter behaviour is unlike that of the melanogen of melanotic urine which rapidly darkens in the cold when ferric chloride alone is added.

An attempt was made to prepare the ethereal sulphate from the products of the enzyme action which had not dissolved in warm pyridine as described above. The residue insoluble in pyridine was heated in a water-bath under a reflux condenser with a mixture of 15 ml. pyridine, 75 ml. chloroform and 4 ml. chlorosulphonic acid for 10 hours. On working up the product in the same way as described for the pyridine-soluble material practically no substance giving the Ehrlich and Thormählen reactions was obtained.

DISCUSSION.

It is very probable that the melanogen produced by the administration of 5 : 6-dihydroxyindole to rabbits is identical with the chromogen of human melanuria. The artificially produced melanotic urine possessed all the characteristic properties of human melanotic urine, whilst the chromogenic material could be separated from both the human and rabbit urines by the same method and showed the same colour reactions, precipitation reactions and solubility in organic solvents in each case. Unfortunately, no conclusions could be drawn from an analysis of the products as they were certainly not pure. It has been demonstrated that a non-chromogenic material, exactly similar to the melanogen in its solubility in organic solvents and precipitation with salts of lead and mercury, occurs in normal rabbit urine and must therefore have been admixed with the rabbit melanogen; it may also have been present along with the human melanogen.

In their general properties the human and rabbit melanogens we have studied closely resemble the ether-insoluble chromogens described by Eppinger [1910], Feigl and Querner [1917], and Fürth and Kaunitz [1932]. The fact that some preparations of the chromogen obtained by Fürth and Kaunitz failed to give the Thormählen reaction was possibly due to a partial decomposition of the melanogen; in the present investigation preparations have been made which decomposed so far as to lose the Thormählen reaction without loss of the others. On the other hand, Eppinger's crystalline product failed to show the Ehrlich reaction while it still gave the Thormählen reaction. As we have already noted, however, there is some reason for doubting whether this substance was actually a melanogen. The existence of ether-soluble chromogens may also be questioned. Previous investigators have inferred their presence from the fact that methyl alcoholic solutions, from which the melanogen has been precipitated by ether, may retain the chromogen reactions. The melanogen is very soluble in methyl alcohol and it is reasonable to suppose that the addition of ether will not remove it completely from solution.

The foregoing experiments strongly suggest that the chromogen is a simple derivative of 5 : 6-dihydroxyindole. The latter substance shows many of the properties associated with the melanogen, including the ready oxidisability to melanin and the positive Ehrlich and Thormählen reactions—the latter reaction is not given by such closely related compounds as the 2-carboxylic acid and the *N*-methyl derivative. In the body it is converted into the chromogen; that this is not a general property of 5 : 6-dihydroxyindole derivatives is shown by the fact that the 2-carboxylic acid fails to produce a melanogen under such conditions. The stability of the chromogen towards alkali proves that it cannot be 5 : 6-dihydroxyindole itself. Now phenolic and similar hydroxylic compounds are excreted in the urine chiefly in combination with sulphuric or glycuronic acid. 2-Hydroxyindole, for example, is excreted as indican. It is therefore probable that if 5 : 6-dihydroxyindole were to arise in the body it would be excreted in the form of an ethereal sulphate or glycuronate. Such derivatives would be stable towards alkalis and readily hydrolysed by acids to 5 : 6-dihydroxyindole which would then oxidise to melanin. The behaviour of the melanogen would be explained by this hypothesis and there is a certain amount of evidence that it represents the actual state of affairs. In the present investigation a small percentage of ethereal sulphate was always associated with the chromogen and accounted for about 80 % of the total sulphur content. The dipotassium disulphate of 5 : 6-dihydroxyindole is, however, more stable than the chromogen of melanuria; it does not darken with ferric chloride unless heated in strongly acid solution. It is, of course, quite possible that the monosulphate is a more unstable compound. Glycuronates were always found with the melanogen, though it must be remembered that, in the experiments with rabbits at least, the melanogen could not be separated from a glycuronate occurring in normal urine.

The close relationship between the chromogen of melanuria and 5 : 6-dihydroxyindole is in agreement with the view that melanin is formed in the higher animals by the same series of changes that take place when tyrosine is oxidised by tyrosinase *in vitro*. Fürth and Kaunitz [1932] have pointed out that on this basis it is easy to account for the appearance of a catechol derivative in some melanotic urines by supposing that the decomposition of the 3 : 4-dihydroxyphenylalanine which is the first oxidation product of tyrosine can take place along two paths: either (i) there is oxidation to the quinone, followed by ring closure and the formation of 5 : 6-dihydroxyindole as previously described by Raper [1927], or else (ii) there is oxidation of the side chain in the usual way, leading to the formation of catecholacetic acid.

SUMMARY.

1. The chromogen of human melanuria has been studied and its separation from other constituents of urine by precipitation with lead acetate and mercuric acetate is described.

2. The administration of 5 : 6-dihydroxyindole to rabbits causes the excretion of a melanogen in the urine. The properties of this melanogen suggests its identity with the human melanogen.

3. 5 : 6-Dihydroxyindole-2-carboxylic acid does not produce a condition resembling human melanuria on administration to rabbits and is unlikely to be a precursor of the melanogen.

4. There is evidence that the chromogen is a simple derivative of 5 : 6-dihydroxyindole, possibly an ethereal sulphate or glycuronate.

5. The synthesis of 5 : 6-dihydroxyindole dipotassium disulphate is described.

A part of the expense of this investigation has been defrayed by a grant from the Government Grant Committee of the Royal Society for which the authors express their thanks.

XI. BROMINE IN THE TISSUES.

By THEODORE FREDERIC DIXON[1].

From the Central Pathological Laboratory of the London County Mental Hospitals.

(*Received November 13th, 1934.*)

THE findings of Zondek and Bier [1932, 1; 1933] with respect to the low blood bromine values of manic depressive psychotics have been criticised by many [Fleishhacker and Scheiderer, 1932; 1933; Hahn, 1933; Holtz and Roggenbau, 1933; and Dixon, 1934] on the ground that the method of bromine determination employed, that of Pincussen and Roman [1929], is untrustworthy. Since other investigators using the same chemical technique have confirmed these results on manic depressives [Urechia and Retezeanu, 1933; Sacristan and Peraita, 1933] or have found very constant values for normal blood [Kuranami, 1932] it seemed desirable to repeat these determinations, using the method of Dixon [1934]. It was thought also that confirmation was needed for the theory that a bromine-containing compound was stored in the pituitary which circulated in the blood causing sleep and sedative effects [Zondek and Bier, 1932, 2]. This theory followed on the earlier findings of Bernhardt and Ucko [1926] who claimed that the pituitary had a bromine content 15–30 times that found in blood.

It was therefore decided to investigate the variability of normal human blood bromine values. The results below were obtained with donors including medical officers, laboratory co-workers, *etc.*

D.	0·53 mg./100 ml.	McC.	0·986 mg./100 ml.
N.C.	0·42 ,,	C.N.	1·358 ,,
Hst.	0·63 ,,	C.	0·78 ,,
How.	0·71 ,,	P.	0·84 ,,
Mort.	0·69 ,,	I.	0·39 ,,

The values are so widely divergent that it might be thought, in view of the constancy of the blood bromine claimed by other workers, that errors had been made in the experimental technique or in the selection of the blood donors. Assuming that the experimental technique is correct, the possibility that the blood donors had been subjected to some form of bromide therapy must still be excluded. Since it is known that any ingested bromide is excreted from the body very slowly especially if the food is low in chloride [Hastings *et al.* 1932; Palmer and Clark, 1932] great care was exercised to ensure that the blood donors had received no bromide or iodide for over six months previous to the taking of the blood sample. This could be done easily in the normal series. In the case of inmates of mental hospitals where case-books were the only record there was necessarily less certainty. It was further found almost impossible to rely on blood samples from in-patients of a general hospital. Thus a group of 12 in-patients at King's College Hospital, untreated with bromide since admission, were investigated with respect to their blood bromine, using Walter's [1924] approximate clinical method for the determinations. In two cases the blood bromine was over 10 mg./100 ml. (The clinical method does not detect values of

---

[1] Maudsley Research Fellow.

1 mg./100 ml.) These facts indicate some of the difficulties in the interpretation of values obtained for the bromine content of blood or tissues if the possibility of bromide dosage is not considered. They also make it probable that the variations in normal series are due to differences in bromine intake.

Little systematic work on the bromine content of common foodstuffs has been done, although von Damiens and Blaignan [1931; 1932], using methods for bromine estimation which are not grossly inaccurate, have demonstrated its presence in varying amounts throughout the vegetable kingdom. The abbreviated table below, taken from their results, shows a wide range of variation both in the absolute bromine amount and in its relation to the corresponding chloride content.

	mg. Br/100 g. dry weight	g. Cl/100 g. dry weight	Br/Cl
Bread	0·09–0·61	0·82–1·8	0·0007–0·000046
Potatoes	0·27–1·43	0·63–0·319	0·0004–0·004
Lentils	1·02	0·012	0·083
Melon	9·45–26·2	0·765–1·04	0·012–0·025

Cooking salt contains small amounts and the present author has found a sample of such salt to contain 1 mg. Br/g. Cl, or Br/Cl = 0·001. It is thus easy to understand why the normal human blood bromine varies from one individual to another when the bromine and chlorine intakes may be widely different.

A series of bromine determinations were next done on the blood of manic depressive psychotics, untreated with bromide or iodide for at least six months previously.

Lark.	1·716 mg./100 ml.	Lo.	0·453 mg./100 ml.
Est.	0·328 ,,	Sh.	0·78 ,,
Ed.	0·512 ,,	Si.	0·90 ,,
Pr.	0·572 ,,	M.	0·59 ,,
Ant.	1·64 ,,	McD.	0·46 ,,
Ps.	0·28 ,,	W.	0·97 ,,

It is clear that these individuals exhibit the same type of variability in their blood bromine as do normal persons.

Bromine determinations were then carried out on human and animal hypophyses to find out if these glands really contained high amounts of bromine (15–30 mg./100 g. wet weight) as stated by Zondek *et al.* The method previously described for blood was used except that the tissues were desiccated so that they could be stored before the analyses without fear of decomposition. Amounts of 1–2 g. dry tissue were used for the determinations as preliminary experiments on ox hypophyses and showed only a trace of bromine. One gram of dry human hypophysis represents 5–6 g. wet tissue equal to approximately 10 human hypophyses (average wet weight of each hypophysis 0·5 g.). A preliminary alkaline hydrolysis for 4 hours on the water-bath was employed before evaporation and ashing as in the blood determinations. The human hypophyses, large numbers of which were obtained from mental hospitals, were divided into groups according to type of mental disorder. No division into groups according to age or sex was made. Table I shows that considerable variation in the bromine contents of different batches of pituitaries occurs. Unless otherwise stated, the pituitaries were obtained from patients who had had no bromide during the last six months of life. The only ones which showed excessive amounts of bromine comparable with the values of Zondek were those from mental hospital patients who had definitely received bromide during life.

Table I. *Bromine determinations on batches of hypophyses.*

	mg. Br/100 g. dry weight	mg. Br/100 g. wet weight calculated
Ox	2·8	0·6
Pig	1·35	0·27
Human:		
(1) G.P.I.	8·27	1·65
(2) Idiots	2·10	0·42
(3) Miscellaneous insane	6·97	1·39
(4) Normals	4·22	0·84
(5) Normals	11·85	2·39
(6) Miscellaneous insane (known to have received bromide)	46·5	9·84
(7) " " "	133	26·6
(8) Seniles	3·53	0·7
(9) "	6·77	1·35
(10) Melancholics	8·46	1·69
(11) Manics	9·1	1·8
(12) Miscellaneous insane (some possibility of bromide dosage)	27·9	4·7
(13)	26·1	4·4

These results show then that the amount of bromine normally in the pituitary, which is of the same order as that in blood, is inconsistent with the belief that a bromine-containing substance is either stored or secreted by that organ.

It was then decided to investigate the relationship between bromine and chlorine in the animal body and as it was thought that *post mortem* human material was not reliable, pigs, which were available, were chosen. The organs of two pigs were examined with respect to their bromine and chlorine contents. The method of Dixon [1934] was employed for the bromine estimations, using 10–15 g. tissue, and the method of Eisenman [1929] for the chlorine estimations, using about 2 g. fresh tissue.

The results are shown in Table II.

Table II. *Results of bromine and chlorine determinations, in mg. per 100 g. tissue, on pig's organs.*

	Boar			Gilt		
Organ	Bromine	Chlorine	Br/Cl	Bromine	Chlorine	Br/Cl
Serum	1·25	314	0·004	0·75	320	0·0023
Kidney	0·445	203	0·0022	0·361	197	0·0018
Lung	0·551	218	0·0025	0·397	216	0·0018
Ovaries	—	—	—	0·647	—	—
Testes	0·334	184	0·0018	—	—	—
Liver	0·295	104	0·0028	0·213	101	0·002
Brain	0·192	126	0·0016	0·191	142	0·0014
Pancreas	0·259	110	0·0025	0·265	109	0·0025
Adrenal	0·368	107	0·0035.	—	—	—
Pituitary	0·270	145	0·0019	—	—	—

The pituitary figures, which represent duplicate determinations on groups of twenty pooled organs obtained from pigs in the same sties, are clearly not very different from those found for other organs. These two pigs had been fed for 5 months previous to death on a diet, the essential constituents of which, from the standpoint of bromine and chlorine content, are given below. A rough estimate of the relative bromine and chlorine content of this diet was made, using the results of von Damiens and Blaignan [1931] and those of the present author on cooking salt.

Constituent	Barley meal	Wheat middlings	Salt	Total
% in diet	60	35	0·33	
Cl g./100 g.	0·050*	0·06*	60·7†	
Cl g./100 g. diet	0·03	0·021	0·20	0·251 (g.)
Br mg./100 g.	0·45*	0·18*	60·7†	
Br mg./100 g. diet	0·27	0·063	0·20	0·533 (mg.)

* Data of von Damiens and Blaignan [1931]. † Data of the author.

From this table it will be seen that the Br/Cl ratio $(0{\cdot}533/0{\cdot}251 \times 1000 = 0{\cdot}002)$, although only very approximate, is roughly the same as that found in the pig tissues.

CONCLUSIONS.

Determination of the bromine distribution in the animal body leaves its rôle in the organism as mysterious as ever. It seems probable that its presence is fortuitous and dependent on food intake. No evidence has been obtained in support of the theory that a bromine-containing hormone exists in the pituitary. Bromine metabolism does not appear to bear any relation to mental disease.

The author wishes to thank Dr F. L. Golla, Director of the Central Pathological Laboratory, and Dr S. A. Mann for their advice and criticism. He is also indebted to Drs J. Brander, A. Davies and R. A. McCance and to the medical officers of the London County Mental Hospitals for their kindness in providing the material.

XII. THE BODY FATS OF THE PIG.

IV. PROGRESSIVE HYDROGENATION AS AN AID IN THE STUDY OF GLYCERIDE STRUCTURE.

By THOMAS PERCY HILDITCH and WILLIAM JOHN STAINSBY.

From the Department of Industrial Chemistry, University of Liverpool.

(*Received November 14th, 1934.*)

It was pointed out in an earlier communication in this series [Banks and Hilditch, 1932] that the relationship between the content of fully-saturated glycerides and the degree of saturation as a whole of pig, ox and sheep depot fats and also cow milk fats (a group in which the saturated fatty acids ranged from 34 to 72·5 mols. % of the total fatty acids in each fat) was closely similar to that of a series of progressively hydrogenated cottonseed oils. Cottonseed oil resembles the most unsaturated type of pig body fat in so far as it contains about 25 % of saturated (almost all palmitic) and 75 % of unsaturated acids, all the saturated acids being present in the form of mixed, saturated-unsaturated glycerides. In the present paper the glyceride structure of a similar group of hydrogenated pig fats is described, since it was considered of some interest to compare the increase in fully-saturated glycerides, in fats produced by progressive hydrogenation of an animal depot fat of the most unsaturated type, with that observed in the series of natural lards, tallows and butters.

The experimental material required for this purpose was also suitable for the study of other features of the glyceride structure of the original pig fat employed. We have been able to estimate, by two independent methods, the total content therein of glycerides consisting wholly of C_{18} (stearic, oleic and/or linoleic) acids, to show that the monopalmitoglycerides of the fat were almost entirely, if not wholly, β-palmito-$\alpha\alpha'$-diacylglycerides, and finally, to give a more detailed statement than previously of the probable proportions of the chief component glycerides of the original fat.

The inner layers of the pig back fat, the component acids of which had already been examined [Dean and Hilditch, 1933] and found to be practically the same throughout the layer, served as the primary material for the present study. Owing to the large quantity of material required by the present work, it was necessary to commence from the inner back fat; the amount of the outermost layer of back fat (which would have provided a still better starting-point, owing to its somewhat greater unsaturation) was not sufficient to provide the requisite quantities of all the desired hydrogenated products.

The mixed inner back fat had a mean saponification equivalent of 286·2 and a mean iodine value of 63·0. Its mixed fatty acids (setting-point 40·7°) were analysed by the ester-fractionation method; the results, together with the corresponding figures of Dean and Hilditch [1933] for the outermost (I), middle (II) and innermost (III) layers of the inner back fat, are given in Table I.

Portions of the fat were hydrogenated to varying degrees by agitation with a small proportion of nickel on kieselguhr in hydrogen at atmospheric pressure at 175–180°, and products of the following iodine values were thus prepared: 48·9, 43·0, 35·8 (800 g. of each), and 28·9, 18·7, 10·0 and 0·2 (400 g. of each).

Table I. *Component acids of original inner back fat.*

Acid	Weight percentages				Molar percentages			
	I	II	III	Mixed	I	II	III	Mixed
Myristic	2·9	2·8	3·0	2·3	3·5	3·3	3·6	2·8
Palmitic	24·9	25·5	24·6	25·6	26·6	27·3	26·2	27·3
Stearic	14·5	14·5	14·5	14·9	14·0	14·0	14·0	14·4
Oleic	42·7	41·3	42·8	42·2	41·4	40·1	41·6	40·9
Linoleic*	13·9	14·5	13·7	13·8	13·6	14·2	13·4	13·5
C_{20-22} unsaturated	1·1	1·4	1·4	1·2	0·9	1·2	1·2	1·1

* Some of the C_{18} unsaturated esters isolated from the original pig fat were examined qualitatively. It was found that the oleic and linoleic acids present were respectively the common forms of $\Delta^{9:10}$-octadecenoic and $\Delta^{9:10,12:13}$-octadecadienoic acids. Oxidation with dilute alkaline permanganate gave 9:10-dihydroxystearic acid, M.P. 131°, and two tetrahydroxystearic acids, M.P. 154° and 172°; a tetrabromostearic acid which was sparingly soluble in light petroleum and melted at 114° was also obtained. The yields of tetrabromo- and tetrahydroxy-stearic acids were of the same order as those given by the linoleic acid from a seed-fat such as cottonseed oil.

Sufficient of each fat (including the original) was oxidised with potassium permanganate in acetone to yield a suitable quantity of fully-saturated glycerides to permit of the component acids of the latter being analysed by the ester-fractionation method with the results[1] shown in Table III.

In Table III are also given the fatty acid compositions of each of the hydrogenated fats. To facilitate comparison between the various products, the latter have been calculated from the original analysis (Table I) in conjunction with the observed iodine values of the fats. This course has been adopted in order to avoid the slight variations otherwise introduced by the small but inevitable experimental errors of analysis [*cf.* Hilditch, 1934]. In view of the good agreement between the four analyses recorded in Table I the figures for the original fat must be considered to be a close approximation to the truth.

We have however made independent ester-fractionation analyses of the component fatty acids of the fats of iodine value 48·9, 35·8, and 10·0 (Table II). The direct analysis of the first-named fat was essential in order to ascertain the extent to which linoleic glycerides were undergoing hydrogenation. The result showed that the hydrogenation had followed the usual, mainly selective course and indicated that linoleic acid would no longer be present in the remaining, more saturated products.

Table II. *Component fatty acids of hydrogenated pig fats (by direct analysis) (mol.* %*).*

	48·9	35·8	10·0
Iodine value of fat	%	%	%
Myristic	2·8	2·2	1·3
Palmitic	25·6	28·1	29·0
Stearic	18·1	28·2	56·3
Oleic (and *iso*-oleic)	50·9	40·5	11·9
Linoleic	0·9	—	—
C_{20-22}	1·7	1·0	1·5

The complete analytical data for each hydrogenated product and its corresponding fully-saturated components may now be considered. In Table III, in which these are summarised, are included the weights of fat from which the fully-saturated glycerides were obtained, and the weights of the esters of the mixed acids of the latter which were subsequently fractionated.

---

† Calculated from iodine value of fat and analysis of acids from original fat of iodine value 63·0.

Comparison of the proportions of fully-saturated components in the partially-hydrogenated pig fats and in natural depot (and milk) fats of similar relative unsaturation.

The relation between the molar content of fully-saturated glycerides and the molar percentages of saturated acids in the total fatty acids of the various fats is shown graphically in Fig. 1. The points indicated by letters refer to the different natural fats (depot fats of pig (L), ox and sheep (T), or butter fats (B)), whilst the unbroken curve has been drawn through the values obtained from the hydrogenated pig fats (Table III). The dotted curve represents the relationship which would obtain if the amount of fully-saturated components in a fat were proportional to the cube of the proportion of saturated acids present in the mixed acids. The broken line shows the fundamentally different relations subsisting in seed-fats, in which fully-saturated glycerides are rarely found in greater amount than that necessary to leave a ratio of about 55–60 % of saturated to 45–40 % of unsaturated acids linked together as mixed saturated-unsaturated glycerides [Collin and Hilditch, 1929].

In fats hydrogenated by metallic catalysts under the conditions which we have used, the linoleic glycerides are very largely converted into oleic derivatives before the stearic content is appreciably augmented. Thus the molar percentage of linoleic acid in the component fatty acids fell from 13·5 to 1, while the increase in stearic acid was less than 2 %, and the fully-saturated glyceride content only rose from 5·6 % to 7·1 %. In this respect the artificially hydrogenated fats form a different series from the natural depot fats in which stearic acid augments mainly at the expense of oleic acid, rather than of linoleic acid. This difference does not however affect the relationships now under consideration, since these are based on the relative proportions of saturated to unsaturated acids as a whole in each fat.

It will be seen that, as in the case of hydrogenated cottonseed oils, the points given on the graph by the natural tallows and lards[1] follow the hydrogenated pig fat curve with a fair degree of consistency. The most arresting feature of the diagram is that, as with the hydrogenated fats, the series of values for the natural fats definitely tends to meet the horizontal axis at a point representing 25–30 % of saturated acids in the total fatty acids. This amount is also of course that of the approximately constant palmitic acid content which has been shown to be characteristic for animal depot fats and also butter fats. If the occurrence of fully-saturated glycerides in these fats were determined by the relative concentration of any one acid, or class of acid, the presence of 25–30 % of palmitic acid alone should suffice to produce 5 % or somewhat more of tripalmitin. Actually, tripalmitin has never been observed in either lards or tallows, the fully-saturated components being almost entirely mixed palmitostearins.

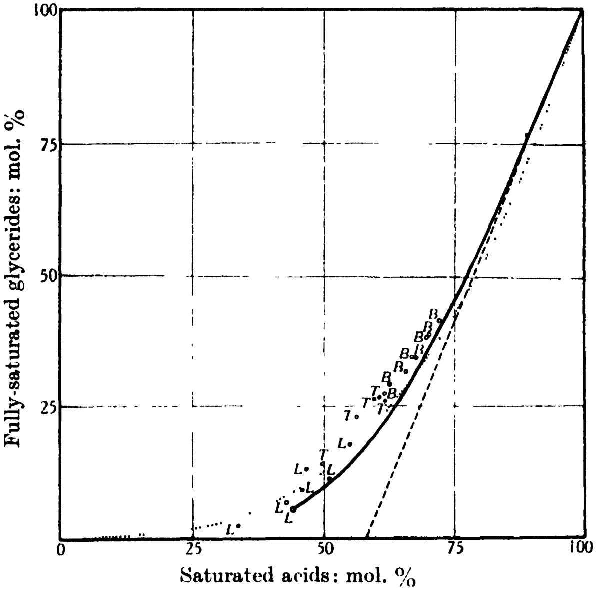

Fig. 1. *L*, pig fats. *T*, tallows. *B*, butter fats. —— Hydrogenated pig fat. - - - - - - Seed fats. · · · · $y \propto x^3$.

These facts, as well as the parallelism in general glyceride structure between the natural fats and the hydrogenated pig fats, accord with the suggestion made in an earlier paper [Banks and Hilditch, 1932] that, in the lard and tallow types of depot fats (with relatively high stearic contents), a mixture of triglycerides, formed initially from about 30 % of palmitic and about 70 % of oleic acids and containing little or no fully-saturated compounds, may undergo subsequent hydrogenation of some of the oleo-glycerides. Mere similarity of chemical structure in two series of compounds is of course no proof of the mechanism by which one of the series may have been produced; nevertheless, specific features in the structure of natural products merit due consideration when hypotheses as to their biosynthesis are elaborated.

---

[1] Fig. 1 shows that the milk fats fall into line with tallows and lards from the point of view of their general glyceride structure, and it has also been found [Hilditch and Sleightholme, 1931, p. 518] that in these fats the united molar contents of the characteristic lower saturated fatty (butyric-lauric) acids together with stearic and oleic acids tend towards a constant figure of about 65 % (mol.)—little different from that of the total C_{18} acids in tallows and lards. There are therefore fundamental and quantitative similarities in the general constitutions of these milk and depot fats.

Content of tri-C_{18}-glycerides in the original pig fat.

Direct methods of determination of the triolein or triunsaturated glyceride content of a fat are still lacking, but it has recently been shown [Hilditch and Jones, 1934] that an approximate estimate of the total tri-C_{18}-glycerides present can be arrived at in suitable cases from the mean equivalents of the fractions obtained by systematic crystallisation of the fat after complete hydrogenation. An independent method, which serves as a check on the foregoing process and which has not been previously described, depends on the fact that palmitostearo-oleins are hydrogenated preferentially to distearo-oleins [Hilditch and Jones, 1932] and that, consequently, after partial hydrogenation to a point at which no dipalmito-unsaturated glycerides are left, the non-fully-saturated glycerides are composed solely of monopalmitodistearins and tri-C_{18}-glycerides. Both these methods have been applied in the present investigation.

(i) *Fractional crystallisation of the completely hydrogenated pig fat* (*iodine value 0·2*). The completely hydrogenated fat (102 g.) was crystallised first from 10 volumes of ether and the separated solids were then crystallised from 15 volumes of ether, the latter process being repeated three times. The fractions obtained and their analytical characteristics are summarised in Table IV.

Table IV. *Fractional crystallisation of hydrogenated pig fat* (*102 g., iodine value 0·2*).

		Glycerides			Corresponding acids (freed from unsap.)	
No.	g.	M.P.	S.E.	I.V.	S.E.	I.V.
A	69·1	68°	289·2	—	—	—
B	5·5	68°	287·3	—	—	—
C	8·5	—	286·1	—	—	—
D	2·9	—	285·9	—	—	—
E	7·9	—	284·5	0·7	272·0	0·5
F	8·1	—	283·8	2·5	270·0	1·3

Assuming that fraction A is a mixture of tristearin (S.E. 296·7) and palmitodistearin (S.E. 287·3), and that the iodine values of the glycerides in fractions E and F are due to oleodistearin, it follows that the fat (102 g.) contained 14·3 g. tristearin and 0·5 g. oleodistearin, corresponding to a molar content of 14·1 % tri-C_{18}-glycerides in the whole fat[1].

(ii) *Estimation of tri-C_{18}-glycerides from some of the partially hydrogenated fats.* Before applying this method, it is necessary to ascertain, (*a*) whether any tristearin has already been formed and (*b*) at what point the absence of dipalmitoglycerides from the non-fully-saturated glycerides can be presumed. The production of tristearin can be followed by subjecting the fully-saturated glycerides of the fats to systematic crystallisation. Thus, the fully-saturated glycerides in the fat of iodine value 18·7 (*v. infra*) showed no tristearin content.

---

[1] This method of examination is unfortunately not sufficiently delicate to take account of the minor component acids (myristic 2·8 %, C_{20-22} 1·1 %) present in the fat. Calculated from the saponification equivalents as combinations of palmitic and C_{18}-glycerides, the molar composition of the hydrogenated fat amounted to: tristearin 13·6 %, palmitodistearin 78·4 %, dipalmitostearin 7·5 % and oleodistearin 0·5 %. This corresponds with a total molar fatty acid composition of palmitic 31 % and C_{18}-acids 69 % (calculated from original ester-fractionation analysis of the original fat: non-C_{18}-acids 31·2 %, C_{18}-acids 68·8 %).

The second question can be answered approximately by examining the relative amounts of stearic and palmitic acids added at each stage of the hydrogenation to the fully-saturated components. This is illustrated in Table V, the (molar) data in which have been obtained from the detailed analysis made of the fully-saturated components of each of the hydrogenated fats.

Table V. *Increase in non-C_{18} and stearic acids in fully-saturated glycerides at successive stages of hydrogenation.*

Stages (Fall in I.V.)	Increase in total saturated acids	Increase in fully-saturated glycerides	Mols. (per 100 g. fat) added of		Ratio C_{18}/C_{16}
			C_{16}*	C_{18}	
63·0–43·0	7·2	5·3	1·95	3·35	1·7
43·0–35·8	8·1	8·7	3·15	5·55	1·8
35·8–28·7	7·7	12·4	4·8	7·6	1·6
28·7–18·7	11·3	21·2	7·8	13·4	1·7
18·7–10·0	9·9	17·9	6·2	11·7	1·9
10·0–nil	11·3	28·9	4·9	24·0	4·9

* Minor amounts of C_{14} or C_{20-22} acids included with C_{16}.

From Table V it appears that the remaining non-fully-saturated components of the fats of iodine values 18·7 and 10·0 both consist solely of monopalmito-di-C_{18}-glycerides and tri-C_{18}-glycerides, since the ratio of C_{18} : C_{16}-glycerides added is almost exactly 2 : 1. It is also seen from Table V that, during the further hydrogenation to iodine value 10·0, there was no indication of the formation of tristearin.

Considering the fats of iodine value 18·7 and 10·0, detailed analyses reveal the data quoted in Table VI.

Table VI. *Component acids (mol. %) in the fully-saturated and non-fully-saturated part of fats of iodine value 18·7 and 10·0.*

	Fat of I.V. 18·7			Fat of I.V. 10·0		
	Whole fat	Fully-saturated	Mixed saturated-unsaturated (by diff.)	Whole fat	Fully-saturated	Mixed saturated-unsaturated (by diff.)
Mols:	100	53·2	46·8	100	71·1	28·9
Myristic	2·8	—	2·8	2·8	—	2·8
Palmitic	27·5	20·7	6·8	27·5	26·1	1·4
Stearic	47·5	32·5	15·0	57·4	44·2	13·2
C_{20-22}	1·0	—	1·0	1·0	0·8	0·2
Oleic and *iso*-oleic	21·2	—	21·2	11·3	—	11·3

In the non-fully-saturated portion of the fat of iodine value 18·7, therefore, there are, by difference, 10·6 mols. of non-C_{18} acids (corresponding to 31·8 mols. of "palmito-di-C_{18}-glycerides") and 36·2 mols. of C_{18} acids. Since 21·2 mols. of C_{18} acids are required in the formation of the 31·8 mols. of mixed glycerides, there remain 15·0 % (mol.) in the form of tri-C_{18}-glycerides.

A similar calculation from the results for the other fat gives 15·7 % (mol.) tri C_{18}-glycerides.

The results of the estimations by methods (i) and (ii) are reasonably concordant and the proportion of tri-C_{18}-glycerides other than tristearin (triolein, oleodistearins, oleolinoleins or similar combinations) in the original fat is clearly about 15 % (mol.).

The occurrence of β-palmito-glycerides in the pig depot fat. Some evidence as to the configuration of the mono-palmitoglycerides of the original pig fat has been obtained from study of the fully-saturated components isolated from the fats which had been hydrogenated respectively to iodine values of 35·8 and 18·7. It has already been shown that, at these stages, no tristearin had been produced in the course of the hydrogenation. Systematic crystallisation from ether of the fully-saturated glycerides from each fat gave considerable proportions of a palmitodistearin which melted at 67–67·5° (Table VII).

Table VII. *Palmitodistearins isolated from the fully-saturated glycerides of hydrogenated pig fats.*

Hydrogenated fat	Fully-saturated glycerides crystallised	Palmitodistearin isolated				Composition of F.S.G. calculated from component acid analysis (Table III)	
						Palmitodistearin	Dipalmitostearin
I.V.	g.	g.	%	M.P.	S.P.	%	%
35·8	19·2	11·2	58·3	67·5°	287·4	77	23
18·7	22·9	15·8	69·0	67°	286·7	84	16

The melting-points of α-palmito-βα′-distearin and of β-palmito-αα′-distearin are respectively 63·5° and 68° [Bömer *et al.*, 1907; 1909; 1913; Amberger and Wiesehahn, 1923; Robinson *et al.*, 1932], and thus the data in Table VII show that the least soluble fractions isolated were β-palmito-αα′-distearin. Moreover the quantity of β-palmitostearin amounted to 76 % and 82 % of the whole of the palmitodistearin present in the respective fully-saturated glycerides and, in the case of the fat of iodine value 18·7, the palmitostearin actually isolated corresponds to about 60 % of the whole of the monopalmito-di-C_{18}-glycerides present in the original fat, although no particular effort was made to obtain quantitative recovery of all the monopalmitodistearin. In view of the relative ease with which the compounds of melting-point 67·5° were obtained and of the well-known difficulties attending the separation of mixtures of the isomeric palmitodistearins by crystallisation, these results are considered to point definitely to the presence, in the original pig fat, of β-monopalmito-glycerides, unaccompanied by any appreciable quantities of the α-monopalmito-isomerides[1].

The exclusive occurrence of one configurational form of a mixed glyceride, as suggested for pig depot fat by these results, may be less uncommon in natural fats than would perhaps be supposed. At all events, the present observations are paralleled by the similar presence of β-oleodistearin in a group of vegetable seed fats, including those of kokum butter and *Allanblackia Stuhlmannii* [Heise, 1897; Hilditch and Saletore, 1933], cacao butter [Fritzweiler, 1902] and Borneo tallow [Klimont, 1904].

---

[1] Dr Banks has suggested to us that the preferential hydrogenation of palmitostearo-oleins to that of distearo-oleins may be due to relative ease of hydrogenation of oleic radicals attached to the α-glyceryl carbon atoms as compared with those attached to a β-glyceryl carbon atom. This possibility is at present being investigated in our laboratory.

The probable proportions of the chief components of the original pig depot glycerides.

The data which have now been discussed allow a somewhat fuller statement to be given than formerly as to the main components of a pig depot fat, subject to the following limitations:

(*a*) The methods employed are not sufficiently delicate to indicate the mode of union of the minor component acids (myristic and the C_{20-22} group) which form only 2 or 3 % of the total fatty acids. They serve however to define the chief combinations of the acids containing 18 carbon atoms with those containing other than 18 carbon atoms in the molecule; in the case of pig depot fat the latter group is very largely composed of palmitic acid, and it thus becomes possible to outline the chief combinations of palmitic and C_{18} acids which occur in the mixed glycerides.

(*b*) Since the methods employed involve hydrogenation, *i.e.* removal of the unsaturated group, it is impossible to discriminate, in what follows, between the linoleic and oleic radicals originally present in the fat. (For the sake of brevity the unsaturated glycerides are referred to in the paragraphs immediately following as “oleins,” “oleic” derivatives *etc.*, the use of inverted commas denoting that both oleic and linoleic, and not only the monoethenoid, compounds may be concerned.)

The data now available include:

(*a*) The proportion (*ca.* 5 %) of fully-saturated glycerides in the original fat, these being mixtures of dipalmitostearin and palmitodistearin.

(*b*) The proportion (*ca.* 15 %) of tri-C_{18}-glycerides present. These might be tri-“oleins,” stearodi-“oleins,” or distearo-“oleins”; the latter are least likely to be present, the monostearo-glycerides being probably the chief representatives of this group, but there may well be at least some triolein or mixed linoleo-oleins in the original fat (the fatty acids of which included 41 % oleic and 13·5 % linoleic acids). Estimates are given below for this group reckoned alternatively as all monostearodi-“oleins,” or as all tri-“oleins.”

(*c*) The remainder of the stearo-glycerides (corresponding to the balance of the total stearic acid unaccounted for in the form of tri-C_{18}-glycerides) must be either palmitostearo-“olein” or palmitostearins (tristearin being absent and the presence of distearo-“oleins” in significant quantities being ruled out as unlikely). The quantity of stearic acid combined as palmitostearins being known (*a*), the residue must be allotted to palmitostearo-“olein.”

(*d*) The monopalmito-derivatives have been shown to be β-palmito-glycerides.

Alternative possible compositions of the main glycerides of the fat can therefore be given, to a rough approximation, according to whether the tri-C_{18}-glycerides contain one stearic residue or not (Table VIII).

Table VIII. *The general composition of the glycerides of pig back fat (iodine value 63·0).*

	Tri-C_{18}-glycerides estimated as		
	(*a*) Stearodi-“oleins” % (mol.)		(*b*) Tri-“oleins” % (mol.)
(β-) Palmitodistearin	2		2
Dipalmitostearin	3		3
Tri-“oleins”	—	to	15
Stearodi-“oleins”	15	,,	—
(β-) Palmitostearo-“oleins”	21	,,	36
(β-) Palmitodi-“oleins”	57	,,	42
Dipalmito-“olein”	2		2

The most abundant constituents of this particular fat are the palmitodi-"oleins" (42–57 %), followed by palmitostearo-"oleins" (21–36 %) and tri-C_{18}-glycerides (15 %, mainly unsaturated).

The possible limits within which the three classes of monosaturated-di-unsaturated, disaturated-mono-unsaturated, and tri-unsaturated glycerides may be present in the fat have been considerably narrowed by the present procedure, in comparison with those which it was formerly possible to indicate by consideration only of the amount of fully-saturated glycerides present. This is shown in Table IX, which also includes the similar values indicated by the old and the present methods for the content of tri-C_{18}-glycerides other than tristearin.

Table IX. *Limiting values for certain classes of glycerides in the pig back fat.*

	(a) From F.S.G. content alone	(b) Present analysis
Mono-unsaturated-disaturated	23–59	23–38
Di-unsaturated-monosaturated	72–0	72–42
Tri-unsaturated	0–36	0–15
Tri-C_{18}-glycerides	10–52	15

Amberger and Wiesehahn [1923], who investigated lards of iodine values 51·5 and 54·7 by fractional crystallisation of the original and of the completely hydrogenated fats, suggested that they contained dipalmitostearin (2 %), palmitodistearin (3 %), oleodistearin (2 %), oleopalmitostearin (11 %) and palmitodiolein (82 %), with possibly some triolein. These figures differ from those given above chiefly in the low proportion assigned to palmitostearo-oleins; this is perhaps to be expected in consequence of the undoubted difficulty of obtaining anything approaching a quantitative separation of these glycerides from the more abundant palmitodi-"oleins" which accompany them.

The data of Table VIII refer to a pig back fat of the more unsaturated type. A more saturated fat, such as a perinephric fat with iodine value about 55, of course must be somewhat differently constituted. Such a fat contains about 14 % of fully-saturated components and its mixed acids include about 70 % C_{18}-acids (of which about 17 % may be stearic acid). The determination of its approximate composition, which would involve the execution of another series of analyses on the lines of those described in this paper, has not been undertaken. It may be pointed out however that (if the leaf fat should contain about the same proportion of tri-C_{18}-glycerides as that in the back fat which we have examined) palmitodi-"oleins" would still be the most prominent components (35–50 %), palmitostearo-"oleins" would probably be present in proportions not differing very greatly from those given in Table IX, whilst, of course, the amount of palmitodistearin would be augmented in consequence of the increase in fully-saturated glycerides as compared with the back fat (possibly distearo-"oleins" might be present in minor quantities).

It will be perceived that the quantitative description of the component glycerides of pig depot fat is still incomplete; nevertheless the work reported above permits us to deduce with some confidence the general relative proportions of the different classes of mixed glycerides (enumerated in Table VIII) for a single specimen of the depot fat, and to indicate the probable alteration in their respective proportions in other pig depot fats of a more saturated character.

SUMMARY.

Investigation of the composition of a pig back fat after its catalytic hydrogenation to varying stages of saturation has led to the following conclusions:

1. The increase in the fully-saturated glycerides in a series of animal fats (pig, ox, sheep depot fats and cow milk fats), in which the total content of saturated acids progressively increases, is very similar to that displayed by the artificially hydrogenated pig back fats. The values for the natural fats, when plotted graphically, suggest that fully-saturated components would be absent from a fat of this group which contained only 25–30 % of saturated acids (*i.e.* palmitic but no stearic acid).
2. Estimations by two different methods showed that the fat contained 15 % (mol.) of tri-C_{18}-glycerides (other than tristearin, which was absent). The precise nature of this group (triolein, oleolinoleins, stearodioleins, or oleodistearin) was not ascertainable, but it is probable that it consists mainly of stearodioleins with perhaps a small proportion of tri-unsaturated glycerides.
3. The monopalmito-compounds present in the fat consist very largely, and quite probably solely, of β-palmito-glycerides (β-palmitodi-"olein" and β-palmitostearo-"olein," with a small amount of β-palmitodistearin).
4. Palmitodi-unsaturated glycerides (chiefly palmitodiolein) are the chief components of the original fat investigated, of which they may form from 42 to 57 %; palmitostearo-"oleins" (21–36 %) and the tri-C_{18}-unsaturated (or semi-unsaturated) glycerides (15 %) are the next most abundant constituents.

The perinephric fats of the pig, which are more saturated, probably contain somewhat less of the palmitodi-"oleins" and not very different amounts of palmitostearo-"oleins," compared with the back fat; but there is a corresponding increase in the palmitostearins present.

The assistance of the Department of Scientific and Industrial Research, in a grant to one of us (W. J. S.), is gratefully acknowledged.

XIII. THE ASCORBIC ACID CONTENT OF THE INTESTINE OF THE GUINEA-PIG.

By SYLVESTER SOLOMON ZILVA[1].

From the Division of Nutrition, Lister Institute, London.

(*Received November 22nd, 1934.*)

It is now established beyond doubt that certain organs and glands of animals whether susceptible to scurvy or not contain ascorbic acid in higher concentration than most of the other tissues. Thus the anterior lobe of the pituitary, the adrenals and to a lesser extent the liver have been shown by the reducing and by the biological methods to be rich in the vitamin. Harde and Wolff [1934], working with the mouse, and Hopkins [1934], working with the rat, indicated that the small intestine belongs to this group of organs. Giroud and Leblond [1934] found that silver nitrate when injected intravascularly is reduced by the intestine much more markedly in guinea-pigs on a mixed diet than in similar animals on a scorbutic diet, from which they deduce that the intestine of the former animals is also rich in ascorbic acid. The results to be produced confirm this conclusion.

When guinea-pigs are maintained on a scorbutic diet for some days, extracts of their tissues lose the capacity for reducing indophenol rapidly in acid solution. On the other hand, when ascorbic acid is offered *per os* or injected into the blood stream of such animals they acquire again this reducing property [De Caro, 1934]. The implication therefore is that the substance which reduces indophenol in this case at a more rapid rate than the other reducing substances present in the tissues is ascorbic acid.

In Table I are given the ascorbic acid contents, calculated on this basis from trichloroacetic acid extracts, of the alimentary canals of three groups of guinea-pigs. The first group, which was almost if not entirely exhausted of ascorbic acid on a scorbutic diet, received 100 mg. of ascorbic acid (synthetic)[2] by means of an injection into the jugular vein under a local anaesthetic, and the animals were

Table I.

killed two hours later. The second was a control group subsisting on a scorbutic diet, and the third received for a number of weeks a mixed diet containing cabbage *ad lib.* and in addition high doses of decitrated lemon juice *per os.* All the animals were killed by stunning and bleeding. There can be little doubt that the rapid reduction of the indophenol in the case of the injected animals was due to ascorbic acid. It is unlikely that the injected substance has either produced from precursors in the tissues, or has been itself converted into, an inactive reducing substance, especially as it has been shown by biological tests [Johnson and Zilva, 1934] that ascorbic acid passes through the organism without change. The animals in group I were killed two hours after the injection, since it was found that by this time an equilibrium was established in the ascorbic acid content of the intestines of these guinea-pigs. It is seen from the Table that the concentration of the vitamin in the alimentary canal is high, especially in the small intestine. This will be appreciated more when it is stated that the average concentration per g. in the liver of the above guinea-pigs on the mixed diet was 0·25 mg. Furthermore the concentration in the intestine is about the same as that observed by Harde and Wolff for the mouse (0·18–0·37 mg. per g.). These authors state, on the other hand, that the concentrations in the two cases differ appreciably ("sensiblement") but give no experimental details for the guinea-pig. They are of the opinion that "il y a une différence fondamentale entre l'élaboration des produits réducteurs dans l'intestin du cobaye et de la souris."

It is perhaps superfluous to add that the above figures (groups 1 and 3) are significant since the titrations were carried out on extracts equivalent to about 2 g. of tissue which usually reduced quickly over 6 ml. of $N/1000$ indophenol in the case of the small intestine. On the other hand the figures obtained in group 2, the control group on the scorbutic diet, are so low that they might be due to very small quantities of ascorbic acid, as given in the Table, or to the presence in higher concentration of "slow" reducing substances such as cysteine.

It therefore emerges from this experiment that when guinea-pigs are on a diet containing ascorbic acid the substance is selectively absorbed by the tissues of the intestinal tract, principally by those of the small intestine. It is above all plain from my results that this accumulation cannot be due to the passage of the vitamin of the ingested food through the gut, since when the ascorbic acid was injected into the blood stream, concentrations of ascorbic acid of an order similar to that obtained with guinea-pigs on a mixed diet were recorded. The guinea-pig, then, resembles the rat and the mouse, which are capable of synthesising ascorbic acid, in concentrating this compound in the same organs and glands, *viz.* the anterior lobe of the pituitary, the adrenals, the liver, the intestine, *etc.* when the vitamin is adequately supplied *per os* or by injection into the blood stream.

XIV. THE CHEMICAL COMPOSITION OF TEETH.

I. THE ESTIMATION OF FLUORINE AND THE FLUORINE CONTENT OF NORMAL TEETH.

By JOAN HYLTON BOWES and MARGARET MARY MURRAY.

From the Department of Physiology, Bedford College, University of London.

(*Received November 24th, 1934.*)

This investigation is part of a general consideration of the composition of dental enamel. The main object is to determine the composition of teeth of good structure, so that later the question of the relationship between chemical constitution and hypoplasia may be considered. The term hypoplasia is used in the sense intended by Mellanby [1923; 1934], who established a correlation between surface texture and histological structure, and the hypoplasia therein exhibited, with susceptibility to caries.

It is fairly generally agreed that the calcium phosphate of teeth and bones is not present as tertiary calcium phosphate, but as a phosphate of the apatite type $3Ca_3(PO_4)_2.CaX.$, in which X can be F_2, Cl_2, $(OH)_2$ or CO_3. Gassmann [1910] suggested carbonato-apatite and Bassett [1927] hydroxyapatite as the bone compound. Robison and Soames's [1925] results on bone support the idea that the chief constituent is an apatite. In a general consideration of the results of various workers for the calcium and phosphorus contents of bones and teeth Robison [1932] came to the same conclusion.

Of recent years bones and teeth have been subjected to X-ray analysis by de Jong [1926], Taylor and Sheard [1929], Roseberry *et al.* [1931], Thewlis [1932], Klement and Tromel [1932] and Bredig [1933]; all have concluded that the chief mineral present is an apatite. The application of this method has so far not been able to settle the question of the particular form of apatite.

Fluoroapatite is geologically common, but other isomorphous forms exist and have been considered in relation to the substance in bone and teeth by Hendricks *et al.* [1932]. The occurrence of fluorine in teeth has been investigated by many workers, but there does not seem to be any generally accepted idea as to the quantity of this element present. The reason is probably the difficulty of estimation. Several textbooks give values of the order of 0·3 % fluorine. The fluorine content of fluoroapatite is theoretically 3·77 %. No recent determinations on teeth have given values of this order of magnitude, so obviously the inorganic substance of teeth is not all fluoroapatite.

Fluorine is not an essential element in the diet. Sharpless and McCollum [1933] proved that fluorine-free diets were better for teeth formation, in rats, than diets containing relatively small amounts, *e.g.* 0·005 %, of fluorine. The occurrence of fluorine in drinking waters, to the extent of more than about two parts per million, is now recognised as the cause of that condition known as "mottled teeth." Such teeth show either a dull opaque chalky appearance or characteristic unsightly brown stains on the enamel. A more detailed description is to be found in a paper by Ainsworth [1933]. Extensive investigations have been carried out in America by McKay, originating in the work of Black and McKay [1916] and reported in the numerous publications of McKay and his collaborators on the subject of mottled teeth. Independently since 1930 Smith *et al.* [1931] have published the results of investigations which have led to the association of fluorine in drinking water to the extent of more than 1·5 parts per million with the occurrence of mottled teeth. Churchill [1931] proved this connection by determination of the fluorine content of the waters.

The effects of feeding sodium or calcium fluoride to animals had been observed by several earlier investigators, notably Sonntag [1916]. McCollum *et al.* [1925] revived the interest in this subject and reported that the inclusion of sodium fluoride in the diet of rats caused marked changes in the growth and appearance of the incisor teeth.

The danger of feeding rock phosphate, which frequently contains fluoroapatite, has been well established by Velu [1931]. He found that natural fluorophosphates fed to rats caused marked diminution of food intake; the animals did not thrive and many died. This condition of chronic fluorosis he called fluoride cachexia. Bone changes resembling osteomalacia have been observed by Christiani and Gautier [1925] in animals living on vegetation in the neighbourhood of chemical works which liberate fluorine, or certain of its compounds, into the atmosphere.

In this country an investigation of the teeth of persons living in Maldon, Essex, by Ainsworth [1933] revealed that mottled teeth are endemic there. The water of Maldon was found at that time to contain 4·5 to 5·5 parts of fluorine per million.

But in spite of this interest in the effects of fluorine, few determinations of the fluorine content of teeth have been made within recent years, so that there have been no definite conclusions as to whether the fluorine affects the deposition of the normal constituents of teeth or whether it enters into the composition of mottled teeth.

As a preliminary to the investigation of this problem it was necessary to find a reliable method for the estimation of fluorine in small amounts of material and suitable for very small percentages of the element. It is with this problem that the present communication deals; it is hoped that later a series of determinations of the fluorine content of the teeth of animals on fluorine-containing diets and of mottled teeth will be possible.

The estimation of fluorine in dental material, with its large proportion of calcium phosphate, is a matter of some difficulty. The earlier workers usually employed volatilisation as hydrofluoric acid or as silicon tetrafluoride, in combination with the glass etching test. Gassmann [1910] using this method found no fluorine in bones or teeth, but Gautier and Clausmann [1913] found 0·02 to 0·056 % in bones and 0·062 % in teeth. Mayrhofer *et al.* [1932] used the silicon tetrafluoride procedure combined with indirect determination of the fluorine by colorimetric estimation of the silicon. This later step is unwise, particularly since the gas was caught in caustic soda in a glass vessel. In the determination of silicon only platinum or "bakelite" vessels should be used. Sharpless and McCollum [1933] used the silicon tetrafluoride method for bones; their determination is referred to later. A method described by Willard and Winter [1933], involving treatment with perchloric acid, in the presence of glass beads, thereby converting the fluorine into hydrofluorosilicic acid, followed by thorium nitrate titration of the fluorine with zirconium alizarinate as an indicator, seems to have much to commend it. Preliminary trials on a known calcium phosphate-sodium fluoride mixture were not satisfactory with regard to the volatilisation. It is to be noted that probably one gram of tooth material contains approximately 0·2 mg. fluorine, so that the determination would be close to the limit of accuracy of the method. About 30 rats' incisors are required to give 1 g. The success of the volatilisation methods seems to depend very much on the amount present, being less reliable for small quantities.

Other methods which have been used include that of Meyer and Schulz [1925; 1926]. This involves precipitation as a lanthanum fluoride-acetate complex. Trebitsch [1927] used this and found 0·29 to 0·59 % in tooth crowns. When we applied this method to a known fluorine-containing powder it proved quite unreliable; the results were too high, as we believe those of Trebitsch to be.

The next method tried was Mervin's [1909] pertitanate method. When fluorides are added to a solution of a pertitanate, made by addition of hydrogen peroxide to a solution of titanic sulphate in sulphuric acid, bleaching of the orange-yellow colour occurs. The extent of the bleaching is compared with that caused by a standard. Since this work has been in progress, Sharpless and McCollum [1933] have used a modification of the titanium method for the fluorine content of bones.

The pertitanate method is certainly more reliable than the lanthanum method, but it is not very sensitive and so is not ideal when small quantities of material only can be obtained. Estimations by this method were carried out in the following way. Approximately one gram of powdered enamel was fused with sodium carbonate in a platinum crucible. The melt was extracted with successive quantities of hot water, a considerable volume being used. The solution was filtered, concentrated and partially neutralised by the addition of $4N$ sulphuric acid in presence of an aqueous solution of phenolphthalein, care being taken to avoid excess of acid. Excess silver sulphate was then added to remove phosphates and the precipitate filtered off and washed. The excess of silver was removed by addition of sodium chloride, the solution filtered, the precipitate washed and the filtrate brought to a known volume by evaporation. Several 100 ml. graduated flasks were then taken and to each were added 10 ml. 65 % by volume sulphuric acid, 10 ml. of the titanic sulphate solution, made according to the directions of Warren *et al.* [1925], 3 ml. 10 volume hydrogen peroxide and then either a known volume of the unknown fluoride or a known volume of a comparable standard sodium fluoride solution. The solutions were allowed to stand and then were compared in a colorimeter. The values obtained for human enamel by this procedure varied from nothing to 0·04 %, the most usual value being 0·01 %. Ten estimations in all were made[1]. We then tested the sensitivity of this method and considered that the low results might be due to its lack of sensitivity. Sharpless and McCollum [1933] obtained less than 0·04 % fluorine in the bones of rats fed on a diet containing very little fluorine, *i.e.* 0·001 % of the ration.

The estimation of fluorine in sea-water and in the waters of districts where mottled teeth are endemic has of recent years been made by a method originally introduced by de Boer [1924] and latterly used and modified by Casares and Casares [1930].

The principle of the method is that solutions of zirconium salts, whether nitrate or oxychloride, and sodium alizarinsulphonate form a red lake, stable in acid solution. The coloured lake is slowly bleached by fluorine, the bleaching being proportional to the fluorine concentration, hence by colorimetric comparison with a standard fluoride solution, an estimation can be made.

Taylor and Thompson [1933] applied this method to sea-water and Elvove [1933] to drinking water. In our determinations we first used the Taylor and Thompson directions for making the lake, but later we employed the Elvove [1933] solutions.

---

[1] We are indebted to Miss M. O. Barrie for these titanium method determinations.

The estimation of fluorine in teeth by this method was complicated by the presence of other substances tending to cause precipitation of the lake. Taylor and Thompson, in their report on the estimation of fluorine in sea-water, state that chlorine and sulphate ions have bleaching actions, but that phosphate and calcium ions do not interfere. It was found however that the concentration of calcium and phosphate ions in our solutions of tooth material definitely caused precipitation of the lake. Samples of sea-water and London tap-water also showed precipitation after 18 hours. Various methods for removing interfering substances were tried. Firstly phosphate precipitation was effected with calcium chloride and ammonia. This procedure when checked on fluoroapatite gave a value of 4·733 % fluorine, which was known to be too high. When greater care was taken to remove ammonia the result was nearer the correct value but still there was a tendency to precipitation. We next tried precipitation of interfering substances by excess of zirconium nitrate, but though this removed the source of precipitation of the lake, excess zirconium salt prevented the bleaching action of fluorides.

Finally we used precipitation by silver nitrate and removal of excess silver by sodium chloride. In many of these preliminary tests, a known fused mixture of calcium phosphate and calcium fluoride was employed in place of enamel. We always determined the chlorine content of our solutions and adjusted the chlorine content of the standard fluorine solutions to be the same. Finally we determined the nitrate content by calculation and adjusted this by addition of sodium nitrate to the standards.

In all these methods, the resulting solution was brought to a known volume, and an aliquot part taken, and to it were added 2 ml. 6*N* HCl and 2 ml. of the zirconium lake solution used by Taylor and Thompson. The solution was then brought to the boiling-point and left for several hours. At the same time solutions containing different standard amounts of sodium fluoride and having the same chlorine and nitrate contents were treated similarly.

The values obtained for the fluorine of human enamel by these procedures were as follows:

Method	Fluorine %
Lanthanum method	Unreliable values
Titanium method	0·0 to 0·04
Zirconium-alizarin method with calcium chloride precipitation	0·093
Zirconium-alizarin method with calcium chloride precipitation and removal of ammonia	0·06
Zirconium-alizarin method, silver precipitation, chlorine content adjusted	0·07
Zirconium-alizarin method adjusted for chlorine and nitrate concentrations	0·02

We realised throughout the determinations that the tooth solutions might contain small traces of substances capable of affecting the colour of the lake and we therefore considered it necessary to make certain that we were estimating fluorine by taking a sample of enamel and treating a portion of it with sulphuric acid to drive off the fluorine as hydrofluoric acid.

This experiment was a crucial one and will be described in detail. Two portions of ashed human enamel, 1·1684 g. each, were taken and fused with 6 g. Na_2CO_3. The melts were extracted very thoroughly with boiling water. One sample B was evaporated to dryness, H_2SO_4 added and the whole heated cautiously to drive off the HF. The residue was extracted with water and solid Na_2CO_3 added to neutralise; the resulting solution was the "blank." This solution and the solution of the other melt, solution A or the "unknown," were each brought to a volume of about 100 ml. and both were treated in the following way. 60 ml. of a strong solution of $AgNO_3$ were added, the precipitates filtered off in the dark and washed. The excess silver was removed by addition of a solution of NaCl and the precipitates filtered off and washed. The resulting filtrates were brought to a known volume and the chlorine concentration of each determined by titration with standard $AgNO_3$, so that later, the chlorine contents of the solutions could be equalised and that of the standard fluorine made the same.

Sulphate ions interfere with the determination; sulphate was therefore removed from B by the addition of the calculated quantity of $Ba(NO_3)_2$, after determination of sulphate. After filtration and concentration, the solution was tested for sulphate and barium; a very small amount of sulphate was present. A trace of Na_2SO_4 was added to A and to the fluoride standards to equalise the sulphate throughout.

The two solutions A and B were then adjusted to the same chlorine content, so that they finally contained equal amounts of their different constituents except fluorine. A solution C was made having the same concentration of NaCl, $NaNO_3$ and Na_2SO_4 as A and B; this served for the making of the standard fluoride solutions. 25 ml. portions of solutions A and B were taken and to them were added HCl and the zirconium-alizarin lake; the solutions were brought to the boil. At the same time, portions of solution C to which were added varying amounts of NaF standard solution were similarly treated. All the volumes were made equal and the solutions matched in Nessler tubes. We found it better to find an exact match for the unknown solutions rather than to compare them in a colorimeter because there is a change of tint as well as intensity.

The unknown solution was definitely bleached as compared with the acid-treated blank. The amount of fluorine in the unknown was determined by finding a fluorine standard which compared with it. It was found that 2 ml. of the standard sodium fluoride (1 ml. = 0·01 mg.) gave slightly less bleaching, while 3 ml. of the standard gave definitely more bleaching.

$$\begin{aligned} &\text{Hence 25 ml. A} &&\equiv 0{\cdot}025 \text{ mg. F} \\ &\therefore \text{250 ml. A} &&\equiv 0{\cdot}25 \quad \text{,,} \\ &\%\ \text{Fluorine} &&\equiv \frac{100 \times 0{\cdot}25}{1168{\cdot}4}\% \\ & &&\equiv 0{\cdot}0214\ \%. \end{aligned}$$

Another comparison was made by taking the acid blank B and adding fluoride to it. When 2 ml. were added there was too little bleaching and when 3 ml. were added too much bleaching, as compared with the unknown. Hence this procedure gave the same answer as before. (It is of interest to note that this fluorine value indicated that the teeth contained 0·51 % fluoroapatite.)

The process is a lengthy one because of the precautions necessary to eliminate precipitation effects and alteration of dye colour by substances other than fluorine.

Recently we have carried out determinations by the titanium method and the zirconium-alizarin method on the same sample of rats' teeth, the results were:

Titanium method	0·034 %,
Zirconium method	0·030 %.

That the latter is more sensitive is shown by the fact that for this method only 20 ml. of the tooth solution were used and matched against a standard solution containing 0·06 mg. fluorine per 100 ml., whereas for the titanium method, 75 ml. solution were taken and matched against a standard containing 2 mg. per 100 ml.

We are at present applying the zirconium method to the estimation of the fluorine content of teeth of rats under various experimental conditions and to mottled teeth.

It has become clear during this investigation that normal teeth, that is non-mottled, may vary in their fluorine content within certain limits.

SUMMARY AND CONCLUSIONS.

1. Methods used in recent years for the estimation of small quantities of fluorine have been reviewed.
2. The zirconium-alizarin method has been applied to solutions of tooth material.
3. The quantity of fluorine in human enamel of the London area was 0·02 %.
4. The teeth of rats fed on diets, not designed to be fluorine-free, contained 0·02 % to 0·03 % fluorine.

This work has been carried out while one of the authors (J. H. B.) was in receipt of a grant from the Medical Research Council. We wish to record our thanks for the grant and for permission to publish the observations.

XV. THE REDUCTION OF GLUTATHIONE BY THE WARBURG-CHRISTIAN SYSTEM.

By the late NORMAN URQUHART MELDRUM[1]
and HUGH LEWIS AUBREY TARR[2].

From the Biochemical Laboratory, Cambridge.

(*Received November 3rd, 1934.*)

Hopkins [1921] suggested that the physiological significance of glutathione might lie in its ability to function as transporter of hydrogen from oxidisable molecules in the cell to molecular oxygen. His observation that certain animal tissues were able to reduce the oxidised form of the peptide, and that the reduced form was autoxidisable, lent support to this view. Furthermore he recognised that glutathione apparently always occurs in the reduced form in animal tissues.

Hopkins and Dixon [1922] discovered that "succinoxidase" was quite unable to reduce glutathione. Elliott [1928] confirmed this observation and showed moreover that the "xanthine oxidase" system would not reduce the oxidised peptide. Hopkins and Elliott [1931] studied the behaviour of glutathione in the freshly excised, chopped livers of various animals and found that livers from well-fed animals reduced glutathione more strongly than did those from starved animals. That certain definite "dehydrogenase" systems were involved in the reduction of glutathione in this tissue was strongly suggested by the fact that much of the reducing power was destroyed by heating liver for an hour at 52°. Their results proved definitely that glutathione could function as oxygen carrier in living cells. The exact nature of the system or systems which reduced glutathione in this tissue was not ascertained.

Shortly afterwards Mann [1932] discovered that the glucose dehydrogenase of liver reduced glutathione under anaerobic conditions, and almost simultaneously Meldrum [1932] observed that intact mammalian erythrocytes possessed some system capable of reducing the oxidised peptide in the presence of glucose. Apparently no other systems in living cells capable of reducing glutathione have been discovered, though it is known that certain bacteria reduce the peptide by virtue of their natural metabolites [Tarr, 1933]. The present work has shown that the isolated dehydrogenase system of Warburg and Christian strongly reduces glutathione.

Experimental.

The barium hexosemonophosphate "natural" ester used in these experiments was obtained from the British Drug Houses. The barium hexosemonophosphate "synthetic" ester was prepared by the method of Levene and Raymond [1931], and the corresponding barium phosphohexonic acid by oxidation of the synthetic ester with bromine [Robison and King, 1931]. Barium diphosphoglycerate was made by the method of Jost [1927] and barium fructosediphosphate was kindly given to us by Prof. Keilin. All these compounds gave analyses for barium and phosphorus in good agreement with theory. The specific rotations and "aldose" and "fructose" titres corresponded closely with the values recorded in the literature except in the case of the "synthetic" ester which had a low specific rotation and gave a definite "Selivanoff test" for fructose [Macleod and Robison, 1929]. However, since the "synthetic" ester proved almost as active as the "natural" ester, it was employed in many of the following experiments.

Crude co-enzyme powder was prepared from horse erythrocytes, and from this the solution was made [Warburg and Christian, 1931]. In the Tables "mg. of co-enzyme" signifies that an amount of solution corresponding to the given weight of co-enzyme was used. The enzyme of the reducing system was prepared from rat blood [Warburg and Christian, 1931] and also from top brewery yeast and from baker's yeast [Warburg and Christian, 1932]. Experience showed that crude co-enzyme prepared as above frequently, though not always, contained fairly large amounts of a substance which, on reduction, gave a strong nitroprusside test (probably glutathione), and for this reason fairly high "iodine titres" were frequently obtained in control experiments[1].

Oxidised glutathione was prepared according to Pirie [1930; 1931], solutions being adjusted to p_H 7·4 with N NaOH before use. The amount of reduced glutathione present in experimental solutions was estimated by titrating with $N/100$ iodine after sufficient potassium iodide (25 %) had been added to bring the final concentration of this salt to 1 %. Starch was employed as indicator.

The reduction of glutathione by Warburg and Christian's reducing system in the presence of various substrates.

1. *Synthetic hexosemonophosphate, fructosediphosphate and glucose as substrates.* The substances noted in Table I were added to 75 ml. Thunberg tubes, the final volume of fluid in each tube being adjusted to 20 ml. with distilled water. 0·05 ml. of caprylic alcohol was added to each tube before evacuation at a water-pump, this substance having the dual virtue of functioning as a germicide and foam preventer. The evacuated tubes were incubated for 6 hours in a water-thermostat at 37°, and then a nitroprusside test (1 ml. used) and iodine titration were made on the contents in each instance. In Table II the results of this experiment are recorded. It is apparent that reduction of glutathione is not effected by the enzyme or co-enzyme alone in the absence of hexosemonophosphate, or by the complete system when heated. Rapid and

* Calculated from the iodine titre after subtracting the control.

practically quantitative reduction of the glutathione occurred in the presence of the complete system and hexosemonophosphate. Fructosediphosphate acted only as a very feeble donator of hydrogen in this system and glucose was not utilised at all. Unfortunately a pure sample of Neuberg's fructosemonophosphate was not obtained; crude samples obtained by the hydrolysis of fructosediphosphate (candiolin) were found to be only slightly more active than fructosediphosphate itself.

2. *Natural hexosemonophosphate, synthetic hexosemonophosphate, phosphohexonic acid and diphosphoglyceric acid as substrates.* The relative values of the above compounds as donators of hydrogen in the reducing system under survey were next determined. The technique was generally identical with that used in the previous experiment. Each Thunberg tube contained 2 ml. of $M/5$ phosphate buffer p_H 7·4, 50 mg. of co-enzyme, 1 ml. of enzyme (from rat blood), 50 mg. of oxidised glutathione and, with the exception of the controls, 10 mg. of the substrate under investigation. All substances were tested in duplicate, and titrations were made at the end of 12 and 24 hours at 37°. The results, which are given in Table III, show that, while both natural and synthetic hexosemonophosphoric acids are readily activated, the corresponding phosphohexonic acid is less readily attacked, and diphosphoglyceric acid is not activated at all. The reduction was almost always complete after 12 hours: whether this was due to a complete utilisation of all available substrate, or to exhaustion of enzyme was not determined.

Table III.

	Time in hours

* The reduced glutathione was calculated from the iodine titre after the controls were subtracted.

Glutathione as oxygen carrier in the Warburg-Christian reducing system.

The oxidation of hexosemonophosphoric acid by the Warburg-Christian reducing system with various concentrations of glutathione as oxygen carrier was studied employing Barcroft differential manometers. In all manometric experiments the temperature was 37° and the gas space was filled with air. Four manometers were used, and the amounts of reagents employed in each are recorded in Table IV. The final volume of liquid in each manometer cup was

Table IV.

made up to 5 ml. with distilled water and 0·05 ml. of caprylic alcohol added as germicide. In the centre tubes filter-papers moistened with 6 % KOH were employed to absorb CO_2 [Dixon and Elliott, 1930]. The manometers were equilibrated for 10 minutes before the taps were closed, and readings were then taken over 10 hours at this temperature. The results are given in Fig. 1. It is evident from this diagram that the addition of glutathione caused a considerable increase in oxygen uptake, the increase in oxidation velocity being approximately proportional to the amount of glutathione added. In no case was the oxygen uptake very rapid, and in no case comparable with that obtained by Warburg and Christian [1931; 1932; 1933] with the same reducing system when either methylene blue or yellow pigment was employed as carrier of oxygen. Perhaps a greater activity of the enzyme preparations employed by these workers accounted in part for this increased velocity. It is possible that the presence of a trace of cysteine would have accelerated the uptake in the case of glutathione experiments [Meldrum and Dixon, 1930]. At the conclusion of the experiment the fluid in each right-hand manometer cup was titrated with $N/100$ iodine solution. The results given in Table V show that the reducing system was powerful enough to maintain practically the whole of the glutathione present in the reduced form even under the strongly aerobic conditions of the experiment. Perhaps the

presence of reducing systems such as this in yeast may account for the results obtained during some studies of the glutathione content of yeast under various conditions [Meldrum, 1930], in which it was found that practically the whole of the glutathione present remained in the reduced form even when aerated and in the presence of cyanide or narcotics.

Cysteine as oxygen carrier in the Warburg-Christian reducing system.

This experiment was run upon similar lines to the previous one, the manometric set up being identical with the exception that cysteine (added as the neutralised hydrochloride) was used in place of glutathione. In this experiment ordinary cysteine, and not cysteine freed from traces of iron, was used. The course of oxidation of the hexosemonophosphate at 37° was followed and the results are plotted graphically (Fig. 2). During the first hour and a half of the experiment in the case of the manometers with added cysteine the oxygen

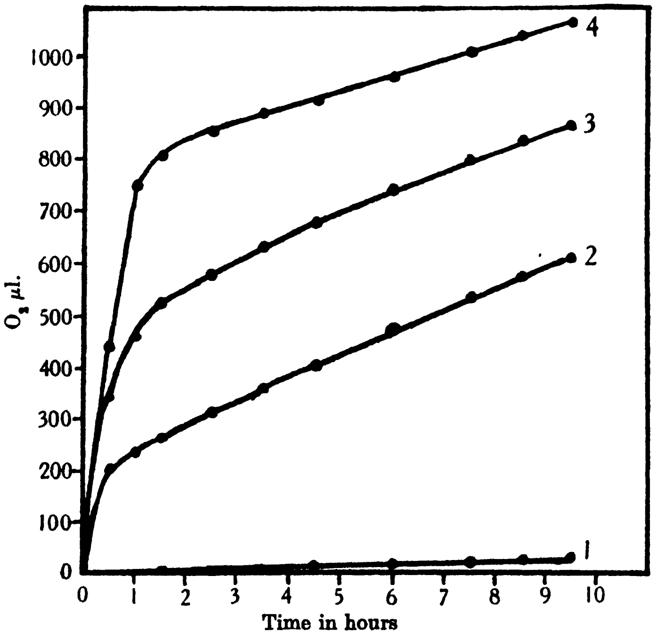

Fig. 2. The effect of cysteine on the oxidation of hexosemonophosphate by the Warburg-Christian reducing system.

1, Control (no added cysteine). 2, 10 mg. of cysteine added. 3, 20 mg. of cysteine added. 4, 40 mg. of cysteine added.

uptake was extremely rapid, this undoubtedly being primarily due to the oxidation of cysteine to cystine. Observation showed that cystine precipitated in flasks to which cysteine had been added. Subsequently the velocity of oxidation became fairly steady and was practically identical in the three experiments in which cysteine was added. However the velocity of oxidation in all three cysteine experiments was considerably greater than in the control without cysteine. At the conclusion of the experiment the amount of —SH present was determined as in the previous experiment, the results being recorded in Table VI. It is

Table VI.

Manometer No.	Nitroprusside test	ml. of $N/100$ iodine required
I	+ + +	1·5
II	–	2·5
III	–	2·6
IV	–	2·7

evident that practically all the cysteine had been oxidised, and had remained in this form, and it appears therefore that the factor limiting the velocity of oxidation in this instance was the velocity of reduction of the cystine, and not, as in the case of glutathione, the velocity of re-oxidation of the reduced form. The fact that no nitroprusside test was obtained in the cystine-containing manometers suggests that the cystine causes the oxidation of the small amount of glutathione present in the co-ferment.

The velocity of the anaerobic reduction of glutathione.

75 ml. Thunberg tubes were employed as usual. Eight tubes each containing 1 ml. enzyme solution, 50 mg. of co-enzyme, 10 mg. of barium hexosemonophosphate, 1 ml. of $M/5$ phosphate buffer p_H 7·4 and 30 mg. of oxidised glutathione were prepared, and two identical tubes without glutathione as controls. The final volume of liquid in each tube was made up to 6 ml. with distilled water, and each was evacuated, incubated and the amount of —SH present determined in the usual manner, estimations being made at intervals in order to obtain an

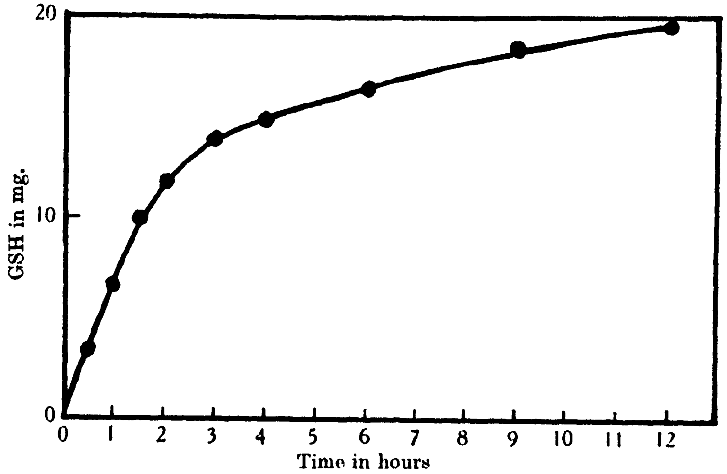

Fig. 3. The velocity of the anaerobic reduction of glutathione by the Warburg-Christian system.

idea of the velocity of reduction. At the end of 12 hours controls without added glutathione gave an average iodine titre of 1·7 ml. of $N/100$ solution, this being due to the —SH present in the co-ferment. In Fig. 3 the absolute —SH production (calculated as glutathione) in the series of eight tubes over a 12-hour period is shown. The reduction was rapid at first and then fell off, and at the end of the time only about 60 % of the glutathione was reduced. It was not determined whether this was due to exhaustion of enzyme or to exhaustion of substrate.

The reduction of glutathione employing yeast enzyme.

In this case the enzyme of the reducing system prepared both from brewer's top yeast and from baker's yeast was employed in place of enzyme made from rat's blood. The method of studying the reduction of glutathione was identical with that described in previous experiments, the final volume of fluid in each tube being 10 ml. The set up of the experiment is shown in Table VII. The results given in Table VIII show that an active enzyme is obtainable from top yeast and that it is inactive with glucose and fructose in place of hexosemonophosphoric acid as substrate.

Table VII.

	Tube No.					
Reagent	1	2	3	4	5	6
Oxidised glutathione (mg.)	20	20	20	20	20	20
Enzyme (from brewer's top yeast) (ml.)	2	0	2	2	2	2
Co-enzyme (mg.)	50	50	0	50	50	50
Barium hexosemonophosphate synthetic (mg.)	40	40	40	0	0	0
Glucose (mg.)	0	0	0	0	40	0
Fructose	0	0	0	0	0	40
$M/5$ phosphate buffer, p_H 7·4 (ml.)	1	1	1	1	1	1

Table VIII.

Tube No.	Nitroprusside test	ml. of $N/100$ iodine required	Estimated GSH in mg.

2	–	0·1	0
3	–	0·1	0
4	–	0·1	0
5	–	0·1	0
6	–	0·1	0

An exactly similar experiment was run using enzyme from baker's yeast, only the experiments with fructose and glucose were omitted. Practically identical results were obtained, the iodine titre in the presence of hexosemonophosphate being 5·3 ml. of $N/100$ solution, which corresponds to 16 mg. of reduced glutathione.

DISCUSSION.

The results of these experiments are of some interest in that they suggest that the hexosemonophosphate system may account for a considerable fraction of the reducing power of cells toward glutathione. Unpublished observations by one of us (H. T.) have shown that Harrison's glucose dehydrogenase preparation [Harrison, 1933] is able to reduce glutathione in the presence of hexosemonophosphoric acid as substrate, and this suggests that a similar system exists in liver. It is possible that such a system was responsible for some of the reduction of glutathione by liver noted by Hopkins and Elliott [1931]. It remains to be found whether or not muscle and other mammalian tissues possess this system. Up to the present time it seems as if only those enzymes which are intimately connected with the oxidation of carbohydrates in the cell are involved in the reduction of glutathione. Whether this fact is of any significance remains to be determined.

SUMMARY.

1. Glutathione is reduced both aerobically and anaerobically by the Warburg-Christian enzyme-co-enzyme system in the presence of hexosemonophosphoric acid.

2. Phosphohexonic acid and fructosediphosphoric acid also function as donators of hydrogen in this system, the former being much less readily utilised than hexosemonophosphoric acid, and the latter being only feebly activated. Diphosphoglyceric acid, glucose and fructose are not utilised.

3. Glutathione functions as oxygen carrier when hexosemonophosphoric acid is oxidised by the Warburg-Christian system in the presence of molecular oxygen, the velocity of oxidation being roughly proportional to the amount of glutathione added. In this case the limiting factor in the oxidation velocity appears to be the rate of re-oxidation of the reduced glutathione.

4. Cystine will also function as oxygen carrier in this system, but in this case the oxidation velocity is practically independent of the cystine concentration, because the limiting factor is the rate of reduction of the cystine.

5. The oxygen uptake in the presence of glutathione is in no instance as great as that obtained by Warburg and Christian when either methylene blue or yellow pigment was employed as oxygen carrier.

6. Enzyme obtained from brewer's top yeast or from baker's yeast can be substituted for enzyme obtained from rat's blood.

The success of this work is largely due to Prof. Keilin, who originally suggested the problem, and to Sir F. G. Hopkins whose interest and suggestions were most helpful. The junior author is indebted to Dr Malcom Dixon for his kindness in reading and criticising the manuscript.

XVI. THE BIOLOGICAL OXIDATION OF CARBOHYDRATES.

IV. THE PHOSPHORUS REQUIREMENTS OF PERCOLATING FILTERS.

By SAMUEL HARRY JENKINS.

From the Fermentation Department, Rothamsted Experimental Station, Harpenden.

(*Received November 3rd, 1934.*)

The purification of sewage and certain trade effluents can be effected in percolating filters by allowing the polluting liquids to trickle through a well-aerated bed of material such as clinker, gravel *etc.*, suitably graded as regards size of particles. The first stage in the purification may be the physical retention of some of the polluting matter within the filter, but ultimately purification depends upon the breakdown and oxidation by living agencies of dissolved or precipitated organic matter. Although the biological nature of the process has long been recognised, insufficient attention has been given to a study of the conditions necessary to maintain the organisms responsible for purification in a state of maximum activity. A study of this kind should include experiments on the effect of changes in concentration of compounds of nitrogen, phosphorus and potassium on the rate of oxidation of the organic matter. Sewages of domestic origin are invariably rich in nitrogenous compounds, while they also contain fats, carbohydrates and salts of potassium and phosphorus. It is improbable, therefore, that the organisms responsible for the oxidation of domestic sewage liquors will be without any essential food material. Some waste waters containing organic matter, such as those from beet-sugar factories, may, however, have insufficient quantities of certain materials to ensure optimum rate of purification in percolating filters.

In a study of the process of biological oxidation of effluents from beet-sugar factories, Richards and Cutler [1933] have shown that the rate of oxidation of the carbohydrates in solution is influenced by the amount of available nitrogen. In view of the lack of data regarding the relationship between the supply of compounds of phosphorus and the rate of oxidation of organic matter, particularly carbohydrates, in percolating filters an investigation has been made with the objects of examining (1) the effect of phosphate on the rate and extent of oxidation of sucrose; (2) the relationship between the quantity of phosphate and the removal of nitrogen from solution; (3) the availability to micro-organisms of organic compounds of phosphorus; (4) the influence of phosphate supply on the development of an active biological film on the filter media. The results are described in the present paper. Similar work published by Barritt [1931] while these experiments were in progress will be referred to later.

EXPERIMENTAL.

Filters constructed from glass tubes containing glass medium made from broken bottles were used for the first set of tests and the results are described in Exp. 1. After the filters had been supplied for 28 days with solution containing 0·1 % sucrose, pools of liquid formed on the surface of one filter owing to a heavy growth of film in the upper portion. Choking was avoided in a second series of experiments by using glass tubes as medium instead of broken glass. Details of construction of the filters have already been described [Jenkins, 1933, 1]. The results of this second set of tests are described as Exp. 2. In Exp. 3 the results are given of a large-scale trial at a beet-sugar factory. The main purpose of the experiment was to test the effect of inoculating selected organisms on to a filter. The liquids filtered were effluents from the beet-pulp presses of the factory after treatment in a sedimentation tank to remove suspended solid matter. During the period of sedimentation some fermentation occurred and the liquids became acid.

Method of analysis. Sugars, nitrogen as ammonia, nitrite and nitrate were determined by methods described previously [Jenkins, 1933, 2]. Phosphorus in the inorganic and organic forms was determined colorimetrically by the Denigès method as modified by Parker and Fudge [1927]. In the determination of phosphorus in organic combination, however, 1 ml. of 10 % calcium acetate solution was used instead of $Mg(NO_3)_2$ for igniting with the residue left after evaporation to dryness.

Experiment 1.

Each filter consisted of four glass cylinders with perforated metal plates at the lower ends. The sections were joined together by rubber bands and could easily be disconnected when samples of the effluent from any of the upper sections were required. The filtering medium was broken glass graded $\frac{1}{16}$–$\frac{1}{4}$ in. Solutions of nutrient substances in the concentrations given below were filtered at a rate of 2 litres per day (100 gallons per cubic yard of filtering medium per day, abbreviated g.y.d.). These solutions each contained 5 parts N per 100,000 and the concentrations of P_2O_5 were 0, 0·3 and 3·0 parts per 100,000 to filters A_1, B_1 and C_1, respectively. From the 23rd day until the end of the experiment on the 150th day 0·05 g. K_2SO_4 per litre was added to the solution to ensure an excess of potassium. Ammonium bicarbonate replaced ammonium chloride as the source of nitrogen from the 68th day until the end of the experiment for a reason given later, but the amount of N added remained unchanged.

Solutions filtered from beginning of experiment until the 22nd day.

Filter	A_1 g.	B_1 g.	C_1 g.
Sucrose	1·000	1·000	1·000
NH_4Cl	0·191	0·191	0·191
$MgSO_4, 7H_2O$	0·050	0·050	0·050
$CaCl_2, 6H_2O$	0·050	0·050	0·050
$NaCl$	0·005	0·005	0·005
K_2HPO_4	Nil	0·00736	0·0736
Fe_2Cl_6	Trace	Trace	Trace
Distilled water to	1 litre	1 litre	1 litre

The results of the experiment, showing the amounts of sucrose, P_2O_5 and N left in the effluents are given in Table I.

Oxidation of sugar. A small proportion of the sugar in the solution fed to filter A_1 appeared to be oxidised during passage through the filter, but the amount did not exceed 18 % of the sugar in the nutrient solution. The filtering medium was apparently devoid of organic film but microbiological examinations made by Miss Dixon proved that a few protozoa were present. It is concluded

Table I. *Effect of phosphate on biological oxidation of sucrose and removal of nitrogen.*

Exp. 1. Glass filters and glass medium ($\frac{1}{16}$ in. to $\frac{1}{4}$ in. graded glass).

Filter A_1 received sucrose equivalent to 105·3 parts glucose per 100,000 of solution, and no P_2O_5.
Filter B_1 received the same amount of sucrose as A_1, and 0·3 part P_2O_5 per 100,000.
Filter C_1 received the same amount of sucrose as A_1, and 3·0 parts P_2O_5 per 100,000.

Parts per 100,000.

Day of exp.	P_2O_5 in effluent from filter		Sucrose in effluent from filter calculated as glucose. Amount supplied, 105·3 parts			Nitrogen in effluent from filter. N supplied, 5 parts		
	B_1 (0·3 supplied)	C_1 (3·0 supplied)	A_1	B_1	C_1	A_1	B_1	C_1
14	0·0	1·25	86·0	3·6	0·4	4·800	3·530	1·430
19	0·012	1·50	95·9	19·6	1·9	4·809	3·907	3·170
27	0·0	2·50	—	0·9	1·1	4·539	3·998	4·556
36	0·002	1·50	100·4	2·6	0·7	4·916	3·041	1·176
43	0·0	1·39	—	2·3	0·3	4·460	3·442	2·675

therefore that in filter A_1 the absence of phosphate almost inhibited the growth of film so that not more than 18 % of a 0·1 % solution of sugar could be oxidised.

The addition of 0·3 part P_2O_5 per 100,000 as potassium phosphate to filter B_1 had a marked effect on the amount of sugar oxidised. When the first analyses were made after the filters had been in operation for 13 days 96·6 % of the sugar was being oxidised and over the first 43 days of the experiment the average amount decomposed was 94·5 %. Although the percentage oxidation of sugar was high the amount of film in B_1 was not considerable and consisted of a thin slime covering the glass medium in the uppermost sections, with much less in the three lower sections. The greatest contribution towards the total amount of sugar oxidised was made by section 1, which alone accounted for 89·7 % out of a total average oxidation of 94·5 %.

Filter C_1 received 3 parts P_2O_5 per 100,000 as K_2HPO_4 and gave a daily average oxidation of sugar of 99·2 % over the first 43 days. It should be pointed out that differences of a few per cent. are of greater significance when the purification figure approaches 100 % than at, say, 50. The amount of work, measured by extra filter space, required to increase a percentage purification from 50 to 60 is much less than that required to produce the same increment from 90 to 100. Thus section 1 of C_1 oxidised 98 % of the total sugar but a small amount of sugar was still present in the final effluent.

In filter C_1 the growth of film covered the surface of the medium and by the end of the first month the solution dropping on to the filter did not pass through immediately but gathered in pools on the surface and drained through the filter at a slower rate than was desired. This condition of ponding led to the initiation of the second series of experiments, the results of which are described later.

Removal of phosphorus and nitrogen. When no phosphate was supplied the amount of sugar removed from solution was, as previously stated, small and the amount of nitrogen removed was also small. Out of a total of 5 parts N supplied as NH_4Cl an average of only 0·3 part was taken up over a period of 43 days (Table I). An addition of 0·3 part P_2O_5 to B_1 increased the average removal of N over the 43 days to 1·416 parts. The quantity of P_2O_5 added in this case apparently did not provide enough phosphorus to cause all the dissolved sugar to be oxidised since some sugar remained after all the phosphorus had been removed from solution. Not more than a trace of phosphorus was ever found in the final effluent from B_1. The figures obtained with filter C_1, however, showed that 3 parts P_2O_5 per 100,000 provided more than enough phosphorus. Practically all the sugar supplied was oxidised while only 1·63 parts of the P_2O_5 were removed. The fall in concentration of nitrogen in C_1 was 2·4 parts from an initial supply of 5 parts N.

Although it seemed unlikely that intermediate compounds such as hexosephosphate would be present in the effluents, as these substances do not ordinarily pass out of the living cell into the substrate, tests were made for the presence of soluble organic compounds of phosphorus in the effluents from the filters. The effluents were analysed for inorganic and organic forms of phosphorus as soon as sufficiently large volumes had been collected. In consequence the solutions were on an average 2 hours old at the time of analysis. The p_H values of the effluents of filters B_1 and C_1 were about 3·0. Under these conditions soluble organic compounds of phosphorus were invariably absent, although it is almost certain that at times organic phosphorus would be contained in the small amounts of film in suspension occasionally washed out of the filters. The effluents were settled for a few minutes so as to exclude visible suspended matter from the samples used for the determination of phosphorus.

In order to determine the amount of organic phosphorus which could be recovered in a typical hexosephosphate by the Parker and Fudge modification [1927] of the Denigès method, an examination was made of a sample of barium hexosephosphate, kindly supplied by Prof. A. Harden. The preparation contained 9·5 % moisture and the phosphorus content of the dry substance was approximately: total P_2O_5, 22·7 %; organic P_2O_5, 20·6 %; inorganic P_2O_5, 2·1 %. Solutions of 10 mg. of the barium compound per litre were made up so that there were present: total P_2O_5, 2·05 parts per million: organic, 1·87 parts; inorganic, 0·18 part. The corresponding figures as determined colorimetrically by the modified Denigès method were 2·1, 1·9, and 0·2 respectively, showing that it was reliable for the determination of the organic phosphorus in hexosephosphates. The p_H value of the distilled water in which the solutions were made up varied between 5·5 and 6·0. After storage for several hours it was observed that the amount of inorganic phosphorus in the hexosephosphate solutions had increased. Thus on one occasion 0·86 part inorganic P_2O_5 per million was found after the solution had stood for 8 hours, while on another occasion all the hexosephosphate had been completely hydrolysed after standing 24 hours at room temperature. It seems that very dilute aqueous solutions of hexosephosphate undergo hydrolysis on storage: the solutions were made up in distilled water but no precautions were taken to ensure that they were sterile. An alternative colorimetric method described by Zinzadzé [1932] was tried, since the colour standards are more permanent than in the Denigès method, but the hexosephosphate appeared to be hydrolysed to inorganic phosphorus during analysis, owing to the greater concentration of mineral acid used by Zinzadzé.

It has already been mentioned that the p_H values of the final effluents from filters B_1 and C_1 were about 3·0. When the source of nitrogen added was changed on the 68th day from ammonium chloride to ammonium bicarbonate, the p_H values of the solutions were either unchanged or increased on filtration through B_1 and C_1. The p_H values of the nutrient solutions supplied to the filters were 5·5 for B_1 and about 6·0 for C_1. Barritt [1931] filtered 0·2 % solutions of sucrose *plus* ammonium sulphate through sectional filters and found that the p_H of the liquid changed from an initial value of 7·0 to 5·5 in the second upper section and to 7·1 in the sixth and final section; the reduction and subsequent increase in p_H were attributed to the production and oxidation of organic acids. The following considerations indicate that the observed differences in the p_H values of the solutions supplied to the filter and of the final effluents in Exp. 1 (Table II) were due mainly to the removal of nitrogen from ammonium chloride and the liberation of an equivalent quantity of free HCl. This was not neutralised or absorbed by the glass medium and therefore passed out with the effluent. For example, on the 19th day of the experiment the amounts of nitrogen expressed in parts per 100,000 removed by filters A_1, B_1 and C_1 were 0·19, 1·09 and 1·83 respectively. Assuming that equivalent amounts of free HCl were liberated, the strength of acid in the effluents would be 0·137, 0·781 and 1·308 $N/1000$ for A_1, B_1 and C_1 respectively. Sufficient acid would thus be produced to cause the drop in p_H value from 5·6 in the nutrient solution to 5·0 in the final effluent of A_1, from 5·4 to 3·2 in B_1 and from 6·0 to 2·8 in C_1. If chlorine ions, equivalent to the nitrogen assimilated, were taken up by the filter this argument would be untenable. Determinations of Cl were made therefore with silver nitrate and the following results were obtained:

Table II. *Effect of source of nitrogen on formation of acid.*

Filters fed with sucrose solution and N as NH_4Cl (made up in distilled water) from start of experiment until the 68th day: after this they received N as NH_4HCO_3.

A_1 received no P_2O_5.
B_1 received 0·3 part P_2O_5 per 100,000.
C_1 received 3·0 parts P_2O_5 per 100,000.
N removed expressed as parts per 100,000.

Cl in nutrient solutions and effluents from filters.

Parts per 100,000.

Filter	A_1	B_1	C_1
Cl in nutrient solution	14·29	14·29	14·29
„ effluent of section 1	14·26	14·26	14·87
„ „ 2	14·26	14·57	14·57
„ „ 3	14·27	14·72	14·72
„ „ 4	15·17	15·02	14·26

These results show that there was no uptake of Cl by the filters commensurate with the removal of nitrogen. If the decreases in p_H recorded with filters B_1 and C_1 were caused entirely by organic acids ionised to the same degree as acetic acid, then the concentration of acid required would be greater than 0·1 %. As the original amount of sugar was only 0·1 % a larger quantity of acetic acid could not be present. Moreover when determinations of the relative amounts of organic matter in the nutrient solutions and in the effluents were made by a test in which both sugar and organic acids are oxidised, *viz.* the biochemical oxygen demand, known as the "Dissolved oxygen absorbed test" in the Ministry of Health Methods [1929], results as follows were obtained:

Biochemical oxygen demand (B.O.D.) in 5 and 20 days.

Average results of five analyses made at different times on the liquids filtered and the effluents from the sections.

Parts per 100,000.

Filter	Crude liquor filtered		Effluent of section 1		Effluent of section 2		Effluent of section 3		Effluent of section 4	
	5 days	20 days	5 days	20 days	5 days	20 days	5 days	20 days	5 days	20 days
A_1	69·2	103·6	71·1	93·6	63·4	78·7	61·1	99·4	56·3	95·3
B_1	64·1	105·3	46·2	73·2	39·1	55·0	45·1	69·2	33·1	55·4
C_1	69·6	96·2	26·4	41·9	25·4	45·1	15·4	28·4	8·6	18·3

A 0·1 % solution of sugar, acetic or lactic acid has a maximum B.O.D. figure of about 112, which is approached in 20 days. Even if the whole of the B.O.D. were due to one of these organic acids there would still be insufficient acid to account for the observed fall in p_H value during filtration of the sugar solutions. This evidence indicates that the differences in p_H values of the original solution and filter effluents are caused by mineral acid set free from the ammonium salt, a conclusion not necessarily conflicting with that of Barritt, if the differences between the two experimental conditions are considered. The 0·2 % sugar which Barritt used may have given a growth of film in which acid production proceeded more quickly than oxidation of sugar and acid.

Experiment 2.

This experiment was undertaken because (*a*) two of the filters used in Exp. 1 showed signs of choking before the completion of the work, (*b*) the development of highly acid effluents consequent on the use of ammonium chloride as a source of nitrogen may have interfered with the development of organic film and nitrification processes. To provide a larger air space in the glass filters used for Exp. 2 the broken glass medium was replaced by tubes, 1 cm. diameter and 1·5 cm. long. The sectional filters employed were A_2, B_2 and C_2 and they received solutions of the same composition as were supplied to A_1, B_1 and C_1 respectively in Exp. 1, except that (1) nitrogen was supplied as ammonium bicarbonate, (2) the nutrient solution filtered in A_2 contained 0·05 g. K_2SO_4 per litre. A rate of flow of 2 litres per day, equivalent to 100 g.y.d., was maintained and the experiment was continued for 73 days.

Development of film. At the end of the experimental period of 73 days there was no film visible on any of the glass tubes in filter A_2; the filter did not appear to retain liquid as long as B_2 or C_2. The film in B_2 increased slowly in amount as the filter aged and apparently had not reached maximum activity at the termination of the experiment. Filter C_2 had a white gelatinous growth on the surface within a fortnight and after this the film spread downwards through the first and second sections. At the end of the experiment the first section had a thick, pale yellow, gelatinous film but it was not choked, and liquid could be filtered at twice the desired rate without surface ponding. Section 2 in filter C_2 contained much film, though this was less in amount than in section 1, while there was considerably less film in section 3 than in section 2. In section 4 the small quantity of film present consisted of a thin slime on the glass tubes. It was observed in the early stages of the experiment that much of the film in sections 2 and 3 was formed by growths in the section above being washed into the one below, forming centres of inoculation from which the film spread to other parts of the filter.

Table III. *Effect of supply of phosphate on sucrose oxidation and removal of nitrogen.*

Exp. 2. Glass filters and tubular glass medium: Rate of flow = 100 g.y.d.

Filter A_2 received sucrose equivalent to 105·3 parts glucose per 100,000 and no P_2O_5.
Filter B_2 received sucrose equivalent to 105·3 parts glucose per 100,000 *plus* 0·3 part P_2O_5.
Filter C_2 received sucrose equivalent to 105·3 parts glucose per 100,000 *plus* 3·0 parts P_2O_5.

2 litres of nutrient solution supplied daily = 100 g.y.d.

Parts per 100,000.

Day of exp.	P_2O_5 in final effluent		Sugar in final effluents: glucose equivalent			Nitrogen in final effluents (5 parts N supplied)		
	B_2 (0·3 supplied)	C_2 (3·0 supplied)	A_2	B_2	C_2	A_2	B_2	C_2

* Filter C_2 received 4 litres daily from 61st day.

Oxidation of sugar (Table III). The amounts of sugar oxidised in the three filters A_2, B_2 and C_2 at different stages of the experiment are shown in Fig. 1.

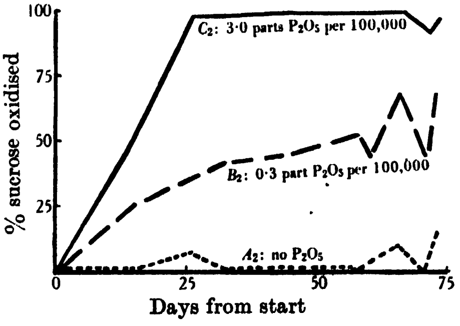

Fig. 1. Effect of phosphorus supplied on oxidation of sucrose

The curves indicate a definite relationship between the supply of phosphorus and the amounts of sugar oxidised, provided adequate additions of other essential mineral salts are made to the nutrient solutions. In the absence of added phosphorus filter A_2 rarely oxidised more than 14 % of the sugar, and the average amount oxidised over a period of 73 days was only 2·6 %. Filter B_2, however, with 0·3 part P_2O_5 per 100,000 decomposed 36 % of the carbohydrates after a period of 26 days. The percentage oxidation increased steadily to 50 after 50 days and on the 73rd day, at the end of the experiment, filter B_2 was oxidising 68 % of the sugar. The trend of the curve for B_2 suggests that the amount of sugar oxidised by this filter would have continued to increase if the experiment had been prolonged. The results show that the smallness of the amount of phosphorus supplied restricted the growth of a population sufficiently active to oxidise all the sugar. As the filter accumulated phosphorus and the film developed, the amount of organic matter oxidised increased. Two of the many factors which influence biological oxidation in percolating filters are thus seen to be the supply of phosphorus and the time factor. When the results obtained with filters B_1 and B_2 are compared a striking difference is observed in the amounts of sugar oxidised. After receiving 0·1 % solution of sugar daily for 43 days (Table I) filter B_1 oxidised 98 % daily whereas B_2 oxidised only 43 % after operating for the same period (Fig. 1). This comparison emphasises another important factor in filtration, *viz.* the relationship between the size of filtering medium and the efficiency of the filter. Apart from the change made in the source of nitrogen the only difference between B_1 and B_2 was that B_1 contained small pieces of solid glass while B_2 was filled with larger pieces of tubular glass. This difference in size of medium affects the phosphorus requirements of the filters in the following manner. Sufficient phosphorus must be provided to B_1 to build a film able to retain the solution passing through the filter long enough for the sugar to be decomposed. With the small grade of medium in B_1 a limited growth of organisms was sufficient to join up the particles of medium and so increase the time of contact of the filter. The quantity of phosphorus used for B_1, when supplied to B_2, gave about the same growth, but here the film only covered the surface of the glass tubes and did not join them together so as to make a continuous growth. Spaces were thus left in the filter through which sugar passed and escaped oxidation. With filter C_2, which received 3 parts P_2O_5 per 100,000, the amount of sugar decomposed reached 98 % in the first 26 days and later continued to improve until the oxidation attained was almost quantitative. Even when the rate of flow was doubled on the 60th day of the experiment over 93 % of the carbohydrate underwent oxidation.

The effect of supply of phosphorus on the contribution made by the different parts of the filter towards the total oxidation of the carbohydrate was found by dismantling the filters at various intervals and analysing the effluents of the different sections of the three filters. The results appear in Table IV. The samples were taken successively from the different sections over a period of 16 hours, beginning at section 4 and working upwards. Consequently the samples did not correspond exactly, and probably for this reason, the analytical results do not always show a regular decrease in sugar content from the inlet to the outlet of the filter. The figures in Table IV show that the effect of withholding phosphate from filter A_2 was to inhibit inversion and oxidation of sugar. Traces of invert sugar were generally present in the effluents from the first section of A_2 and in these cases the same quantity persisted almost unchanged in the effluents from lower sections. These small amounts of invert sugar may have been due to analytical errors in the Hagedorn-Jensen method as carried out by the author [Jenkins, 1933, 2]. With filter B_2 a high proportion of invert sugar always appeared in the effluent from section 1 with a tendency for the

amount of invert sugar to increase on passage down the filter. On two occasions the sugar in the final effluent was largely the inverted product, there being 56·4 parts invert sugar in a total sugar content of 61·5 parts on the 33rd day and 50·1 out of a total of 58·0 on the 44th day. The view has previously been advanced [Jenkins, 1933, 2] that the occurrence of a large proportion of invert sugar in the effluents of a filter receiving solutions of sucrose is a sign of an immature film, and that increase in efficiency of oxidation brings about a decrease in the proportion of invert sugar in the total sugar. The observations made above on the composition of the effluents from the different sections support this view, since B_2 never reached maturity during the 73 days of the experiment. Although the film in B_2 was unable to oxidise the carbohydrates that passed through it, the filter was yet able to invert a large proportion of the sugar it received. The film in section 2 of filter B_2 was small in amount and considerably less in the two lower sections. All these sections however were able at times to bring about the inversion of appreciable quantities of sugar in the absence of measurable amounts of inorganic phosphate in the effluents (less than 0·002 P_2O_5 per 100,000) but were unable to carry the decomposition much beyond this stage. The addition of 3 parts P_2O_5 per 100,000 to the sugar solution fed to filter C_2 resulted in the growth of much film in section 1 and less in section 2. Only a very small amount of growth took place in sections 3 and 4, owing to the low concentration of sugar in the solutions reaching these sections. As previously observed, some of the film in section 2 was washed down from the upper part of the filter.

A large proportion of the sugar which passed through filter C_2 was hydrolysed to invert sugar: on the 30th day all the sugar contained in the effluent of section 4 appeared in this form. The concentration of sugar in effluent 4, filter C_2, was negligible after the 30th day as long as the rate of 100 g.y.d. was maintained.

Phosphorus and nitrogen removed. The quantities of phosphorus and nitrogen taken up by the filters are given in Table V. The figures show that with one exception the phosphate added to B_2 was removed quantitatively by this filter. Reference to Tables IV and V shows that section 1 of B_2 was responsible for the removal of the whole of the phosphate and for the oxidation of most of the sucrose. The absence of phosphorus from the solutions of sugar leaving this section accounts for the poor development of film in the remaining sections of this filter. Varying amounts of nitrogen were taken up by B_2 during the early stages of the experiment but later small amounts were removed continuously. An average of 1·02 parts N per 100,000 was removed from the solutions, which before filtration contained 5 parts. Table V shows that most of the nitrogen was absorbed by section 1 of B_2 and only small amounts by lower sections. The solutions leaving section 1 therefore contained sugar and ammonium salts but practically no phosphorus. On the other hand, filter C_2 received more than enough phosphorus for its requirements (Table V), an average of 1·54 parts P_2O_5 being taken from a supply of 3 parts. This uptake of phosphorus enabled C_2 to oxidise almost completely 2 litres of a solution of 0·1 % sucrose every day for the first 60 days and 4 litres daily after the 60th day of the experiment.

Table V. *Phosphate and nitrogen in effluents at different levels of the filters.*

Exp. 2. Glass filters and tubular glass medium: rate of flow - 100 g.y.d.

Filter A_2 received sucrose equivalent to 105·3 parts glucose per 100,000 and no P_2O_5.
Filter B_2 received sucrose equivalent to 105·3 parts glucose per 100,000 *plus* 0·3 part P_2O_5.
Filter C_2 received sucrose equivalent to 105·3 parts glucose per 100,000 *plus* 3·0 parts P_2O_5.

The average amounts of nitrogen retained by the filters are obtainable from the data given in Table V and show that the uptake of this element depends upon the quantity of phosphorus available for the growth of the film. Thus in the absence of phosphorus only 6·6 % of the N supplied to A_2 was removed: B_2 and C_2, which received 0·3 part and 3 parts P_2O_5 respectively, took up 20·5 and 44·9 % of N respectively.

Figures for the total amounts of C, N and P removed from solution by filters B_2 and C_2 during the experiment are presented in Table VI. The difference in the ratios of C, N and P in B_2 during the first 44 days and the last 29 days means that more carbon was oxidised for a given supply of N in the later stages of the experiment than in the earliest part. Although the C/N/P ratios for the last 29 days of B_2 and the whole period for C_2 are similar in respect of C and N yet the actual amounts of C and N oxidised and removed differed considerably in the two filters. The suggestion was made in a previous paper [Jenkins, 1933, 3] that nitrogen would be used most economically in a filter oxidising sugar if the initial C/N ratio were kept at about 30/1. A C/N ratio of 19·8/1 was obtained with C_2 because an excess of N was supplied. In the presence of less N the same amount of sugar would probably have been oxidised and C and N removed in a wider ratio. According to the figures given above, the minimum proportion of phosphorus required for the efficient utilisation of nitrogen would lie between 0·12 and 0·31 part available P (0·28 and 0·71 parts respectively P_2O_5) per part of nitrogen.

Table VI. *Carbon, nitrogen and phosphorus removed from solutions.*

C in sugar solutions supplied to B_2 and C_2 = 42·1.
N in sugar solutions supplied to B_2 and C_2 = 5·0.
P in sugar solutions supplied to B_2 and C_2 = 0·13.

As previously mentioned, the formation of acid in percolating filters was found to arise from the use of NH_4Cl as the source of nitrogen. In Exp. 2 slight variations were found in the p_H values of the solutions undergoing filtration (Table VII) but reductions in p_H of the order observed when ammonium chloride was the source of N were not detected. There is thus no evidence that intermediate organic acids were formed to any considerable extent during the aerobic oxidation of 0·1 % sugar by the mixed flora of the percolating filter operated under the conditions observed in these experiments.

Experiments 3 (a) and 3 (b).

The availability of compounds of phosphorus in percolating filters.

Exp. 3 (a). The apparatus used for this experiment was the large scale filtration plant previously described by Richards and Cutler [1933]. The liquid treated by the biological filters was the effluent from the beet-pulp presses of a beet-sugar factory, diluted and partly fermented, so that it gave approximately the following results on analysis:

	Parts per 100,000
Oxygen absorbed in 4 hours from permanganate ...	122
Biochemical oxygen demand in 5 days	109
Biochemical oxygen demand in 20 days	156
Sucrose	68
Acetic acid	20
Lactic acid	20
Solids in suspension (4 % ash)...	42
P_2O_5, all organic	0·85
Nitrogen in organic combination	2·5
Nitrogen as ammonia	0·01

p_H, 5·1

The suspended matter consisted of cellulose and fibre derived from the sugar-beet root, while the organic nitrogen was mostly of protein origin and less readily available to micro-organisms than ammonia. The organic compounds of phosphorus were probably hexosephosphate, nucleoproteins and phospholipins derived from organisms and the cell contents of the beet. Liquid of the average composition given above was distributed at a rate of 50 g.y.d. over two filters. As the chief object of the experiment was to test the effect of inoculation on the rate of oxidation of the constituents of fermented press water, one of the filters was inoculated with organisms selected by Mr D. W. Cutler and Miss L. C. Crump, while the other filter was not inoculated. Despite this difference the final effluents of both filters were almost identical in chemical composition. Hence they have been considered as duplicates for the purpose of this experiment: the figures given are the averages of the analytical data from the inoculated and uninoculated filters. During the first 20 days the organic compounds of nitrogen and phosphorus present in the liquids filtered varied according to the composition of the factory press water, but known quantities of ammonia or potassium phosphate were added. The liquids filtered during this period could be classified as follows:

(1) For the first 7 days the liquids contained nitrogen as ammonia and in organic combination as well as 0·85 part P_2O_5 per 100,000 as organic phosphorus supplied by the pulp liquor.

(2) From the 8th day to 13th day the liquids contained nitrogen as ammonia and in organic combination besides phosphorus in organic combination and as added K_2HPO_4.

(3) From the 14th day to 18th day the substances in (2) were present, though the amounts of N and inorganic phosphorus were less.

(4) After the 20th day the liquids contained organic nitrogen, phosphorus in the organic and inorganic states and traces of ammonia.

The results of operating the filters under the conditions given above are summarised in Table VIII. The figures for percentage purification represent the averages of the amounts of oxidation of organic matter in the two filters as measured by the B.O.D. test. It must be pointed out that the conclusions

* Approximate.

drawn should be regarded as tentative or as supporting those already given in the early part of the paper, for the reason that liquors of different composition were treated in the same filter in its early stages and not simultaneously in different filters. Hence comparisons are available only between the results of filtering liquids of different composition at different periods in a filter undergoing development.

If the results given above are considered with respect to the changes made in operating the filters the following conclusions may be drawn:

(1) *1st–7th days.* In the presence of organic phosphorus and nitrogen in organic and inorganic combination not more than 25 % of the organic matter was oxidised on filtration and only 17 and 39 % respectively of the inorganic and organic nitrogen supplied were removed by the filters. The amount of organic phosphorus removed from the liquid was not determined, but as an approximation it is assumed that the quantity was proportional to the uptake of organic nitrogen.

(2) *8th–13th days.* The response to the addition of an inorganic source of phosphorus on the 8th and on successive days was immediate. Inorganic phosphorus to the extent of 90 % was removed in the first 2 days and an average retention of 85 % was recorded over the period 8th to 13th days. The removal of inorganic nitrogen by the filters increased progressively from 33 % on the 8th day to 98 % on the 13th day, while the percentage purification increased from 28 to 86 in this period. This increase in percentage purification probably included the improvement in efficiency which generally accompanies the ageing or maturing of a filter. Cutler and Crump (unpublished work) found that the bulk of film rapidly increased in both filters between the 8th and 13th days.

(3) *14th–18th days.* A reduction in the amount of added phosphorus resulted in a greater percentage retention of P_2O_5, which increased to about 98. As long as ammonia was present, nitrogen in this form was removed almost quantitatively. The average oxidation of organic matter amounted to about 80 %.

(4) *20th day* et seq. When ammoniacal nitrogen was withheld the removal of inorganic phosphorus decreased and a rapid fall in the percentage oxidation followed. In the continued absence of inorganic nitrogen the percentage purification of organic matter remained at a low figure, in spite of the presence of an inorganic compound of phosphorus.

The figures above therefore show that (*a*) the phosphorus in the organic compounds contained in the press water of a sugar-beet factory is not so readily available to the micro-organisms in a percolating filter, even in the presence of sufficient available nitrogen, as an inorganic supply of phosphorus such as K_2HPO_4; (*b*) in the presence of potassium phosphate, nitrogen as ammonia is removed by the micro-organisms of a filter in preference to the organic compounds of nitrogen present in press water, with consequent improvement in the percentage purification of organic matter by the filter; (*c*) the removal of phosphorus as dissolved phosphate by a filter is slow and incomplete if the liquids filtered do not contain nitrogen in a form which can be rapidly utilised by the micro-organisms responsible for the activity of the filter. Press water appears to be deficient in this form of nitrogen.

Exp. 3 (*b*). The last conclusion, (*c*), received substantial corroboration from the results of an experiment briefly described below.

Two small laboratory filters were filled with gravel and supplied with solutions of the same composition as those used for Exp. 3 (*a*), at a rate of 100 g.y.d. Sufficient K_2HPO_4 was added to the solution fed to one filter to provide 1·5 parts P_2O_5 per 100,000: no such addition was made to the liquid supplied to the control filter. The crude liquor of both filters contained approximately 0·85 part P_2O_5 as organic phosphorus during the experimental period of 26 days. Analyses were made on 21 days and the following average results for percentage purification were obtained:

Average percentage purification of diluted press water.

Control filter received press water containing 0·85 part organic P_2O_5 per 100,000.

Phosphate filter received press water containing 0·85 part organic P_2O_5 and 1·5 parts inorganic P_2O_5 per 100,000 added as K_2HPO_4.

Oxygen absorbed from $N/8$ $KMnO_4$ % purification		B.O.D. in 5 days % purification		B.O.D. in 20 days % purification		% removal of total sugar	
Control	Phosphate	Control	Phosphate	Control	Phosphate	Control	Phosphate
46	52	44	38	36	37	53	37

In any one of the above tests the differences between the averages of the percentage purifications for the control and the phosphate filter are not significant.

The experiment therefore shows the oxidation of the organic matter in fermented press water by a percolating filter to be unaided by the addition of an available supply of phosphorus, if only those organic compounds of nitrogen normally found in press water are present.

DISCUSSION OF RESULTS.

The experiments described in this paper demonstrate that the influence of phosphorus on the rate of oxidation by a percolating filter of carbohydrates and the organic matter present in the press water of a beet-sugar factory is dependent on several factors, *viz.* (*a*) size of grade of filtering material, (*b*) the amount and nature of the compounds of phosphorus present, (*c*) the nature of the compounds of nitrogen present.

In order to build up a film able to oxidise a given quantity of carbohydrate at a given rate of flow a filter filled with $\frac{1}{16}$ to $\frac{1}{4}$ in. medium requires a smaller amount of available phosphorus than a filter with a coarse grade of material such as glass tubes 1·5 cm. long and 1 cm. bore. The primary function of the phosphorus is to supply the nutrient necessary for the growth of enough film to increase the time of passage of the dissolved organic matter through the filter. The results of Exps. 1 and 2 bring out the difference caused by filtering solutions of the same composition through filters filled with different grades of material. Filter B_1, with a small size of medium, received 0·3 part P_2O_5 per 100,000 and decomposed daily 98 % of a 0·1 % solution of sucrose after the filter had been in operation for one month, while B_2, which contained a larger grade of medium, but received the same amounts of phosphorus and sugar, oxidised less than 50 % of the sugar after operating for the same period. Filters with too fine a grade of medium suffer from the disadvantage of choking whenever vigorous growth of film occurs. Thus, increasing the supply of phosphorus to 3 parts P_2O_5 per 100,000 in Exps. 1 and 2 led to the choking of the fine medium in filter C_1, whereas the coarse medium in filter C_2 showed no signs of ponding although it received solution of the same composition as that passed through C_1. This observation might be of importance in actual practice where the ponding of filters increases operating difficulties and lowers the efficiency of the filter.

When 0·1 % solutions of sucrose containing 0·3 part P_2O_5 per 100,000 were filtered the phosphorus was, with one exception, quantitatively absorbed by the filter. An increase to 3 parts P_2O_5 in the liquids undergoing filtration led to a removal of about 1·5 parts P_2O_5 and the remainder passed out as inorganic phosphate with the effluent. Organic compounds of phosphorus were never detected in the effluents from any sections of the filters, although by the method used [Parker and Fudge, 1927] it was possible to determine as little as 0·002 part P_2O_5 as hexosephosphate per 100,000 of solution. Barritt [1931] treated a 0·2 % solution of sucrose, containing about 23 parts P_2O_5 per 100,000 as mixed potassium phosphates, in a percolating filter and found that the whole of the phosphate was not taken up by the filter. Even when one-sixth of this quantity of phosphate was used, *viz.* about 4·0 parts P_2O_5 per 100,000, he observed that inorganic compounds of phosphorus still appeared in the effluents. The results given in this paper would suggest that the occurrence of phosphate in the effluents from Barritt's filters was the result of supplying the filter with more phosphate than it could remove from solution. No evidence was found to indicate that hexosephosphate appeared in the effluents and became hydrolysed during analysis. Harden [1923] supposes that hexosephosphates are formed within the living cell first by the diffusion of sugar from the substrate through the cell wall, followed by the union of sugar with the phosphate already present in the cell. This compound is then split up into simple products and the phosphate which is regenerated is again able to unite with sugar.

The experiments on the filtration of press water from a beet-sugar factory show that hitherto unsuspected differences may exist as regards the availability of compounds of phosphorus in a percolating filter. In previous work reported by Richards and Cutler [1933] an ample supply of available nitrogen was recognised as essential for the rapid oxidation of dissolved organic impurities. The organic compounds of nitrogen and phosphate in press water probably have varying degrees of availability. Such compounds are removed mechanically by the filter before being assimilated by micro-organisms. The rate of oxidation of the organic matter passing through the filter is limited by the rate at which the nitrogen becomes available and this rate does not seem to be increased by supplying compounds of phosphorus which are readily utilisable by micro-organisms. If, however, nitrogen exists in the filter in an easily assimilable form such as ammonia, the rate of oxidation of organic matter is considerably increased by the supply of an available form of phosphorus.

Solutions of sugar and ammonium chloride suffered a considerable reduction in p_H on filtration, from a figure of 5·4 in the nutrient solution to 3·2 in one effluent, and from 6·0 to 2·8 in another. As previously mentioned, tests for the amount of dissolved organic matter showed that the decrease in p_H was too great to be accounted for solely by the production of organic acids from the sugar: negative results were obtained on testing for simple organic acids in the final effluents. It was also observed that the concentration of chloride in the solution undergoing filtration remained practically constant throughout its passage down the filter. Furthermore the p_H of the nutrient solution was not reduced appreciably when ammonium bicarbonate was substituted for ammonium chloride. These facts all indicate that the acid production in a percolating filter operated under the conditions described herein is chiefly derived from the mineral acid liberated by the removal of ammonium ion from the chloride or sulphate. Barritt [1931] found that organic acids may be produced in the upper part of a percolating filter if 0·2 % solutions of sugar are filtered: a reduction in p_H is observed in that part of the filter but the acid is oxidised as the solutions pass downwards, with corresponding increases in the p_H values of the effluents.

SUMMARY.

1. Experiments have been carried out on the biological oxidation in percolating filters of (*a*) 0·1 % sucrose *plus* different amounts of phosphate as K_2HPO_4 and with NH_4Cl or NH_4HCO_3 as the source of nitrogen, using broken glass as the filtering medium; (*b*) 0·1 % sucrose *plus* NH_4HCO_3 and different amounts of phosphate, with glass tubes as the filtering medium; (*c*) diluted press water from a beet-sugar factory; in this case the effect of organic componds of phosphorus on the oxidation of organic matter was studied in the presence of sources of nitrogen readily available to micro-organisms, and in the presence of compounds of nitrogen available only with difficulty.

2. The amount of phosphate required to ensure rapid oxidation of sugar in a 0·1 % solution is influenced to a large extent by the nature of the filtering medium. To ensure freedom from choking, the medium should be of a large size and of a suitable shape. Under these conditions a 0·1 % solution of sugar requires at first a maximum of about 1·5 parts P_2O_5 and 2·2 parts N per 100,000 for complete oxidation of the sugar; once the film becomes mature 0·3 of P_2O_5 and 1 of N.

3. Excess of phosphate supplied to the filters passes out apparently unchanged. No organic compounds of phosphorus were ever found in the effluents from any of the sections of the different filters.

4. The organic compounds of phosphorus in the press water of a beet-sugar factory are only slowly available to the micro-organisms on a percolating filter as compared with potassium hydrogen phosphate, and this may limit the rate of oxidation of organic matter by a percolating filter. In the absence of a form of nitrogen which is readily assimilated by micro-organisms the full effect of a supply of available phosphorus is not shown.

5. When percolating filters filled with glass medium were supplied with sugar, ammonium chloride and various amounts of K_2HPO_4 the p_H values of the solutions before and after filtration were:

(*a*) 5·6 and 5·0 respectively, without P_2O_5;
(*b*) 5·4 and 3·2 respectively, with 0·3 part P_2O_5 per 100,000;
(*c*) 5·0 and 2·8 respectively, with 3·0 parts P_2O_5 per 100,000.

The cause of acid production was found to be the removal of NH_3 from NH_4Cl and the liberation of free HCl. Quantitative tests and measurements of the dissolved organic matter present in the effluents showed that this acidity was not due to organic acids.

Acknowledgements are made to Mr E. H. Richards for supervising this work, to Mr D. W. Cutler and staff for permission to refer to unpublished results and to Mr A. S. Roberts for assistance at one stage of the experiments. The investigation was carried out as part of the programme of the Water Pollution Research Board of the Department of Scientific and Industrial Research, and the results are published with the permission of the Department.

XVII. A STUDY OF SEASONAL VARIATION IN BUTTER FAT.

II. A SEASONAL SPECTROSCOPIC VARIATION IN THE FATTY ACID FRACTION.

BY ROLAND GORDON BOOTH AND STANISŁAW KAZIMIERZ KON
National Institute for Research in Dairying, University of Reading,
AND WILLIAM JOHN DANN AND THOMAS MOORE
Dunn Nutritional Laboratory, University of Cambridge and Medical Research Council.

(*Received November 7th, 1934.*)

IN previous communications [Booth *et al.*, 1933, 1, 2], the seasonal variations in the carotene and vitamin A contents of the butter fat produced from typical English milk were described, and a seasonal variation in the power of butter fat to inhibit the reaction between vitamin A and antimony trichloride was established. We also mentioned that the fatty acids prepared from summer and winter butter fats appeared to show certain differences, namely (1) acids from summer butter fats showed more intense absorption at $230 m\mu$ than those from winter butter fats, and (2) summer acids turned brown more rapidly than winter acids when treated with the antimony trichloride reagent. It was not clear at the time whether or not these two properties were related to the greater inhibitory power of summer butter fat in the antimony trichloride test. Further work has now demonstrated that neither the $230 m\mu$ absorption nor the rate of brown colour formation can be correlated with the inhibitory power. The rate of brown colour formation, indeed, is greatly increased in aged or oxidised fats, and any decision as to whether a seasonal variation of this property does actually exist must be postponed until one is in a better position to understand the nature of the reaction involved. On the other hand we have satisfied ourselves that the variation in absorption at $230 m\mu$ is of a genuinely seasonal character. Data in support of this view are given below.

EXPERIMENTAL.

Collection of butter fat etc. 15 specimens of butter fat were examined, selected from a large number of samples accumulated between April 1932 and May 1933. The period investigated thus included two occasions on which the cows were turned out to grass after stall feeding during the winter. The fatty acids were prepared by the following routine method: 5 g. of the butter fat were boiled for 2 minutes with 2·2 ml. of saturated aqueous KOH and 10 ml. of alcohol. The mixture was then diluted with 40 ml. of water and extracted twice with 75 ml. of ether each time, in order to remove the unsaponifiable matter. 20 ml. of 10 % sulphuric acid were then added and the free fatty acids extracted with 75 ml. of ether. The ethereal solution was washed twice with 10 ml. of water each time (with vigorous shaking) and once with 50 ml. of water (with gentle agitation) and dried by filtering through anhydrous sodium sulphate. The ether was evaporated under partial vacuum, and the residual fatty acids were transferred to a specimen tube.

Spectroscopic examination of the fatty acids. For the spectroscopic examination a Hilger E 3 quartz spectrograph with echelon cell photometer was used throughout. Solutions of the different samples of fatty acid were made in pure cyclohexane for the spectroscopic examination. A suitable concentration was found to be about 25 mg. in 10 ml. of the solvent.

Seasonal variation of intensity of absorption by the fatty acids at 230 $m\mu$.

The variation in the intensity of absorption at 230 $m\mu$ is shown in Fig. 1 (continuous curve). It will be seen that for winter butters $E^{1\%}_{1\,cm}$ for the acids has a value of 10 or slightly less (minimum value observed April 19–20, 1933 = 8·4) whereas the value for acids from summer butters is increased to 20 or more (maximum value observed, May 12–13, 1932 = 25·0)[1]. The increase in absorption, as judged from data obtained in the springs of 1932 and 1933, takes place coincidently with the cows obtaining access to grass. In both seasons significant increases were observed after one week of pasture feeding.

The effect of prolonged saponification on the absorption of the butter fat acids.

In our experiments the only departure from the standard method of saponification occurred during the early stages of the work, when a few of the specimens were saponified for the unnecessarily long period of 1 hour, instead of the usual period of 2 minutes. To rule out any possibility of a simulation of a seasonal variation through differences in the duration of saponification, acids prepared from typical winter and summer butter fats were submitted to prolonged boiling under reflux (15 hours) in alcoholic potash. A slight increase in the absorption

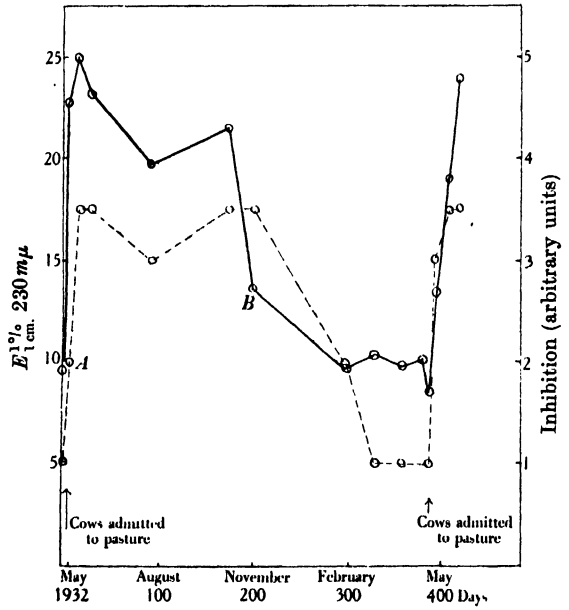

Fig. 1. --- Inhibitory power of butter fat. —— Absorptive power of acids of butter fat.

---

[1] Slightly higher figures were obtained in subsequent determinations outside the series from which Fig. 1 was drawn.

of the winter butter acids was observed. It was, however, quite inadequate to account for the disparity between the absorption of typical winter and summer acids. A slight increase, probably falling within the range of experimental error, was also observed in the absorption of the summer acids.

	1 min. sap.	15 hrs. sap.
Winter acids, Feb. 24–27, 1933	12·6	15
Summer acids, May 19–22, 1933	27·1	30·0

Differentiation of 230 mμ *absorption and inhibitory power in $SbCl_3$ reaction.* In Fig. 1 the inhibitory power of the butter fat is indicated by the broken curve and the absorption of the acids by the continuous curve. Except for a few samples (notably those of May 3–4, 1932, marked *A* in Fig. 1, and Oct. 31, Nov. 3, 1932 marked *B*) there is a fair degree of parallelism between 230 *m*μ absorption and inhibitory power. To test this correlation samples of a typical summer butter fat (May 19–22, 1933) were submitted to various treatments and the effects on absorption and inhibitory power compared. It was found that whereas ageing and irradiation of the fat led to a marked decrease in inhibitory power, the absorption at 230 *m*μ was only slightly decreased. Aeration of the hot fat on the other hand caused reductions both in absorption and inhibitory power. To indicate the degree of severity of the various treatments iodine value determinations were carried out.

Table I. *Inhibitory power of butter fat.*

Butter fat of May 19–22, 1933. The inhibitory power has been expressed in arbitrary units by noting the depression in the blue reading caused by adding 0·5 ml. of the fat to 8 γ of B.D.H. vitamin A concentrate before the addition of 2 ml. of $SbCl_3$ reagent. The blue reading was taken immediately after adding the reagent. In the case of the aged, irradiated and oxidised specimens brown colorations developed on standing much more rapidly than with the untreated fat. Iodine values were determined by the Wijs method.

Treatment	Details	$E^{1\%}_{1\,cm}$ 230 *m*μ	Blue reading in absence of fat	Blue reading in presence of fat	Inhibitory power	I.V.
Untreated	—	25·9	7	2	5	48·5
Ageing	Fat was kept for several weeks in shallow layer in bottle on laboratory bench	18·8	7	5	2	46·9
Irradiation	Fat was exposed for 20 mins. to irradiation by mercury arc lamp at distance of 20 cm.	21·5	7	5	2	46·5
Oxidation	Fat was melted on water-bath and aerated by passing a current of air for about 24 hrs.	11·0	7	5	2	43·4

DISCUSSION.

230 mμ *absorption.* The fact that the mixed fatty acids of butter fat show an absorption maximum at 230 *m*μ was first pointed out by Gillam *et al.* [1931]. The band, however, is by no means specific and is observed in varying intensity in most fatty acids, *e.g.* in the mixed fatty acids of cod-liver oil [Edisbury *et al.*, 1933]. The main interest of the present work lies in the fact that the magnitude of the seasonal increase in absorption cannot be accounted for on the basis of our accepted knowledge of the relative composition of winter and summer butter fats and of the extinction coefficients of their known constituents. Since Ramart-Lucas *et al.* [1930] have shown that all saturated acids have very small and similar extinction coefficients at 230 $m\mu$, our attention, in attempting to account for the absorption of the mixed butter acids, may be restricted to oleic and linoleic acids, which according to Hilditch and Sleightholme [1930] are the main unsaturated components. In Table II the percentage of acids present has been taken from data obtained by Hilditch and Sleightholme with butters similar to those examined in the present work. The extinction coefficients for oleic and linoleic acids were observed by Dann and Moore [1933], using commercial preparations of acids, and may be taken as maximum values which probably would exceed those shown by the pure freshly prepared acids.

Table II.

	Absorbing component	% present in mixed acids	$E_{1\,\mathrm{cm}}^{1\%}$ 230 $m\mu$	Contribution towards E of mixed acids
Winter butter acid (coconut cake feeding)	Oleic	31·7	16·5	5·23
	Linoleic	2·4	9·6	0·23
		Total calculated E		5·46
		Observed		8·4
		Excess of observed over calculated		54 %
Early summer butter acids	Oleic	40·9	16·5	6·75
	Linoleic	4·1	9·6	0·39
		Total calculated E		7·14
		Observed		25·0
		Excess of observed over calculated		250 %

Two explanations for the excess of the observed over the calculated absorption seem possible. (1) Small amounts of unknown acids having very high extinction coefficients may be present in butter fat, the concentration being relatively low in winter and considerably increased in summer. (2) One or more of the known acids may be present in butter fat in a more highly absorptive form than that in which it exists in specimens prepared from vegetable sources. The second of these explanations is made attractive by our observation, reported in an accompanying communication [Dann *et al.*, 1935] that when certain oils are fed to the cow there is evidence of the appearance in the butter fat of acids having much higher extinction coefficients than the acids originally present in the oils. Although no definite decision can be reached as to the exact nature of the acids causing absorption, it seems probable that acids of the linoleic type, and possibly also more highly unsaturated acids, are involved.

Differentiation of 230 $m\mu$ *absorption and inhibitory power of the* $SbCl_3$ *reaction.* Although the above experiments permit no direct advance in our knowledge of the substances present in summer butter fat which cause inhibition of the blue coloration in the vitamin A test, it may be inferred that these substances, whatever their chemical character may prove to be, are extremely sensitive to oxidation and to irradiation. In these respects they are much less stable than the substances responsible for absorption at 230 $m\mu$, which are affected only by more vigorous treatment.

SUMMARY.

1. The absorption of the fatty acids of butter fat at 230 $m\mu$ shows a pronounced seasonal variation, being more than doubled during the summer months when the cows have access to pasture.

2. The increase in absorption runs approximately parallel with the increased inhibitory power of the butter fat in the antimony trichloride reaction for vitamin A as previously described. The substances responsible for inhibitory power, however, are much more sensitive to oxidation and irradiation than those responsible for 230$m\mu$ absorption.

3. The increased absorption of the acids from summer butter fat must be ascribed either to the presence of small amounts of unrecognised acids possessing high extinction coefficients or to the presence of modified forms of known unsaturated acids in a highly absorbing state.

Our thanks are due to Prof. H. D. Kay and Dr L. J. Harris for their valuable criticism.

XVIII. A NEW SPECTROSCOPIC PHENOMENON IN FATTY ACID METABOLISM. THE CONVERSION OF "PRO-ABSORPTIVE" TO "ABSORPTIVE" ACIDS IN THE COW.

BY WILLIAM JOHN DANN AND THOMAS MOORE
Dunn Nutritional Laboratory, University of Cambridge and Medical Research Council

AND ROLAND GORDON BOOTH, JOHN GOLDING AND STANISŁAW KAZIMIERZ KON
National Institute for Research in Dairying, University of Reading.

(*Received November 7th, 1934.*)

IN an accompanying communication [Booth *et al.*, 1935] we have reported that when the cow is turned out to pasture after the winter the fatty acids obtained from the butter fat show greatly increased absorption for radiation of wave length $230 m\mu$. The work described in the present paper owes its origin to an attempt to correlate this increased absorption with the marked fall in the amount of fat in the milk which, as is already known, also frequently occurs when the cow first obtains access to green pasture. Now past work has shown that the feeding of cod-liver oil likewise causes a marked diminution in the amount of butter fat in the milk [Drummond *et al.*, 1924]. Further, cod-liver oil was reputed to yield acids having very high absorption for radiation of wave length $230 m\mu$ [Gillam *et al.*, 1931]. It seemed possible, therefore, that the depression of the fat might be linked up with the presence in it of highly absorbing[1] acids, derived either from grass or from cod-liver oil.

This explanation in its simplest form was ruled out when it was found by Dann and Moore [1933] that the high absorption of the fatty acids of cod-liver oil, recorded by Gillam *et al.*, is not observed if the acids are prepared by a brief saponification, but only after the acids have been submitted to prolonged treatment with the hot alkali. It remained possible, nevertheless, that acids which resembled those of cod-liver oil in showing increased absorption after suitable treatment might exert a similar depressing influence on the amount of fat in milk. Support for this view was afforded by early experiments in which we found that the absorption of the butter fat was indeed greatly increased when the relatively non-absorbing cod-liver oil was fed to the cows.

Further experiments have shown that fats capable of depressing the milk fat certainly do as a general rule possess unusual potency in raising the absorption at $230 m\mu$. The same property, however, is shared, if in a less degree, by other fats possessing no noticeable depressing action. The increase of absorption would indeed appear to be of a general character. It may occur in two ways, either *in*

---

[1] The word "absorption" is used throughout the present communication to designate the extinction coefficient at the head of an absorption band at $230 m\mu$. Unless specifically excepted in the text, all figures for the extinction coefficient $E^{1\%}_{1\,\text{cm.}}$ at $230 m\mu$ (shortened for brevity to $E/230$) refer to the head of a band.

vitro as the result of chemical treatment, or *in vivo* in the course of the absorption of the fats by the cow and their secretion among the constituents of milk fat. The present communication is devoted to the description of this phenomenon. The possible bearing of our results on the nature of the substances responsible for the depression of the milk fat is being postponed for discussion elsewhere.

EXPERIMENTAL.

The conversion of "pro-absorptive" into "absorptive" acids by chemical means[1].

Experiments in vitro. Data relating to the absorptive properties and iodine values of the mixed acids obtained from the five oils used in our feeding experiments (two specimens of cod-liver oil, sardine oil, linseed oil, rape oil), both as prepared by a short saponification and after prolonged treatment of the acids by boiling with alcoholic potash, are given in Table I. The acids were prepared by the method described in the accompanying paper [Booth *et al.*, 1935]. Prolonged treatment with alkali was applied to the acids after their preliminary preparation and separation from unsaponifiable matter by the routine 2 min. saponification. Any complication arising through the possible action of the alkali on the unsaponifiable matter was thereby avoided.

It will be seen that for each oil the acids prepared by a short saponification showed only low absorption at $230 m\mu$. As the result of prolonged treatment with alkali there was in every instance at least a tenfold increase in absorption. In regard to the iodine values slight falls were observed in the acids from crude cod-liver oil (8 % decrease), medicinal cod-liver oil (10 %) and linseed oil (7 %). There was no change in the iodine values of acids from sardine oil and rape oil.

Table I. *Influence of prolonged treatment with alcoholic potash on the absorption of various fatty acids.*

Mixed acids from	Time of treatment	$E/230$	I.V.
Sardine oil (crude)	2 mins.	7·7	168
	48 hrs.	185	167
Cod-liver oil (crude)	2 mins.	7·9	166
	48 hrs.	196	153
Cod-liver oil (Engelberg's medicinal)	2 mins.	8·6	185
	37 hrs.	121	166
Linseed oil	2 mins.	6·3	188
	48 hrs.	67·9	181
Rape oil (deodorised)	2 mins.	5·0	114
	48 hrs.	65·8	115

The conversion of "pro-absorptive" acids into "absorptive" acids in vivo.

Feeding experiments. The feeding experiments extended over the late winter and early spring seasons of 1933 and 1934, the absorption of the butter acids on each occasion having reached its minimum level as a result of the fact that the cows had subsisted on stall feeding since the previous autumn. The oils, or oil fractions, were usually fed twice daily. The butters were prepared, the fats rendered and the fatty acids prepared according to routine methods[1].

---

[1] A "pro-absorptive" fat or fatty acid is one which itself possesses little specific absorption but is capable of being converted into one which possesses such absorption, either *in vitro* or *in vivo*.

Experiments of Series I (1933). *The effect of feeding crude cod-liver oil and crude sardine oil on the absorptive properties of the mixed butter acids.* Two cows (Lena 3 and Welcome 7) were given 2 ozs. of crude cod-liver oil twice daily on March 14th, 3 ozs. on March 17th and 4 ozs. on March 20th, from which date 8 ozs. per day was continued in two doses till the end of the experiment. Two other (Flora 6 and Winsome 2) were given similar doses of crude sardine oil. The butter fats of Lena 3 and Welcome 7 were compounded, but since Winsome 2 took her sardine oil incompletely her butter was not compounded with that of Flora 6. By an oversight no samples of butter were taken from any of these cows to establish that the absorption of the butter acids had actually reached the typical winter level before the commencement of dosing. The results obtained during oil feeding may be compared however with those obtained upon butter given by the same cows after the cessation of dosing, or upon the butter given by the typical herd receiving the basal ration only during the period of dosing. The results obtained are given in Table II. It will be seen that as the result of feeding either cod-liver oil or sardine oil the absorption of the butter acids was greatly increased

Table II. *Exp. 1. Crude cod-liver oil and crude sardine oil feeding.*

Cows	Date of collection of milk	Remarks	$E/230$ of mixed acids
Typical herd	March 31–April 4	No oil given	13·1
Lena 3 and Welcome 7	March 30–April 3	4 ozs. cod-liver oil twice daily	48·4
Lena 3 and Welcome 7	April 20	After discontinuation of cod-liver oil feeding	18·0
Flora 6	March 30–April 3	4 ozs. sardine oil twice daily	42·8
Winsome 2	March 30–April 3	4 ozs. sardine oil twice daily, badly consumed	28·6
Flora 6 and Winsome 2	April 20	After discontinuation of sardine oil feeding	12·0

Experiments of Series II (1934). *Feeding experiments with linseed oil and rape oil.* Two cows (Flora 16 and Flora 20) were first given twice daily 2 ozs. of deodorised rape oil on February 19th, on March 6th this was increased to 3 ozs. and on March 9th to 4 ozs. On March 14th the rape oil feeding was discontinued and 3 ozs. of linseed oil were given twice daily to each cow. This was increased to 4 ozs. on March 16th. Since the sample taken during the feeding of linseed oil was prepared from milk collected 13 days after the discontinuation of the rape oil, there would appear to be little danger of the previous diet seriously affecting the result obtained. In this experiment also control samples were unfortunately not taken before the commencement of dosing, but the average value for specimens collected daily between April 7th and April 12th (about 1 week after the discontinuation of linseed oil feeding) may be accepted as a normal control.

The value $E/230 = 14{\cdot}4$ obtained for the butter acids during the rape oil period was only slightly higher than the value observed for acids obtained from the same cows after the discontinuation of dosing, and it is doubtful whether it was significantly higher than values around 10 which we would consider typical for winter butter fat. The value (20·0) obtained for the acids during the feeding of linseed oil showed a definite increase well beyond the range of experimental error.

---

[1] Since our experimentswere not all carried out with the same immediate object in view it is unavoidable that there should be some lack of uniformity in the collection and presentation of results. Thus in some experiments the effect of feeding oil has been examined only by taking single specimens of butter fat at arbitrary periods after the commencement of oil feeding, in other experiments specimens have been collected daily over considerable periods.

Table III.

Cows	Inclusive dates of collection of milk	Remarks	*E*/230 of mixed acids
Flora 16 and Flora 20	p.m. March 13–a.m. March 14	4 ozs. of rape oil twice daily	14·4
Flora 16 and Flora 20	p.m. March 27–p.m. March 28	4 ozs. of linseed oil twice daily	20·0
Flora 16 and Flora 20	April 7–April 12	Average value over the period mentioned. Linseed oil feeding discontinued on March 30, p.m.	11·8

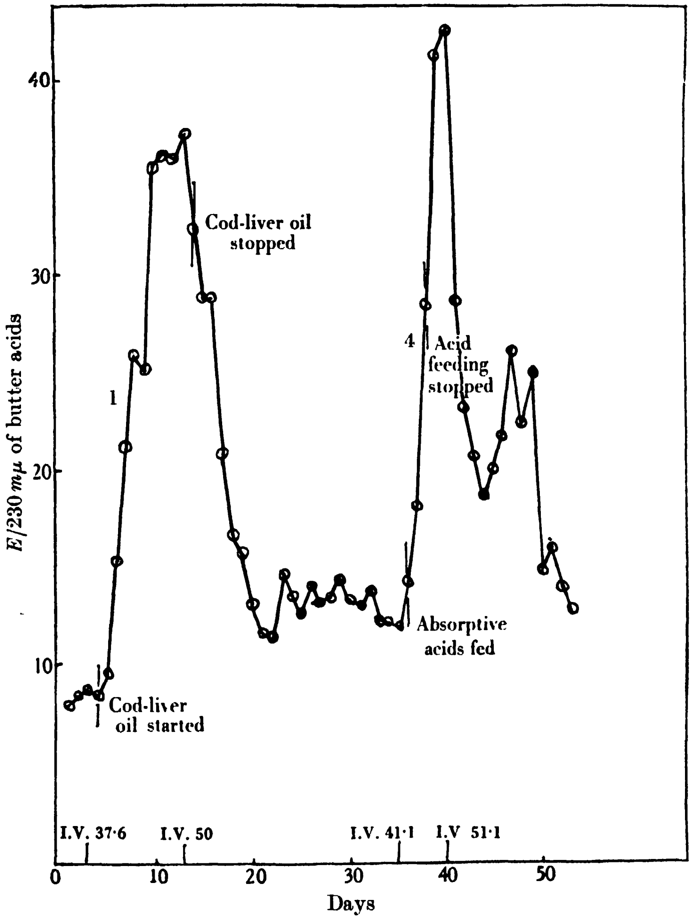

Fig. 1. Welcome 7. (1) Cod-liver oil feeding; (4) absorptive acid feeding.

Experiments of Series III (1934). *The feeding of medicinal cod-liver oil* (*Engelberg's*). In this series of experiments specimens of the butter acids were prepared daily. It has therefore been possible to study the time which elapses before foreign acids appear in the butter fat and before their disappearance after the cessation of dosing. The results obtained in the various experiments are shown graphically in Figs. 1 and 2.

(1) *Whole oil feeding* (Welcome 7, Fig. 1). Dosing was commenced at the rate of 2 ozs. twice daily, subsequently raised to 3 ozs. twice daily. The feeding of the cod-liver oil resulted in an extremely rapid rise in the absorption of the mixed butter acids. From an average value of 8·4 on the 3 days preceding dosing, $E/230$ for the mixed acids rose to 15·4 on the third day of dosing and to 35·2 on the seventh day of dosing. At this point a maximum value for the particular level of dosing appeared to have been reached. After 11 days on cod-liver oil, dosing was discontinued, with the result that the absorption of the acids fell almost as rapidly as it had risen. It may be noted, however, that the absorption did not quite return to the level observed before dosing began and also showed a number of minor fluctuations during the post-experimental period. Iodine value determinations on selected specimens of butter acids taken just before dosing and at the point when the absorption of the fatty acids had reached its maximum gave values of 37·6 and 50 respectively, the former value being about the usual level for winter acids.

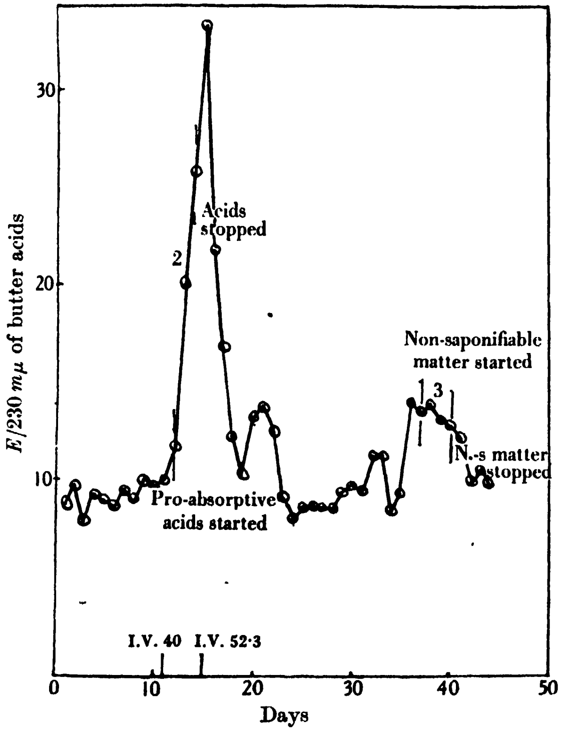

Fig. 2. Lottie 5. (2) Pro-absorptive acid feeding; (3) non-saponifiable matter feeding.

(2) "*Pro-absorptive*" *acid feeding* (Lottie 5, Fig. 2). The acids were prepared in bulk by a technique essentially similar to our usual routine method, the time taken over the saponification being kept short by ensuring that the alcoholic potash was at boiling-point before the addition of the cod-liver oil. Previous to dosing, $E/230$ for the mixed acids had shown a value not greater than 10 for 11

days. The cod-liver oil acids were given over a period of 3 days, in doses as follows:

p.m. 8. iii. 34	... ...	2 ozs.
a.m. 9. iii. 34	... ...	2 ozs.
p.m. 9. iii. 34	... ...	3 ozs.
a.m. 10. iii. 34	... ...	3 ozs.
p.m. 10. iii. 34	... ...	3 ozs.
a.m. 11. iii. 34	... ...	1·5 ozs.
	Total ...	14·5 ozs.

On the second day of dosing $E/230$ had risen to 20·0. The maximum value: 33·3, was reached one day after the cessation of dosing, after which the absorption fell rapidly. As in the previous experiments there were several minor fluctuations in the absorption during the post-experimental period. Iodine value before dosing 40, at point of maximum absorption 52·3.

(3) *Feeding of the non-saponifiable residue* (Lottie 5, Fig. 2). The crude unsaponifiable matter obtained by evaporation of the ether extracts of the soaps during the preparation of the acids was fed in doses calculated to correspond to the amounts of acids previously given. The period of dosing happened to correspond with a minor upward fluctuation in the "absorptive" power, probably related to previous acid feeding, otherwise the values obtained showed no divergence from the normal winter level.

(4) *Feeding experiments with "absorptive" acids* (Welcome 7, Fig. 1). The "pro-absorptive" acids ($E/230 = 8·6$), after preparation in the manner described above, were converted into the "absorptive" acids ($E/230 = 121$) by boiling for 37 hours with alcoholic potash. The doses given were the same as the doses of "pro-absorptive" acids described in (2), and 14·5 ozs. were fed over the period p.m. 23. iii. 34—a.m. 26. iii. 34.

The absorption of the butter acids rose rapidly, reaching a maximum value ($E/230 = 42·4$) 4 days after the commencement, and 2 days after the cessation, of dosing. The fall of the absorption from the maximum value was checked by a considerable upward fluctuation of several days' duration. Iodine values—before dosing 41·1, at point of maximum absorption 51·1.

The behaviour of the butter acids on treatment in vitro *by boiling with alcoholic potash.* In order to gain some insight into the proportion of "pro-absorptive" acids secreted in the butter fat, selected specimens from the group of butters described above were submitted to prolonged treatment with alcoholic potash, which was calculated to increase the absorption by significant amounts if "pro-absorptive" acids were present in quantity. The results obtained are given in Table IV. It will be seen that in no case was there more than a slight rise in the absorption as a result of this treatment. The behaviour of the acids was thus the same as that of the acids from normal winter or summer butter [Booth *et al.*, 1935].

Table IV.

	Butter fat acids		
Material given to cows	Time of treatment	$E/230$	I.V.
"Pro-absorptive" acids of cod-liver oil	2 mins.	33·3	52·3
	48 hrs.	26·5	46·5
Linseed oil	2 mins.	20	49·6
	48 hrs.	23·4	51
Rape oil	2 mins.	14·4	49·5
	48 hrs.	17·9	49·1

Differentiation between the "absorptive acids" and the "inhibitory substance" of the antimony trichloride test. Experiments, which need not be described in detail, have demonstrated that while the absorption of acids from butter fats of cows fed on linseed oil, cod-liver oil or sardine oil might be equal to or greatly exceed that of normal summer acids, the inhibitory power was invariably much lower.

DISCUSSION.

The conversion of "pro-absorptive" into "absorptive" acids. The above experiments demonstrate that certain fatty acids characterised by a slight absorption in the far ultra-violet ("pro-absorptive acids") can be converted *in vivo* and *in vitro* into acids having a much stronger absorption in the same region. The change can be brought about either by feeding the fatty acids (or the fat) to the cow or by treating the acids for long periods with caustic potash. For the present it must remain doubtful whether the changes occurring *in vivo* and *in vitro* are identical in all respects, but as a working hypothesis it will be assumed that the two processes are similar. Since the absorption of the butter acids from cows receiving ordinary diets or dosed with various oils shows no significant increase after prolonged treatment with potash, it seems probable that almost the whole of the ingested acids capable of transformation into the strongly absorbing substance either undergo the transformation or are not secreted into the milk.

Quantitative aspects of the transformation. The increase in the absorption of the fatty acids from the various oils brought about by treatment with caustic potash is self evident. On the other hand, the increased absorption of the fatty acids of the butter following the ingestion of the oils might seem to be explicable on other grounds than the transformation of "pro-absorptive" into "absorptive" acids. Two such alternative explanations may be advanced, but both can be excluded by examining the data quantitatively. In the first place it might be considered that the increased absorption was essentially due to the depression in the actual amount of butter fat secreted, on the assumption that the depression might take place at the expense of the non-absorbing constituents of the butter acids. Since however the depression seldom amounted to more than 30 %, while the absorption was sometimes increased 4–5 fold, it is obvious that this explanation would be inadequate. Secondly it might be argued that the increased absorption of the mixed butter acids over that of the ingested fat might be due not to an actual increase in the specific absorption of the ingested acids, but to the concentration in the milk fat of highly absorbing components present in low concentration in the ingested acids. This explanation also fails, however, since the increased absorption of the butter acids, calculated on weight basis, was always much greater than the absorption present in the ingested acids. To illustrate this point we may take the figures for Lottie 5, which was given a preparation of the acids of cod-liver oil in the "pro-absorptive" state. If we study the "absorption units" secreted in the butter acids during a 12-day period commencing with the 3 days during which the acids were administered, we may draw up the following balance sheet:

		$E/230 \times$ g. units
Absorption units secreted in butter acids. (Calculated by multiplying the daily butter acid yield in g. by the daily value for $E/230$.)		82,000
Allowance for basic absorption due to butter on winter scale (calculated by multiplying the total butter acid yield over the 12 days (5050 g.) by the average value for $E/230$ over 11 days preceding dosing (9·2))		46,000
Increase due to cod-liver oil acid feeding	=	36,000
Absorption present in cod-liver oil acids as ingested (411 g. having $E/230 = 8·6$)	=	3,500

The increase in absorption of the mixed acids of the butter fat was therefore about 10 times greater than the absorption of the ingested acids.

The nature of the change involved. At the present stage little can be said about the nature of the acids capable of showing increased absorption. Judging however from the limited experience of Dann and Moore [1933] it appears probable that the property is confined to acids having two or more unsaturated linkages. As to the cause of increased absorption, it appears probable that intramolecular changes take place. The possibility that oxidative changes might be involved appears to be ruled out by (1) iodine value determinations. In the *in vitro* experiments, the absorption rose to high values with little and in some cases no fall in the iodine value. This would indicate that only small amounts of oxidation products can have been formed. If these were responsible for the increased absorption, then the specific absorption must have been of an unusually high order. (2) Preliminary experiments have indicated that the "absorptive" acids are themselves unstable to oxidation and are therefore unlikely to be the end-products of an oxidative reaction. Thus when the mixed acids of cod-liver oil were first converted into the "absorptive" state by prolonged treatment with potash and then aerated for 24 hours at 95°, $E/230$ fell from 121 to 20·6. (3) Oxidative treatment of the "pro-absorptive" acids from cod-liver oil increases slightly the extinction coefficient at $230 m\mu$, but the characteristic band at that wave length is no longer evident, and the absorption is non-specific end absorption. The above evidence, of course, does not rule out the possibility of oxidative changes of the peroxide formation type, if those changes can be visualised as occurring without affecting the iodine-absorbing capacity of the unsaturated linkages.

The rapidity of transference of exogenous fats to the milk fat. As a point of secondary interest the above experiments provide a good illustration of the great rapidity with which foreign fats may be secreted in the milk fat, since when cod-liver oil, or preparations of its acid fraction, were administered, a distinct rise in the absorption of the butter acids could always be detected on the following day. The presence of the cod-liver oil acids in the butter fat could be readily observed by the formation of dark brown soaps on treatment of the fat with alcoholic potash. This is a property of the cod-liver oil acids, whereas the acids of butter fat form colourless soaps when obtained from cows subsisting under normal nutritional conditions.

SUMMARY.

1. In the mixed acids prepared from cod-liver oil, sardine oil, rape oil and linseed oil the absorption of radiation at wave length $230 m\mu$ is small. When the oils were fed to the cow the acids secreted in the butter fat possessed much greater absorption in this region.

2. A similar increase in absorption could be brought about by the prolonged boiling of the "pro-absorptive" acids with alcoholic potash.

3. The change from slightly absorbing ("pro-absorptive") acids to strongly absorbing acids is not an oxidative one; it is postulated that a molecular rearrangement occurs with production of an isomeric form.

Our thanks are due to Dr L. J. Harris and Prof. H. D. Kay for their valuable criticism.

APPENDIX.

Samples of two of the butters examined in the above experiments, and also two other samples not examined were sent to Prof. T. P. Hilditch who has kindly sent the following analyses: (Letter dated May 11th, 1934.)

Cow or cows ...	Gertie 3	Flora 16 Flora 20	Flora 16 Flora 20	Portia 3
Oil fed ...	None (control)	Rape oil	Linseed oil	Cod-liver oil
Milk collected from	p.m. 14. iii. 34	p.m. 13. iii. 34	p.m. 27. iii. 34	a.m. 17. iii. 34
to, inclusive	a.m. 16. iii. 34	a.m. 14. iii. 34	p.m. 28. iii. 34	p.m. 18. iii. 34
Reichert-Meissl value	33·6	28·5	28·9	16·0
Polenske value	3·3	1·8	2·1	1·4
Kirschner value	24·3	21·7	22·4	13·9
Saponification equivalent	239·2	251·2	249·3	264·2
Iodine value	34·5	44·5	46·0	51·7

Prof. Hilditch quoted these figures at the Meeting of the British Association at Aberdeen. He said, "These results indicate sufficiently clearly that intake of fatty oil by the cows may cause considerable modification of the milk fat; the influence of cod-liver oil on the character of the butter fat is especially marked in its diminution of the most volatile acids and the 50 % increase in mean unsaturation as compared with the control."

XIX. VITAMIN A AND CAROTENE.

XII. THE ELIMINATION OF VITAMIN A FROM THE LIVERS OF RATS PREVIOUSLY GIVEN MASSIVE DOSES OF VITAMIN A CONCENTRATE.

By ALAN WILLIAM DAVIES and THOMAS MOORE.

From the Dunn Nutritional Laboratory, University of Cambridge and Medical Research Council.

(*Received November 30th, 1934.*)

In a previous paper [Davies and Moore, 1934] we presented data showing that very high concentrations of vitamin A may be attained in the liver of the rat when large amounts of vitamin A concentrate are included in the diet. It was calculated that the amount of vitamin A stored might represent as much as 5 % of the dry weight of the liver, and be sufficient, if used economically, to satisfy the normal requirements of the animal for a theoretical period of about 200 years. The experiment to be described below was carried out to decide whether this theoretical economy would hold good in practice, or whether the reserve would be dissipated more rapidly. Under the particular experimental conditions adopted, the second alternative has been found to be correct.

EXPERIMENTAL.

32 female piebald rats were used. Until 10 months old they had been employed for breeding purposes, receiving a mixed dietary which included milk, liver (once weekly), green vegetables and carrots in sufficient amounts to permit the accumulation of a very high concentration of vitamin A in the liver even without further treatment. After retirement from breeding they were given the same mixed diet until 18 months old, when they were taken for use in the present experiment.

Preliminary "saturation" of the liver with vitamin A. With the exception of 3 animals, which were used in determining the level of the vitamin A reserve attained on the previous mixed diet, all the rats were now given a diet containing large amounts of vitamin A concentrate ("light white casein" 20 %, sugar 50 %, coconut oil containing vitamin A 25 %, salt mixture 5 %, dried yeast 10 %, wheat germ 5 %). The amount of vitamin A was adjusted so that 10 g. of diet contained 2 mg. of vitamin A concentrate (=6000 B.U.). Groups of three rats were killed at intervals, and the vitamin A reserves per g. of liver were determined by our usual method [Davies, 1933]. Although the feeding of this diet was continued for 12 weeks the liver reserves, as indicated by the mean values of the groups of three animals, rose only slightly (about 25 %) above the level attained on the mixed dietary. At this level a maximum value for these particular conditions of feeding appeared to have been reached.

The mean vitamin A reserves for each group of rats during this period are shown in the ascending part of the graph in Fig. 1. Although the values obtained in the individual rats of each group (see Table I) showed considerable variation from the mean value (usually about 33·3 %), the means for the groups gave a consistent series of values except for one group, which gave an anomalous mean indicated by point *A* in Fig. 1. One of the rats in this group gave an unexpectedly low result (1400 B.U. per g. as compared with the expected mean of 14,000 B.U. per g.).

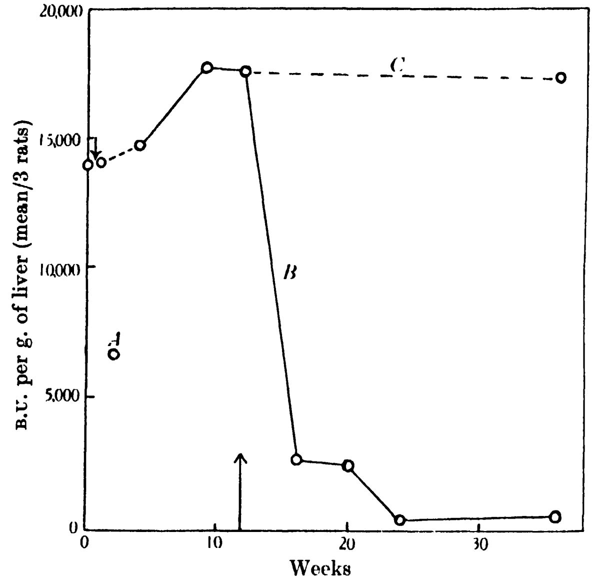

Fig. 1. *B*, Actual rate of decline. *C*, Calculated rate of decline of liver reserve assuming expenditure to be in accordance with physiological requirements. ↑ Rats given vitamin A-free diet. ↓ Rats given large amounts of vitamin A concentrate.

Table I.

Weeks from commencement of experiment	Weeks on vitamin A-free diet	Individual vitamin reserves. B.U. per g.			Mean vitamin A reserve B.U. per g.	Remarks
0	—	7,400	16,000	19,000	14,000	As taken from breeding stock
1	—	11,000	19,000	11,000	14,000	Vitamin A concentrate given
2	—	1,400	11,000	8,000	6,700	do.
4	—	1,100	16,000	17,500	15,000	do.
7	—	10,500	24,000	19,000	18,000	do.
12	—	14,000	20,000	19,000	18,000	do.
16	4	3,500	3,500	1,100	2,700	Vitamin A-free diet
20	8	2,500	2,500	2,400	2,500	do.
24	12	460	250	475	400	do.
36	24	600	500	470	500	do.

Dissipation of the vitamin A reserve on a diet deficient in vitamin A. The surviving rats were next given a diet having a composition similar to that recently proposed for use in vitamin A tests by Morgan[1] [1934] (extracted meat meal 10 %, coconut meal 30 %, ground rice 48 %, dried yeast 8 %, salt mixture 4 %, radiostol 1 drop per rat per week). This diet was found to be virtually free from vitamin A by independent growth tests with young rats.

[1] Our thanks are due to Lever Brothers, Ltd. for the gift of the special materials used in this diet.

Groups of three rats each were killed after they had received the vitamin A-free diet for periods of 4, 8, 12 and 24 weeks. The rapid fall in vitamin A reserves is shown in the descending part (*B*) of the graph in Fig. 1. After 4 weeks the mean liver reserve was found to have fallen to about $\frac{1}{6}$ of its previous value (2700 B.U. per g. as compared with 18,000 B.U. per g.), after 8 weeks the mean value (2500 B.U. per g.) was much the same as after 4 weeks, but after 12 weeks there was a further fall to 400 B.U. per g. The value obtained after 24 weeks (500 B.U. per g.), however, was virtually the same as that observed after 12 weeks, suggesting that a level of more stable storage had now been reached.

DISCUSSION.

The above experiment proves that superfluous reserves of vitamin A held in the liver may sometimes be eliminated at a much greater rate than that demanded to satisfy the known physiological requirements of the organism. In Fig. 1 a broken line (*C*) has been drawn to represent the rate of decrease in the mean vitamin A reserve per g. of liver which would have been expected if the vitamin had been used up at a rate consistent with physiological requirements, on the assumption that $0{\cdot}2\,\gamma$ (or about 1 B.U.) of pure vitamin A per g. of liver would be metabolised daily[1]. It will be seen that the rate of decrease of the mean reserve on this basis would be extremely slow, amounting to less than 1 % of the initial value during the 24 weeks under investigation. In contrast the mean reserve actually fell at the rate of about $100\,\gamma$ (=500 B.U.) of pure vitamin A per g. of liver per day during the first 4 weeks after the adoption of the vitamin A-free diet, while after 12 weeks about 98 % of the initial reserve had been eliminated. At this point there was a definite check in the rate of expenditure of the vitamin, since no further decrease could be detected after a further period of 12 weeks. It may be significant that the level of storage was now of the same order as the value of 250 B.U. per g. which we would consider a typical value for the healthy human being[2].

The above results stand in contrast with those obtained by Dann and Moore [1931], who used rats whose vitamin A reserves had been raised to high levels (up to 7000 B.U. per g.) as the result of their receiving red palm oil, a rich source of carotene. The vitamin A reserves of these rats after they had been restricted for 5–6 weeks to a diet deficient both in vitamin A and B were found to be as high (within the limits of experimental error) as those of similar rats which received the diet containing red palm oil up to the time of killing. Moore [1931] also failed to observe any spectacular reduction below the reputed initial values in the vitamin A reserves of two rats kept for periods of 10 and 68 days on a vitamin A-free diet, although after the longer period it is possible that a deterioration of up to 40 % may have occurred. From Fig. 1 the reduction during the same period in the present experiments must have amounted to 90 %.

Two explanations of the divergence between the present results and those obtained in previous work are possible. The more rapid decline of the vitamin A reserve in the present experiments may be due either to the use of a different form of vitamin A-free diet, or to the fact that the reserves were built up from alimentary supplies of preformed vitamin A instead of carotene which was used in the previous work. Both these possibilities are now under investigation, but in view of the time-consuming nature of the work we have thought it advisable to publish an account of our results at their present stage of development.

---

[1] This estimate is more generous than that previously assumed [Moore, 1931].

[2] Data kindly made available by Dr A. Leese indicate that the vitamin A reserves per g. of liver in wild rats, as determined for specimens caught in the Edinburgh Zoological Gardens, are of about the same order as in the human being.

As a point of secondary interest arising in the course of the present investigation, we may draw attention to the extremely high level which the vitamin A reserve of the liver of the rat may reach in rats receiving an ordinary dietary containing carrots, green vegetables and moderate amounts of liver. According to our observations the concentration of vitamin A produced under such conditions is only slightly lower than that which may be obtained by the feeding of vitamin A concentrate.

SUMMARY.

Adult rats, already possessing high liver reserves of vitamin A, were given a diet containing massive doses of vitamin A concentrate. The liver reserves under these conditions reached levels having a mean value of about 18,000 B.U. per g., representing a supply sufficient to satisfy the theoretical requirement of the rat for about a century, if used up at a rate corresponding to the minimum physiological requirements.

When the rats were subsequently restricted to a diet free of vitamin A, however, a rapid elimination of vitamin A from the liver took place, the mean vitamin A reserve falling to 400 B.U. per g. after 12 weeks. At this level a condition of stable storage of the vitamin appeared to have been attained, since no further fall in the mean reserve could be detected after a further period of 12 weeks of restriction to the vitamin A-free diet.

These results stand in contrast with those obtained in previous experiments carried out in this laboratory, in which a similar rapid elimination of vitamin A from the liver was not observed. The possible causes of the difference are discussed.

Our thanks are due to Dr L. J. Harris for his valuable criticism.

XX. THE AVAILABLE CARBOHYDRATE OF FRUITS

DETERMINATION OF GLUCOSE, FRUCTOSE, SUCROSE AND STARCH

By ELSIE MAY WIDDOWSON and
ROBERT ALEXANDER McCANCE.

From the Biochemical Department, King's College Hospital, London.

(*Received November 24th, 1934.*)

It is now generally recognised that determinations of available carbohydrate in fruits and vegetables are of much more value for dietetic purposes than those of total carbohydrate, whether the latter have been determined by acid hydrolysis or calculated by difference.

Figures for the available carbohydrate of the fruits and vegetables commonly eaten in this country were given by McCance and Lawrence [1929]. An acid hydrolysis was used, followed by a determination of "total" reducing power. Realising, however, that this reduction was partly due to the products from easily hydrolysable pentosans and other non-fermentable sugars, McCance and Lawrence determined these constituents separately and deducted their reducing value from that of the total sugar. The remainder they considered to be available carbohydrate. Their figures in some instances are too low because the strong acid employed and the prolonged time of boiling led to a destruction of a considerable proportion of the fructose. They mentioned that something of this sort was taking place, but considered that for practical purposes the error could be neglected.

A study of the available carbohydrates of fresh fruits has now been made by the most reliable methods which can be obtained. Sucrose, fructose, glucose and starch have each been determined separately. Since these are generally considered to be the only fruit carbohydrates which are absorbed as sugars from the gut, their sum constitutes the available carbohydrate of the fruit. Small amounts of maltose may be present in starchy fruits such as the banana. If this is the case, the error so introduced must be insignificant, since determinations of glucose and fructose by two independent methods have been found to agree. From the nature of the methods employed this would not have been the case if appreciable amounts of maltose had been present (*vide infra*).

Fresh, raw fruits only have been used, and all determinations have been carried out on the edible portion.

METHODS.

Preparation of the fruit. Almost all the fruit has been obtained from the Amalgamated Fruiterers and the Army and Navy Stores. Each variety of English and foreign fruit came from at least four, and usually from six, different sources and was known therefore to have been grown under various soil and climatic conditions. Thus a representative sample of the fruit was obtained. The analyses were all carried out during the 1934 season.

The method used for the preparation and extraction of the fruit was similar to that described by Archbold [1932] for apples. About 3 lbs. of small fruit and 6–8 lbs. of larger varieties were prepared as for eating, and the proportion of waste was determined. The edible portion was then cut up finely and well mixed. Water was determined on duplicate samples of 50 g. by drying to constant weight at 50°.

Duplicate portions of 100 g. were extracted with about 200 ml. of cold 95 % alcohol overnight. The tissue was next extracted with hot 80 % alcohol in a Soxhlet apparatus for about 16 hours, and the alcohol from the united extracts was evaporated off under reduced pressure at a temperature always below 30°. The residue was made up to 200 ml. in a graduated flask (Solution A). Free acid was determined on 20 ml. of this extract by titration with $N/10$ NaOH. Phenolphthalein was used as indicator.

Determination of reducing sugars. 50–100 ml. of Solution A were measured into a graduated 500 ml. flask, diluted with water, almost neutralised with $N/10$ NaOH and cleared with basic lead acetate and saturated sodium phosphate solutions [Archbold and Widdowson, 1931]. The solution was made up to volume and filtered. Reducing sugars were determined in this cleared filtrate (Solution B) by Lane and Eynon's [1923] copper titration method, in which methylene blue is used as an internal indicator. Dilution of Solution B was sometimes necessary before the estimations could be carried out.

Determination of sucrose. Total sugar was estimated in Solution B after inversion with 10 % citric acid for 10 mins. at 100°. The difference between the percentage of total sugar and of reducing sugar, calculated from Lane and Eynon's invert sugar table, gave the percentage of sucrose in the fruit. Preliminary tests on various fruits indicated that the values for sucrose obtained in this way were the same as those obtained after inversion with invertase (see Table I).

Table I. *Sucrose content of fruits after inversion by citric acid and by invertase.*

Results expressed as percentage in fresh material.

Fruit	Sucrose by citric acid	Sucrose by invertase
Gooseberry	0·23	0·22
Banana	4·2	4·3
Apple	2·6	2·7
Lemon	0·34	0·28
Strawberry	1·32	1·32
Tomato	0·0	0·0

Determination of the fructose/glucose ratio. Before carrying out the iodimetric procedure for the determination of the fructose/glucose ratio, it was necessary to decolorise solution B. 100 ml. were boiled with 0·5 g. B.D.H., decolorising charcoal for 1 min. and filtered. This process was repeated until the liquid was colourless. The charcoal was thoroughly washed with boiling water and the filtrate and washings made up to 200 ml. (Solution C). It has previously been shown that this procedure removes only negligible amounts of sugars from solution [Widdowson, 1931]. The iodine value of solution C was determined exactly as described by Archbold and Widdowson [1931]. The fructose/glucose ratio was calculated by solving the simultaneous equations obtained from the iodimetric determination and from the estimation of the reducing power of solution B by Lane and Eynon's copper method.

Fructose has also been determined directly in Solution B in a number of different fruits by the method described by Oppel [1930]. This is a colorimetric method based upon the colour developed when fructose is heated with diphenylamine and strong hydrochloric acid. Since the acid hydrolyses any sucrose present, the value obtained for fructose is the sum of the free fructose and the fructose derived from the sucrose. A standard solution of sucrose was used for the comparisons. Table II shows the amounts of fructose (including free fructose and sucrose-fructose) in a variety of fruits as estimated by the two independent methods.

Table II. *Total fructose in fresh fruits estimated by Fehling's solution and iodine and by diphenylamine.*

Results expressed as percentage of fructose in fresh fruit.

Fruit	Fehling's solution and iodimetric method	Diphenylamine method
Pear	7·9	7·7
Blackberry	3·6	3·6
Grapefruit	2·3	2·6
Pineapple	4·9	5·0
Orange	4·0	4·1
Grape	8·0	7·9
Cranberry	0·8	1·1
Date	29·9	29·4
Banana	6·9	7·0

It will be observed that in most cases agreement is very close. In the case of cranberries the slightly higher results given by the diphenylamine method can be explained by the fact that in this fruit there is a large excess of glucose with which the reagent reacts to a small extent.

Determination of starch. The fresh fruit was in every case tested with iodine in order to detect the presence of starch. Of all the fruits examined, starch was found to be present only in the banana, apple, pear and tomato. The residue remaining after alcoholic extraction of these fruits was dried at 100° overnight and weighed.

The dried residue from the banana was ground up in a mortar and sifted. Duplicate samples of 0·5 g. were weighed out and soaked in 10 ml. water for several hours. It was impossible to grind the residues from the apple, pear and tomato owing to their tough and leathery nature. These were therefore weighed out without grinding and soaked in water as just described. The wet material in each case was ground up in a mortar to a fine pulp and transferred quantitatively to a small flask with a further 40 ml. of water, which was then boiled.

Takadiastase was used to hydrolyse the starch, and the reducing power was determined on the filtrate after clearing with basic lead acetate by Hanes's [1929] modification of the Hagedorn and Jensen ferricyanide technique. Full details have been described by Widdowson [1932].

RESULTS.

The results of the analyses are shown in Table III.

Values are given for the percentages of glucose, fructose, sucrose and starch in the edible portion of the fruits, and the total available carbohydrate is calculated as the sum of these 4 individual carbohydrates. The water content of the fruits is also shown and their titratable acidity. For each fruit a factor is also given. By

Table III. *Available carbohydrate content of fruits.*

Fruit	Percentage in edible portion						Titratable acidity ml. $N/10$ NaOH ≡ 100 g. fruit	Conversion factor	Nature of edible (analysed) portion and waste

multiplying the percentages in the edible portion by the factor, the quantities which would be obtained from the food as purchased can be derived. The final column shows the parts of the fruits which were included in the edible portion.

DISCUSSION.

It will be noticed that only a very small proportion of the ripe fruits contains starch, and even in these cases the amount present is negligible. Bananas are exceptional. 16 % of the total available carbohydrate was present as starch in the samples examined, *i.e.* 3 % of starch in the fresh fruit. It is a well-known fact that the starch/sugar ratio in the banana depends upon the degree of ripeness of the fruit, and quite different results would no doubt have been obtained had unripe or over-ripe fruits been analysed.

Most of the fruits examined contain approximately equal amounts of free fructose and glucose, but apples and pears have much more fructose than glucose, and plums, damsons, apricots and similar fruits and also cranberries contain more free glucose than fructose. Grapes contain glucose and fructose in nearly equal amounts.

A few fruits, notably cherries, grapes, figs, tomatoes, pomegranates and mulberries, contain no sucrose at all. In one or two cases, *e.g.* apricots and peaches, sucrose constitutes the greater part of the total sugar present.

Comparison of the present results with those obtained after acid hydrolysis.

It has been stated earlier in the paper that McCance and Lawrence's [1929] figures for the carbohydrate contents of fruits were too low, owing to a destruction of part of the fructose during the acid hydrolysis. This is shown to be the case by the fact that on boiling a 2 % solution of fructose with hydrochloric acid (5 % by volume), 28 % of the total fructose present was destroyed during the first hour and 48 % after 2 hours. Glucose was almost unchanged by this treatment.

Samples of seven of the fruits used in the present investigation were boiled with 5 % acid for 2 hours and estimated as described by McCance and Lawrence. The results of these determinations are shown in Table IV, Column 1. Column 2 shows the pentose content of fruits and Column 3 the available carbohydrate after deducting the pentose sugars [McCance and Lawrence, 1929]. Taking the

Table IV. *Comparison of available carbohydrate in fruits as determined in the present investigation and after acid hydrolysis.*

Results expressed as percentage of edible portion of fresh fruit.

Pears, cooking	7·9	1·7	6·2	9·5	9·3

* Blackberries have been analysed on 3 occasions. The figure in Table III is the mean of all three analyses, while the figure in this table is the result of one of them.

figures for fructose found in the present investigation (free fructose + sucrose-fructose), and assuming that 50 % of this had been destroyed during the 2 hours' hydrolysis, the figures in Column 3 have been corrected, and the results are shown in Column 4. It will be seen that in almost every case they agree very closely with the present results for total available carbohydrate calculated as the sum of the glucose, fructose, sucrose and starch (Column 5). It is evident therefore, that McCance and Lawrence were justified in deducting the values for pentose sugars, and that their figures for vegetables which contain no fructose were probably correct. Further, McCance and Lawrence's published results were not so much too low as the differences between Columns 2 and 4 suggest, since they took the mean of a 1- and 2-hour hydrolysis, and the present figures were obtained after treating for a full 2 hours with the acid.

SUMMARY.

The glucose, fructose, sucrose and starch in 41 varieties of fruit have been determined.

Sucrose was estimated by the increase in reducing power after inversion.

The glucose/fructose ratio was calculated by solving the simultaneous equations obtained from an iodimetric determination and from the estimation of reducing power by Fehling's solution. Fructose was also determined by diphenylamine with concordant results.

Starch was estimated as glucose and maltose after digestion with takadiastase.

The sum of these four individual carbohydrates was taken to represent the available carbohydrate of the fruit.

Part of the expenses of the investigation has been defrayed by the Medical Research Council. One of us (E. M. W.) is indebted to the Medical Research Council for a part-time grant.

XXI. THE EFFECT OF POTASSIUM ON THE GLUCOLYSIS OF BRAIN TISSUE WITH REFERENCE TO THE PASTEUR EFFECT.

By CHARLES AMOS ASHFORD[1] and
KENDAL CARTWRIGHT DIXON.

From the Biochemical Laboratory, Cambridge.

(*Received November 29th, 1934.*)

Various explanations have hitherto been put forward as to the mechanism of the Pasteur effect. Meyerhof *et al.* [1925] and others have suggested that the lactic acid formed in anaerobiosis is also formed under aerobic conditions, but here removed by oxidation and perhaps resynthesis. Another explanation has been given by Lipmann [1933], who considers that oxygen interferes with the activity of the fermentative or glucolytic enzyme and thus spares glucolysis. It seemed also possible that one of the reactants in the lactic acid-forming reaction (as demonstrated by the work of Embden *et al.* [1933] and Meyerhof and Kieseling [1933] in the case of muscle) might be removed by oxygen. Thus, assuming glucose to split into two molecules a and b which react together to give lactic acid, we have glucose $= a + b = 2$ lactic acid. If either a or b is removed by oxygen, lactic acid formation is lessened, and furthermore one atom of oxygen could prevent the formation of 2 molecules of lactic acid. That is, one molecule of oxygen absorbed prevents 4 molecules of lactic acid from accumulating, and in this way a maximum Meyerhof quotient of 4 could be explained.

In the original project, it was decided in the first place to investigate the effect of adding α-glycerophosphate and pyruvate (which was already known [Bumm *et al.*, 1933; Mendel *et al.*, 1931] to increase anaerobic glucolysis) to tissues in which oxygen was exercising its sparing action on glucolysis. If either of these substances occurred in the normal glucolysis and was removed by oxygen, addition of this substance during aerobiosis might restore and increase the aerobic glucolytic rate.

It was necessary to use for this purpose a tissue with low aerobic glucolysis, and for this purpose brain slices were selected for a start, although it is not believed [Ashford and Holmes, 1929; Ashford, 1933; 1934] that the Embden-Meyerhof scheme for glucolysis obtains in brain tissue. The work reported here is the outcome of these experiments.

Methods.

The tissue employed was the cortex of rabbit's brain. Slices of this were cut immediately after the rabbit was killed. These slices were immersed in 10 ml. of liquid which contained Ringer in normal concentration and 0·025M sodium bicarbonate. In this solution glucose was present in a concentration of 0·2 %, also any substance whose effect on glucolysis was to be determined. This volume of fluid containing the slices was contained in flasks provided with glass stoppers (as described in a previous paper [Ashford, 1934]). Oxygen or nitrogen containing 5 % CO_2 was bubbled through the liquid in which the slices were immersed for about 20 mins. Then the taps were closed and the flasks with their contained slices under physiological conditions were shaken in a bath at 37° for periods of 1, 2 or 3 hours. At the end of the period of shaking the flasks were removed from the bath, and 3 ml. of 20 % trichloroacetic acid were added to the contents of each which were quantitatively filtered and washed into a 50 ml. volumetric flask after standing about 10 mins. The slices contained in each shaking flask were transferred from the filter-paper into weighing bottles and their dry weight determined.

---

[1] Beit Memorial Research Fellow.

The filtrates were made up to 50 ml. with water, and their lactic acid contents were determined, after treatment with copper lime, by Friedemann, Cotonio and Shaffer's [1927] method.

EXPERIMENTAL.

The effect of potassium α-glycerophosphate on the aerobic and anaerobic glucolysis was first studied. This salt was prepared in approximately 4 % solution by treatment of Merck's "Calcium glycerophosphoricum neutrale" with potassium oxalate at 0°. The calcium oxalate was centrifuged off, and the resulting filtrate was tested for freedom from both calcium and oxalate ions by the addition of small quantities of potassium oxalate or calcium chloride. The results of a number of experiments are shown in Table I. It will be seen that the addition of potassium α-glycerophosphate has markedly increased the aerobic glucolysis while at the same time the anaerobic glucolysis is so depressed as to be below the level of the aerobic in the presence of the potassium α-glycerophosphate.

Table I. *Effect of potassium glycerophosphates on anaerobic and aerobic glucolysis.*

All values in mg. lactic acid per g. dry tissue per hour.
The salts used had a final concentration of about 0·7 %.

		Nitrogen		Oxygen		
Exp. No.	Time	Glucose alone	Glucose + glycerophosphate	Glucose alone	Glucose + glycerophosphate	Remarks
1	3 hours	41·0	17·0	15·0	57·0	α-salt
2	3 hours	57·0	25·0	15·5	45·0	α-salt
3	2 hours	66·5	26·0	—	—	α-salt
4	2 hours	59·5	22·0	—	—	β-salt
5	2 hours 10 mins.	62·0	25·6	23·1	57·6	α-salt

The next step was to try the effect of potassium β-glycerophosphate and also the effects of the sodium salts (Tables I and II). In Table I it is shown that

Table II. *Effect of sodium glycerophosphates on anaerobic and aerobic glucolysis.*

All values in mg. lactic acid per g. dry tissue per hour.

Exp. No.	Time hours	Gas	Glucose alone	Glucose + α-glycero-phosphate	Glucose + β-glycero-phosphate	Remarks
1	3	N_2	58·0	85·0	81·0	0·4 % salts
		O_2	26·0	27·0	21·0	,, ,,
2	3	N_2	65·0	61·0	54(?)	0·6 % salts
		O_2	17·0	27·0	24·0	,, ,,
3	3	O_2	12(?)	27·7	21·7	0·9 % salts
		O_2	15·4	16·5	—	0·3 % ,,
4	2	N_2	53·5	—	61·0	0·3 % salts

potassium β-glycerophosphate has the same inhibitory effect on the anaerobic glucolysis as the α-salt. The sodium salts, however, have no effect, except in one case perhaps causing a slight rise in aerobic glucolysis, but not by any means of the same order as that caused by the potassium salt (Table II).

A further step was to see how much of this effect was due to the potassium ion or whether the glycerophosphate was the determining factor. To test this parallel experiments were carried out using potassium α-glycerophosphate and a solution of potassium choride against one another. Table III shows the result of the experiment and makes it clear that this ability to stimulate aerobic glucolysis and to inhibit anaerobic glucolysis in brain is a property of the potassium ion. It has already been noted [Ashford, 1934] that the presence of a potassium phosphate buffer reduces the anaerobic glucolytic rate in brain tissue.

Table III. *Comparison of effects of potassium α-glycerophosphate and potassium chloride on aerobic and anaerobic glucolysis.*

All values in mg. lactic acid per g. dry tissue per hour.
Duration of experiment—2 hours.

Gas	Glucose alone	Glucose + 1·4 % K α-glycero-phosphate	Glucose + 0·9 % KCl
N_2	50	16	9
O_2	13	75	51

Experiments were next performed to determine whether sodium chloride had any similar effect to potassium chloride. It is shown however in Table IV that sodium chloride has no significant effect on glucolysis, while experiments with the same concentration of potassium chloride show the effect in a marked manner.

Table IV. *Comparison of the effects of potassium and sodium chlorides on aerobic and anaerobic glucolysis.*

All values in mg. lactic acid per g. dry weight per hour.

Gas	Glucose alone	Glucose + 0·1*M* NaCl	Glucose + 0·1*M* KCl
N_2	75	66	23
O_2	18	22	61

The effect of variation in concentration of potassium chloride was next studied. In Table V, the results of four experiments with 5 different concentrations of potassium chloride are shown. (It was unfortunately not possible to perform aerobic and anaerobic experiments on the same brain owing to the im-

possibility of obtaining sufficient tissue.) The results are shown in Fig. 1, where the glucolysis is plotted against the logarithm of the potassium chloride concentration, each experiment being plotted as a separate curve. It brings out clearly that the effect of potassium is greatest at a concentration of about $0{\cdot}1M$. The aerobic glucolysis has been increased 200 % while the anaerobic has been reduced 75 %, and it is worthy of note that at this concentration the aerobic glucolysis is 4 or 5 times as large as the anaerobic.

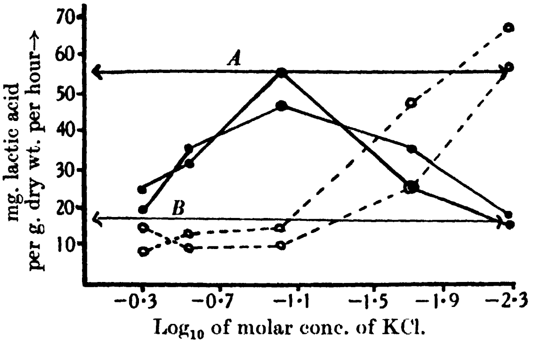

Fig. 1. Relation between anaerobic and aerobic glucolysis and potassium chloride. *A*, average level anaerobic, no KCl. *B*, average level aerobic, no KCl.

●—●—● Aerobic glucolysis. ○– –○– –○ Anaerobic glucolysis.

It would appear probable that at the concentration of normal Ringer, potassium does not exert this effect. Lasnitzki [1933] has shown that the absence of potassium and to some extent of calcium from the incubation fluid markedly reduces anaerobic glycolysis in tumour, but he did not study the aerobic effect. Beebe [1904] and Clowes and Frisbie [1905] have reported high values for potassium content of malignant tumours and these were often associated with low calcium content. Since high aerobic glucolysis is shown by tumours it was decided to ascertain whether glucolysis in brain was affected by the absence of calcium from the Ringer (Table VI). It will be seen that the marked effect of high potassium concentration is not shown by lack of calcium.

Table VI. *Effect of calcium-free Ringer on glucolysis.*

Gas	Medium (containing 0·2 % glucose)	mg. lactic acid per g. dry wt. per hour
N_2	Ringer	65
N_2	Ca-free Ringer	53
O_2	Ringer	13
O_2	Ca-free Ringer	20

It seemed of importance to ascertain whether the addition of pyruvate to brain slices under anaerobic or aerobic conditions would increase the glucolysis and also if the addition of co-ferment T would in any way modify the inhibitory effect of potassium salts on the anaerobic glucolysis, since it has been shown by the work of Mendel *et al.* [1931] and by that of Bumm *et al.* [1933] that in the phenomenon of inhibition by glyceraldehyde, in the case of tumour slices, this inhibition is removed by pyruvate and by co-ferment T. It will be seen from Table VII that in these experiments pyruvate does not increase the aerobic or anaerobic glucolysis. The absence of effect on the latter process is readily ex-

Table VII. *Effects of pyruvate and of pyruvate in the presence of KCl on glucolysis.*

Exp.	Medium	mg. lactic acid per g. dry tissue per hour Anaerobic	 Aerobic
1	Normal Ringer + glucose	83	22
	„ „ + 0·01M pyruvate	81	24
	„ „ + 0·001M „	—	26
2	Normal Ringer + glucose	70	—
	„ „ + 0·1M KCl	18	—
	„ „ + 0·002M pyruvate	69	—
	„ „ + „ „ + 0·1M KCl	20	—

plained by the fact that the glucolytic rate is already very high and is not further increased by addition of co-ferment T. The result is not therefore out of harmony with the work of the authors just cited, since in their experiments with brain tissue the anaerobic rates without pyruvate were usually of a somewhat low order. The absence of effect on the aerobic process is in agreement with Bumm *et al.* [1933]. Evidently oxidative removal of pyruvate does not influence lactic acid formation, since the addition of pyruvate has not increased the aerobic glucolysis. Table VII also shows that pyruvate has no significant effect on the inhibition of anaerobic glucolysis by potassium.

It has previously been shown that *dl*-glyceraldehyde markedly inhibits the anaerobic glucolysis of tumour [Mendel, 1929]. It was decided to see if the large aerobic glucolysis of brain slices in the presence of added potassium chloride was affected by glyceraldehyde. It was considered that if another mechanism of lactic acid formation in aerobiosis were operative here, this mechanism might not be inhibited by glyceraldehyde, as is the normal anaerobic mechanism. The results of experiments to test this point are shown in Table VIII together with the results of an experiment on the effect of glyceraldehyde on both normal anaerobic and aerobic glucolysis. It is apparent that the high aerobic glucolysis in the presence of potassium salts is inhibited by glyceraldehyde as is the normal anaerobic glucolysis. Further it appears that the aerobic glucolysis in the absence of potassium is also inhibited, though, owing to the small absolute value of the aerobic glucolysis, this can hardly be said to be proved.

Table VIII. *Effects of* dl-*glyceraldehyde and of glyceraldehyde with KCl on glucolysis.*

Exp.	Medium	mg. lactic acid per g. dry tissue per hour Anaerobic	 Aerobic
1	Normal Ringer + glucose	55	11
	„ „ + 0·03 % glyceraldehyde	4	6
2	Normal Ringer + glucose	—	15
	„ „ + 0·03 % glyceraldehyde	—	6
	„ „ + 0·1M KCl	—	40
	„ „ + „ „ + 0·03 % glyceraldehyde	—	6

Reversibility of the potassium effect.

The question as to whether these effects of addition of potassium are reversible has been investigated. The experiments are recorded in tabular form in

Table IX. *Experiment to test the reversibility of the potassium effect.*

All fluids contained 0·2 % glucose.

No. of flask	Gas	Media and procedure	mg. lactic acid per g. dry tissue per hour
1	N_2	Ringer + 0·1*M* KCl, stopped after one hour	19
2	O_2	As flask 1	60
3	N_2 then O_2	Ringer + 0·1*M* KCl, for one hour in N_2, then O_2 bubbled through and incubated for one hour further	17 (in 2nd hour)
4	N_2	Ringer + 0·1*M* KCl for one hour, then slices to flask 5	19
5	N_2	Ringer (no KCl) + slices from 4, for one more hour	4
6	O_2	Ringer + 0·1*M* KCl, for one hour, then slices transferred to flask 7	44
7	O_2	Ringer (no KCl) + slices from 6 for one more hour	20

Table IX, the numbers of the glass flasks in which the slices were incubated and their contents, gaseous and fluid are given, and the glucolysis is also recorded. From the value of the glucolysis in flask No. 3, we see that admitting O_2 to slices which have been in N_2 and KCl for 1 hour fails now to establish a high glucolytic rate, since only 36 mg. of lactic acid per g. dry weight are formed in No. 3, and 19 mg. of this have been formed in the first hour as in No. 1, 17 mg. having been formed in the second hour in O_2 and KCl. Also the high normal anaerobic glucolysis is not re-established in normal Ringer after the tissues have been incubated anaerobically for 1 hour with added KCl; this is seen from Nos. 4 and 5. On transferring tissues from Ringer with KCl, in which they have been for 1 hour, to normal Ringer, all under aerobic conditions, we see that the aerobic glucolysis now falls approximately to the normal level; this is shown by the figures for Nos. 6 and 7.

It appeared necessary to ascertain if the glucolysis in the second hour when tissues are transferred to another medium, is as high as in the first hour in the original medium, accordingly the experiment recorded in Table X was performed.

Table X. *Effect on glucolytic rates of transferring tissues from one medium to another.*

All fluids contained 0·2 % glucose.

No. of flask	Gas	Media and procedure	mg. lactic acid per g. dry tissue per hour
1	N_2	Ringer, then tissues to flask 2 after one hour	73
2	N_2	Ringer, slices from 1 for another hour	56
3	N_2	Ringer + 0·1*M* KCl for one hour	31
4	N_2	Ringer + 0·1*M* KCl + slices from flask 3 for a further hour	13
5	N_2	Ringer + 0·1*M* KCl for one hour	28
6	O_2	Ringer + 0·1*M* KCl + slices from flask 5 for a further hour	10

Nos. 1 and 2 show that lactic acid formation in normal Ringer falls off to some extent on transferring the tissues from their original fluid. Nos. 3 and 4 demonstrate a falling off in KCl under anaerobic conditions, while Nos. 5 and 6 show again that admission of O_2 to slices which have been an hour in KCl and N_2 cannot restore the high glucolytic rate seen in KCl and O_2.

From these experiments it is seen that the inhibition caused by KCl and N_2 is associated, at any rate after exposure for 1 hour to 0·1*M* KCl, with an irreversible change in the cells, so that they cannot regain a high glucolysis. Also it appears that tissues placed in normal Ringer after having been incubated in O_2 and KCl can now only show their normal low aerobic glucolysis (Nos. 5 and 6). It has been shown that the glucolysis in the second hour in O_2 and KCl is of the same order as in the first, this is seen from figures showing the glucolytic rate calculated from experiments of 1 hour's duration, which give similar figures to the earlier experiments of 2 hours' duration. This is also seen from Table XI where two experiments of 1 hour's duration are recorded.

Table XI. *Glucolytic rates in experiments of one hour's duration only.*

All fluids contained 0·2 % glucose.

Gas	Medium	mg. lactic acid per g. tissue per hour Exp. 1	 Exp. 2
N_2	Ringer	48	64
N_2	„ $+0{\cdot}1M$ KCl	18	25
O_2	Ringer	23	31
O_2	„ $+0{\cdot}1M$ KCl	47	75

Since very high glucolysis is observed in O_2 and KCl, and it has previously been suggested that the lactic acid formed in N_2 is removed in O_2 [Holmes, 1930; Krebs, 1931], it seemed of importance to see if the aerobic removal of lactic acid were inhibited by KCl. Accordingly the rate of disappearance of 0·05 % lithium lactate was measured both in presence and absence of potassium. The figures recorded (Table XII) show that the aerobic removal under conditions similar to those of the former experiments is of a very low order but is not markedly affected by potassium.

Table XII. *Oxidative removal of lactic acid in presence and absence of 0·1* M *potassium chloride.*

Exp. No.	Duration hours	mg. lactic acid removed per g. dry tissue Ringer alone	 Ringer $+0{\cdot}1M$ KCl
1	2·5	17	21
2	2·0	25	32
3	2·0	36	36

It was attempted to ascertain if any intermediaries accumulated in the presence of potassium salts both in O_2 and N_2. The trichloroacetic acid extract when tested for pyruvic acid by the nitroprusside reaction was negative, nor did potassium influence the bisulphite-binding capacity of the extract, which was in any case small.

One further point has been investigated. Dodds and Pope [1933] showed that 2 : 4-dinitro-*o*-cresol increased the metabolic rate of mice and Dodds and Greville [1934] have shown that this substance increases both respiration and aerobic glucolysis in tumour tissue. They did not study the effect on anaerobic glucolysis. It would seem possible that potassium salts might also affect in some way the respiration of brain slices. An earlier preliminary experiment in the Barcroft manometer and in phosphate buffer had suggested that this was not the case, and the point was not pursued, except to show that the rate of lactic acid oxidation was not affected in the presence of potassium, at any rate in bicarbonate buffer. Some manometric experiments have now been made using the Warburg indirect method and simultaneous measurements of oxygen consumption and aerobic glucolysis and also anaerobic glucolysis have been carried out. The results shown in Table XIII amply bear out our results obtained by the chemical method, namely that anaerobic glucolysis is inhibited, while aerobic glucolysis is markedly increased, by 0·1M KCl. Further the very interesting fact emerges that the respiration is also increased by values which range from 50 to 200 % of the normal respiration. Except in Exp. 1, there is no apparent correlation between the increase in respiration and the increase in aerobic glucolysis, which might suggest that in the presence of potassium there is a general stimulation of the aerobic metabolism of the cell and that this increased aerobic glucolysis is one method of manifestation of this phenomenon. The significance of these results is discussed again later. It will be noticed (Table XIII) that the

aerobic glucolysis in the absence of potassium chloride is practically zero, whereas our chemical estimations of $Q_L^{O_2}$ vary from 2·5 to 5·0. Such figures correspond to 10–20 mg. lactic acid per g. of dry weight. This discrepancy is almost certainly due to the fact that some lactic acid remains even in the washed tissue slices and of course is estimated in the chemical determinations, whereas the manometric method is unaffected by initial lactic acid in the tissue.

These results also show that the addition of M/10 KCl inhibits the "Pasteur reaction" in brain tissue, if we accept as a criterion of this inhibition a rise in aerobic glucolysis without any fall in respiration (see Dickens [1934] for further discussion on this point). Moreover, this inhibition is largely reversible as is seen from Exps. 4, 5 and 6 in Table XIII. In each of these the same tissue slices were used throughout. After a period of one hour in the Warburg pots containing Ringer and KCl, the slices were transferred to a second pair of pots containing Ringer without excess KCl, after, of course, washing in normal Ringer. In Exps. 5 and 6, a second transfer back to Ringer and KCl was effected. The manometric results obtained during these periods in different media show that the high aerobic glucolysis and oxygen uptake, characteristic of the slices in KCl, fall to lower and normal values when KCl is no longer in the medium and return again to the high values when $M/10$ KCl is again present. The effect of KCl on the aerobic process is therefore reversible.

One point should be mentioned in connection with these experiments. In Exp. 6 only pots containing a small volume of fluid were employed after the first transfer, so that O_2 uptake was not determined. However, a value for aerobic glucolysis ($Q_L^{O_2}$) can be obtained since the volume used was only 1·5 ml. and it is assumed that none of the CO_2 liberated was retained. How far this assumption is warrantable is shown by comparing the value of $Q_L^{O_2}$ calculated by this simple method with the values obtained by the complete indirect method with pots containing both large (5·5 ml.) and small (1·5 ml.) fluid volumes as shown in Exps. 4, 5 and 6. The values obtained with the simplified method are indicated with an asterisk.

Discussion.

The main result of these experiments, namely, that the anaerobic glucolysis is markedly decreased by the addition of K salts while the aerobic glucolysis is raised to be several times as large as the anaerobic, is hard to explain. It would seem possible that the potassium would merely inhibit the Pasteur reaction and so raise the aerobic glucolysis. At the same time this concentration of potassium might also inhibit the anaerobic glucolytic system. The explanation would only be feasible if the aerobic glucolysis were raised and the anaerobic glucolysis lowered until they attained one and the same level. It cannot possibly be put forward, however, in view of the fact that so far from attaining the same level the aerobic glucolysis is several times as large as the anaerobic in the presence of added potassium.

A possible explanation is that the large formation of lactic acid in the presence of KCl is due to a different system coming into play from that occurring in normal anaerobic glucolysis. One could assume that owing to the presence of potassium some substance in the normal glucolytic chain accumulates slightly, in that its further reaction is inhibited. If, however, this substance could be oxidised directly to lactic acid, then formation of lactic acid would occur in oxygen. Lactic aldehyde is a substance which on oxidation would give lactic acid; it would be interesting to ascertain the effect of this substance on brain slices in view of the fact that it is known to disappear in liver "brei" as does methylglyoxal [Neuberg, 1913]. An argument which militates against a second method of lactic acid formation occurring in O_2 and KCl is that this glucolytic system like the normal anaerobic mechanism is inhibited markedly by glyceraldehyde. However, glyceraldehyde may act at some earlier point common to both mechanisms.

Another possibility, which Dr H. A. Krebs has put before us, is that KCl acts by injury to the slices, thus damaging the glucolytic mechanism, and that this damage is greater in N_2 than in O_2 where only the Pasteur effect is eliminated. This would explain the non-recovery of high glucolysis in N_2 on placing slices again in normal Ringer after they had been incubated in N_2 and KCl for 1 hour, and also the failure to obtain high glucolysis on bubbling O_2 through the medium in which slices were suspended which had been previously incubated anaerobically in the presence of potassium. However, since normally glucolysis occurs to such a high extent under anaerobic conditions, and also since anaerobiosis alone does not seem to kill the brain cells quickly in the presence of glucose, it is difficult to see how the mere presence of O_2 should impede the damage to the cells by potassium when KCl in O_2 does not cause this damage.

It would seem probable that the damage is connected with the inhibition of glucolysis by potassium. Under aerobic conditions there is still a mechanism of lactic acid formation, and this, or oxidation of other substances, may give the cells a necessary metabolic reaction. In N_2, however, glucolysis can no longer proceed, and so the cells are injured irreversibly, perhaps as they have no longer a means of obtaining the energy necessary for life. In this regard it is interesting that Dickens and Greville [1933] have shown that incubating brain slices at 38° for as short a time as 20 mins. anaerobically and without glucose destroys all but 12 % of their power of glucolysis when glucose is added. From these considerations the irreversibility of the effect of addition of KCl in N_2 does not seem contrary to the above theory of two different glucolytic mechanisms, in nitrogen and in oxygen.

From the results of our experiments (Table XIII) in which both respiration and glucolysis were determined, it may be said that KCl definitely inhibits the Pasteur reaction (and further that this inhibition is reversible) provided that the Pasteur reaction is regarded strictly as the inhibition of lactic acid formation by oxygen. It must be emphasised, however, that the mechanism of formation of lactic acid in oxygen when KCl is added may not necessarily be the same as that occurring normally in nitrogen; in fact this appears unlikely in view of the inhibitory effect of potassium chloride on anaerobic glucolysis. Secondly, as well as increasing aerobic glucolysis, the addition of potassium markedly increases the respiration. The significance of this is uncertain; it may be connected with general stimulation of metabolism or perhaps oxidation of some intermediary to lactic acid. It is possibly due to the increasing concentration of lactic acid, but we have shown that the rate of removal of lactic acid is not affected. There is apparently no correlation between increase in oxygen uptake and aerobic glucolysis, though it appears that a relation exists between the total oxygen uptake and the aerobic glucolysis in experiments in which $M/10$ KCl was added. Further the question asked by Dickens [1934], as to whether aerobic glucolysis can be increased in tissues where carbohydrate oxidation is not diminished, can now be answered. These conditions are satisfied in brain slices glucolysing aerobically in the presence of KCl, since presumably here the high respiration is due to an oxidation of the carbohydrate type [see Dickens and Sîmer, 1930]. Thus we can say that KCl does not behave in the same way as Dickens [1934] has suggested for phenylhydrazine, since this substance does not inhibit anaerobic glycolysis.

As regards the original purpose of these experiments, that is to see if oxygen interferes with lactic acid production by removing some reactant in the glucolytic chain, we have not succeeded in demonstrating any positive evidence for this theory by addition of possible substances and so are thrown back on either the explanation of Meyerhof or that of Lipmann as to the mechanism of the Pasteur effect.

From our results, however, the former explanation, that is that lactic acid formed as in N_2 is merely removed by the oxygen, becomes unlikely, at any rate in brain, since if this were the case it would be hard to explain how potassium so markedly increases the aerobic glucolysis when it apparently does not interfere with the removal of lactic acid from brain slices under aerobic conditions. It is possible, however, in view of the increased O_2 uptake, that the general metabolism might be so stimulated as to increase the rate of lactic acid formation in the presence of O_2 and KCl. However, it seems unlikely that increased O_2 uptake would be associated with increased lactic acid production unless the lactic acid production were caused by some direct oxidation. This is, in fact, the same as postulating another mechanism of lactic acid formation coming into play in O_2 and KCl. Another argument against the view that lactic acid is formed as under anaerobic conditions but removed in O_2 is the slow rate of removal of added lactate in brain (Ashford and Holmes [1931] and our more recent observations on brain slices) compared with the high rate of lactic acid formation by similar tissue under anaerobic conditions.

From this we may conclude that the theory of Lipmann is not, as the others are, at variance with these observations. The mechanism of the action of potassium salts is at present completely obscure, and the existence of another mechanism for glucolysis occurring in tissues in O_2 and KCl is still a possibility. An even more disturbing possibility is that under artificial conditions a cell may actually develop a new and different mechanism. If this were so it would throw into doubt much work done on excised tissues and extracts. At present it is simpler to postulate that there are different mechanisms for lactic acid production in oxygen and in nitrogen and that the former is activated by potassium and the latter inhibited.

SUMMARY.

1. The addition of potassium α-glycerophosphate to glucolysing brain slices was found to increase the aerobic and inhibit the anaerobic glucolysis, so that the aerobic glucolysis became several times greater than the anaerobic. This effect is not shown by the sodium salt.

2. Potassium chloride, but not sodium chloride, was found to have the same effect in $0{\cdot}1M$ concentration, the aerobic glucolysis assuming values from 3 to 6 times as large as the much diminished anaerobic glucolysis. The phenomenon is due entirely to the potassium ion.

3. The effect of varying concentrations of potassium chloride on both aerobic and anaerobic glucolysis in brain slices was studied.

4. Potassium does not affect the oxidative removal of lactic acid.

5. *dl*-Glyceraldehyde was shown to inhibit the raised aerobic glucolysis occurring in the presence of $M/10$ KCl.

6. The addition of pyruvate did not increase the aerobic glucolysis or remove the inhibitory effect of potassium on the anaerobic phase.

7. The oxygen uptake was shown to be increased in the presence of $M/10$ KCl.

8. The reversibility of these effects has been investigated. The inhibition of anaerobic glucolysis by KCl in N_2 was shown to be irreversible, whereas the increase in aerobic glucolysis and oxygen uptake by addition of KCl during aerobiosis is reversible.

9. The bearing of these results on the significance of glucolysis and on the Pasteur effect is discussed.

It is a pleasure to thank Sir F. G. Hopkins for his interest in this work. Our thanks are also due to our colleagues Dr H. A. Krebs, Dr H. Laser and Dr E. G. Holmes for their helpful advice and criticism.

One of us (K. C. D.) is indebted to the Department of Scientific and Industrial Research for a grant.

XXII. THE LIVER AND FAT METABOLISM.

By FRANCIS XAVIER AYLWARD, HAROLD JOHN CHANNON
AND HARRY WILKINSON.

From the Department of Biochemistry, The University, Liverpool.

(*Received November 30th, 1934.*)

The outstanding evidence of the importance of the liver in fat metabolism is the intense accumulation of fat which occurs in this organ in widely varying experimental and pathological conditions. Known observations however do not at present provide any adequate reason for this fat accumulation. The desaturation hypothesis of Leathes [1925], based on the work of Leathes and Meyer-Wedell [1909] and of Hartley [1909], presents an attractive suggestion of the reasons why fat may be transported to the liver, for apart from the desaturation of the fatty acids themselves it serves to connect the metabolism of glycerides with that of liver phosphatides. In the last three years work in this laboratory has been directed towards an attempt to obtain further evidence on the function of the liver in fat metabolism, and part of this work has referred in particular to the desaturation theory. The results of these investigations [Channon *et al.* 1934, 1, 2,] together with those of other workers discussed in the former paper, leave us reluctant to accept that part of the hypothesis which is concerned with desaturation until more positive evidence in its favour is acquired. On the other hand, although the investigations of the French school and of many other workers seem to suggest that the phosphatides of tissues and in particular those of the liver may be essential constituents of living cells—"l'élément constant" of Terroine [1919]—yet close consideration makes it not unlikely that liver phosphatides may possess an active metabolic function, for they vary in amount in certain conditions. The fact that the percentage of liver phosphatide usually falls when fat infiltration occurs is an example of such a variation. Further, the extensive work of Best and collaborators [*cf.* Best, 1934] shows the remarkable effect of small amounts of choline in prevention and cure of fatty livers produced by various experimental conditions. Although the effect of choline may be exercised in many ways, one possible means is through the metabolism of choline-containing phosphatides.

The work described in this paper was carried out with a view to obtaining further evidence on the rôle of the liver in fat metabolism. The frequent accumulation of fat in the liver suggested that some changes should be detectable after a meal containing fat. Little definite information on this subject is available, although Artom [1933], who provides a summary of the subject, has obtained results which will be discussed later. It appeared possible that the lack of advance in this field might be due to several reasons. Firstly, any small changes in the amount of the liver lipoids after fat absorption may have been generally masked by variation of the individual animals employed—a fact which appears to have been insufficiently appreciated; for this reason we have used in this work the pooled livers of groups of animals. Secondly, analyses have generally been made at relatively long time intervals and estimations of the total ether-soluble hydrolysis products only have usually been carried out. The former procedure might well fail to reveal a dynamic function of the liver in fat metabolism, while the latter would mask slight changes in the individual lipoid constituents. Thirdly, the recent work of Best and his colleagues suggests that some at least of the negative results may have been due to the presence of choline in the diets employed. If choline is a normal physiological agent for the control of the amount of fat in the liver, the provision to animals of a meal containing fat, but free from choline, would be more likely to result in a transient rise in liver fat. Because work is being carried out in this laboratory on the "cholesterol" fatty liver, it was decided to include cholesterol in the diet with a view to obtaining further evidence on this problem also.

In order that the results might be of greater value in attempting to assess the normal processes occurring in liver following fat absorption, it was felt preferable to administer a diet containing all the primary food constituents, protein, fat and carbohydrate, in place of the exclusively fatty diet which has often been employed in researches of this type, because the production of fatty livers by dietary methods seems to depend on a number of factors concerned with the proportion of all three constituents in the diet, apart from the effect of choline. The general plan of the experiment therefore was to feed a large number of animals on a choline-free diet containing 40 % of fat and 2 % of cholesterol. A similar number received the same diet with the addition of choline chloride. From each series eight animals at a time were killed at intervals up to 13 hours and the amounts of phosphatide, glyceride, cholesterol and cholesteryl ester present in the livers determined.

EXPERIMENTAL.

Eighty rats, which had been maintained on the laboratory stock diet for a considerable period, were divided into ten groups, each of eight animals (3 bucks and 5 does) to give as even weight distribution as possible. Two of these groups were used as controls. Of the remainder, four groups received diet C and four groups diet D. The groups in each series received a corresponding serial number depending on the time at which the animals were killed after receiving their particular diet.

All the animals were liberally fed on the normal stock diet for the last time at 10.0 a.m. on the day before the experiment. At 8.0 p.m. the remainder of the food was removed from the cages and the experiment began on the following day at 9.30 a.m., 13½ hours after food was last available to the animals. At this time weighed amounts of the diets C and D were placed in small dishes in all the cages save those of the two control groups. At 10.30 a.m. the dishes were removed, after carefully adding any food which had been scattered about the cages. The animals thus had access to the diets for 1 hour only. One group from each of the two series was killed at 4, 7, 10 and 13 hours after the provision of the food (9.30 a.m.). The sixteen animals used as the control group were killed at 9.30 a.m., they themselves thus having had no food for 13½ hours.

The composition of diet C was: fat 40, caseinogen 20, glucose 40, cholesterol 2, water 8 parts; diet D was the same as diet C with the addition of choline chloride, 2 parts.

The fat used in the diets was freshly prepared dripping obtained from beef fat by melting and filtration.

The caseinogen used was Glaxo "fat-extracted casein," which as received contained less than 0·2 % "fat." Before use this was extracted four times with boiling industrial alcohol and then four times with ether in order to remove any trace of phosphatide present. By biological assay on rabbit intestine, after hydrolysis followed by acetylation, diet C was found to contain less than 1 mg. choline per 100 g.

The method of mixing the diets was to make the sugar into a paste with water in the case of diet C and with choline chloride solution in the case of diet D. The caseinogen was then added and well mixed. The cholesterol was added to the melted fat and the mixture heated with stirring until the cholesterol had dissolved. It was then added to the sugar-caseinogen mixture. It is to be emphasised that every care was taken by prolonged kneading to ensure that the diet was uniform.

Extraction of the tissues and analysis of the extracts.

Each rat was weighed and then killed by a blow on the back of the head. The livers were removed and weighed, those from each group being pooled as one sample. The alimentary tracts were dissected out, freed from adherent fat as far as possible and the portion from the oesophagus to just above the caecum removed for analysis. The procedure adopted for the extraction of the livers was one which would enable the dry weight of the livers and that of the total ethereal extract to be obtained [Channon and Wilkinson, 1934]. The analyses of the ethereal extracts were carried out as described in that paper and included determinations of the total fatty acids and unsaponifiable matter obtained by alkaline hydrolysis, ether-soluble phosphorus and free and total cholesterol, together with the iodine values of the total fatty acids.

The amount of fat ingested and the amount absorbed were also determined. The fat intake was calculated from the difference between the weight of food administered and that remaining uneaten in the cages. From this figure and that obtained for the fat remaining in the tracts at the time of killing, the amount of fat absorbed could be calculated. The alimentary tracts from each group were therefore heated with 300 ml. 5 % potassium hydroxide for 12 hours. The resulting dark brown solution was acidified in a separating funnel and extracted with ether. Considerable difficulty was encountered because of emulsion formation, which could usually be overcome by the use of alcohol. The extraction difficulties were, however, such as to make it possible that the results obtained were only approximately correct. The combined ethereal extracts were washed with water five times and the "fat" obtained by removal of the solvent *in vacuo*. It was dissolved in light petroleum and allowed to stand overnight, when the purified "fat" was obtained by filtering the light petroleum solutions and removing the solvent *in vacuo*. The resulting material consisted of a mixture of fatty acids and unsaponifiable matter, together with some unhydrolysed glyceride. It was not further hydrolysed to convert it entirely into its constituent fatty acids and unsaponifiable matter, because the figure obtained would not differ sufficiently greatly from the weight of the extract already obtained to make any material difference in the interpretation of the results. From the weight, therefore, one half of the corresponding figure from the tracts of the 16 control animals was subtracted. The fat absorbed was then obtained by subtraction of the resulting figure from that of the fat eaten.

RESULTS.

The detailed figures for the water contents of the livers will not be recorded, for no significant variation was observed, the extreme values for all the groups being 69·3 and 71·6 %; nor is it necessary to present the results of the analyses of the ethereal extracts of the livers in detail. The composition of the liver lipoids as set out in Table I has accordingly been calculated. The ether-soluble phosphorus is assumed to be present as a dioleyllecithin (P 3·86 %, fatty acids 70·4 %). The cholesteryl ester is calculated as the oleate. $\left(\text{Total cholesterol determined on the unsaponifiable fraction } minus \text{ the free cholesterol, } \times\frac{650}{386}.\right)$ The glyceride fatty acids have been deduced by subtracting from the total fatty acids those present in the phosphatide (70·4 %) and those present as cholesteryl ester $\left(\text{cholesteryl oleate } \times\frac{282}{650}\right)$. This difference multiplied by 1·045 yields the figure for glyceride as triolein.

The only other point which need be mentioned is that the weights of liver for groups C 1, C 2, C 3 and C 4 were 53·0, 54·6, 56·0 and 51·2 g. respectively, while the corresponding figures from the D series were 57·3, 52·0, 50·2 and 47·5 g.

Table I. *Composition of the liver lipoids (g./100 g. liver).*

Group	Hours after provision of food	Phosphatide	Glyceride	Free cholesterol	Cholesteryl oleate	I.V. of total fatty acids

D 4	13	3·40	1·105	0·264	0·173	—

DISCUSSION.

One preliminary observation to be made concerns the variation to be expected in the amounts of the different lipoid constituents of the livers of individual animals maintained on a stock diet. Much evidence is available to show that when fat infiltration into the liver occurs, its intensity in individual animals may be strikingly dissimilar. This variation is so great that even batches of pooled livers of groups of several rats, maintained under the same nutritive conditions, may yield analytical results definitely differing one from the other. On the other hand the variation in the amounts of the different lipoid constituents in the livers of rats maintained for considerable periods on a normal constant stock diet and kept without food for twelve hours is small. In these conditions the phosphatide and the free cholesterol show very little variation, while cholesteryl esters are virtually absent. The greatest variation likely to be met with is in that of the neutral fat fraction. In the work under discussion each group consisted of eight animals in the belief that in the conditions of these experiments this number would be sufficiently great to make for reliability in the interpretation of any changes which might occur. This point is mentioned because some authors have used individual animals in such studies and because possible variability must be borne in mind in the interpretation of the results.

The variations in the individual constituents will now be discussed in turn and it will be convenient if these be presented together in a series of curves, because certain reciprocal relationships are thereby made apparent. In Fig. 1 the sequence of changes occurring in the amounts of phosphatide and glyceride and in the iodine values of the total fatty acids are set out.

(*a*) *The phosphatide fraction.* Fig. 1 shows that the phosphatide percentage in the livers of animals which did not receive choline decreases slowly for a period of 4 hours and then falls more sharply to a minimum value, 24·5 % below the control value, at the seventh hour, to rise again to normal after 13 hours. In the D series, however, in which the animals received choline, the corresponding decrease in the phosphatide percentage, 9 %, is not nearly as pronounced. This finding implies one of two things. Either choline has prevented the partial disappearance of liver phosphatide, which according to these results normally occurs after a fatty meal, or alternatively its presence in the diet has enabled synthesis of phosphatide to occur and this newly synthesised phosphatide has replaced that which has disappeared. The latter explanation seems the more probable.

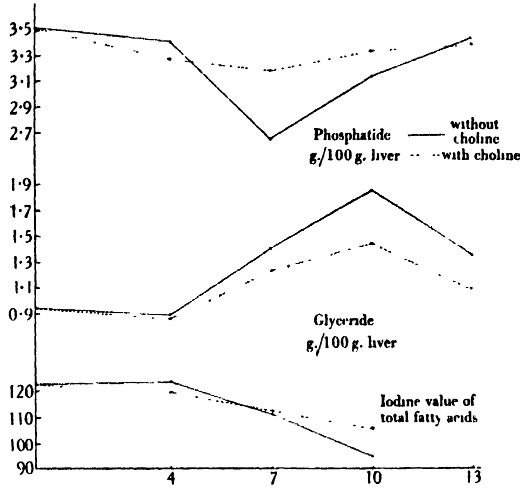

Fig. 1.

Hence, after a meal containing fat and cholesterol, the liver phosphatide falls until the seventh hour and this fall is checked in part by choline administration. It seems possible that this observation may prove a step forward in the solution of the problem as to how choline prevents and cures certain types of fatty liver. It is well known that the phosphatide content of fatty livers is usually markedly decreased and further that such livers after "cure" by choline contain a normal amount of phosphatide. The results under discussion show that a normal fall in phosphatide occurs after the ingestion for 1 hour of what is not a very unphysiological diet for a twelve-hour experiment in the sense that it contained carbohydrate, fat and protein in the ratio of 2 : 2 : 1, and that this fall may be prevented in part by the administration of choline. The unbalanced diets of high fat content and containing little or no choline which have been used to produce fatty livers have been employed for relatively considerable periods (21 days) and from the results under discussion experiments of such a type might be expected to yield fatty livers, for fat absorption in these conditions would be a more or less continuous process and any depletion of liver phosphatide might be persistent. This fall in liver phosphatide may be related to the rise in blood lecithin which has often been reported to occur after a fatty meal at a similar time.

(*b*) *The glyceride fraction.* It appears to be legitimate to make three deductions from the curves in Fig. 1. If the curve for the livers of the animals which did not receive choline be considered, it is seen that no change occurs in the glyceride content of the liver for four hours. In the next six hours, however, a rapid increase occurs and this is steadily maintained to the tenth hour, when a rapid return towards normal occurs in the next three hours. Although many conflicting results occur in the literature, the general outcome of blood fat studies is that a maximum is reached about the seventh hour, followed by a return to normal at the twelfth hour. The curves thus bring out the first point, namely that the amount of liver glycerides varies in a manner somewhat similar to that of blood glycerides after a fatty meal.

The second consideration refers to the relationships between the amounts of the glyceride and phosphatide fractions. Both remain approximately constant until the fourth hour. At this point the phosphatide fraction begins rapidly to decrease while the glyceride fraction immediately increases at an equal rate. At 7 hours the phosphatide is at its minimum value and the glyceride is still increasing, to reach a maximum value at the tenth hour and to fall steadily without completely reaching the normal figure after 13 hours. There thus seems to be a reciprocal relationship between the amounts of phosphatide and glyceride in the liver after a fatty meal.

The third point worthy of mention concerns the effect of choline. Best *et al.* [1934] deduced that the primary effect of choline was on the glyceride fraction of the liver lipoids. In Fig. 1 the curve for the glyceride of the livers of the animals which received choline is at a lower level than that of those which received the choline-free diet. Although the differences are not profound, they exist at every hour at which analyses were made. It seems reasonable therefore to suggest, according to these results, that the effect of choline is observable even in the hours immediately following a fatty meal.

(*c*) *The iodine values of the total fatty acids.* No significant change in the iodine values of the fatty acids of either group occurs in the first four hours. At this point, however, a progressive fall appears, which is maintained to the tenth hour. Further, in the case of group D, which received choline, the value at this point, 106·4, is considerably higher than that of C, 95·5. Unfortunately a breakage prevented the iodine values of groups C 4 and D 4 from being determined. These observations seem in complete accord with the discussion under (*a*) and (*b*). The decrease in phosphatides results in a loss to the liver of their constituent highly unsaturated acids. At the same time as this occurs, the relatively saturated acids of the food fat, of iodine value 40, are entering the liver, with a resultant fall in iodine value. This fall is not nearly as pronounced at the tenth hour in group D, because choline has definitely, though in part only, prevented the increase. Thus while group C at this stage contains 1·863 g. of glyceride per 100 g. of liver, the choline group D contains only 1·455 g. These findings are in accord with the previous work of many authors, who have studied the production of fatty livers by various means, in showing that the iodine value of the liver fatty acids decreases progressively with fat infiltration. Imrie [1914] showed that the degree of fat infiltration could in fact be calculated mathematically from a consideration of the iodine values of the total liver acids, although in our experience such a relationship does not hold strictly. The present results are, however, more particularly interesting in that in these experiments there is no obvious increase in the amount of the total liver fatty acids, the maximum figure reached being 4·049 g. per 100 g. of tissue in group C 3, an increase of only 0·678 g. over the initial value. Calculations which need not be described here lead us to the view that an elaboration of these experiments may throw further light on the desaturation theory and to this problem we are giving attention.

The results under (*a*), (*b*) and (*c*) therefore seem to yield a picture of the normal sequence of events in the liver after ingestion of a meal containing fat and cholesterol, very similar to that which occurs when fatty livers are produced, *viz.* a fall in liver phosphatide, an increase in glyceride and a consequent lowering of the iodine value of the total fatty acids. They suggest a physiological explanation of the fatty liver produced by dietary methods and its prevention and cure by choline administration. For a number of reasons, however, we feel that caution should be exercised in their interpretation. The constancy in the amount of the liver phosphatides has been emphasised by the work of Terroine and Bélin [1929] and of Sinclair [1929] and a fixed impression of this constancy has arisen, whilst hitherto experimental evidence of a change implying a quantitative participation of the liver phosphatides in normal fat metabolism has been, in general, lacking. Little evidence of the latter type is available save that of Artom [1933]. This investigator found that the amount of phosphatide in the livers of dogs starved for periods up to 36 hours was very constant. He then administered to other dogs, starved for similar periods, horse fat to the extent of 20–35 g. per kg. of body weight. Using single animals—a procedure which was quite justified by his findings on his control animals—he found a steady increase in liver phosphatide to the sixth and seventh hours, followed by a return to normal at the tenth hour. His maximum phosphatide increase, 36 %, was obtained at the very time when our maximum decrease, 25 %, occurred. The contradiction of these results is striking and difficult to explain, although many factors may be involved. The amounts of fat ingested by his animals were very high and no other food was given. Further, on basal metabolic considerations the preliminary period of starvation, 12 to 36 hours, was relatively insignificant for his dogs, compared with the corresponding period of 13½ hours which preceded our experiment with rats. The absence of choline from our diet, which included 40 % of carbohydrate and 20 % of protein in addition to 2 % of cholesterol, may be a further cause of the discrepancy.

That the conditions governing the amount of phosphatide in the liver are many was illustrated by a further experiment on rats, in which twelve animals were starved for 17¼ hours, after which six were killed and six were given diet C for a period of 1 hour. Analysis of the livers of the control group and of the fed animals 6½ hours after feeding gave the following results, the control figures being recorded first: total fatty acids 3·17, 4·22 %; I.V. of total fatty acids 101, 74; total cholesterol 266, 360 mg. per 100 g.: ether-soluble phosphorus 122·6, 119·4 mg. per 100 g. Thus in this experiment the changes in the amounts of total fatty acids and cholesterol and in the iodine values of the fatty acids were very similar to those recorded in the previous experiment. On the other hand there was no significant change in the amount of phosphatide. The increase in the amounts both of fatty acids and cholesterol suggest in comparison with the results of the previous experiment that the phosphatide decrease may have occurred earlier, and this different finding may be correlated perhaps with an increased time of starvation. In any case these results also differ from those of Artom and indicate the complex nature of the problem.

For these reasons it is preferable to defer further consideration of the general significance of the findings recorded in this paper until more results are available. We are therefore extending the observations to similar studies on diets containing fat, but free from choline, and with the omission of cholesterol, which may easily be a complicating factor, and we are undertaking a comprehensive study of the blood lipoids at the same time. If the suggestive results concerning a mobilisation of phosphatide from the liver after fat absorption be confirmed, they can then be related to the rise in the amount of blood phosphatide, and the effect of choline administration on the other blood fat constituents can also be studied.

It is to be mentioned also that the amount of fat absorbed by the different groups did not increase regularly with time. Thus groups C 1 to C 4 absorbed 4·90, 4·34, 2·62 and 15·17 g. respectively, while groups D 1 to D 4 absorbed 3·23, 2·90, 7·29 and 6·74 g. The irregularity of these amounts may appear surprising in groups of equal numbers of animals starved for a similar period. We have observed such an irregularity in the amount of fat absorbed on other occasions and we have no explanation to offer for it; it is also possible that some of the results may be connected with this varying degree of absorption. It is of interest also to attempt to assess the amount of choline absorbed in groups D 1 to D 4. The total choline chloride intake of groups D 1 to D 4 was 0·78, 0·67, 0·68, 0·58 g. respectively. Each animal in all the groups thus ingested about 60 mg. of choline and presumably this amount was absorbed.

(*d*) *Cholesterol.* Table I shows that no significant changes occur in the amounts of free cholesterol in the livers of either groups, the extreme values being 257 to 283 mg. per 100 g. of liver. On the other hand striking increases in the amount of cholesteryl ester took place in the livers of both groups of animals. These are illustrated in Fig. 2.

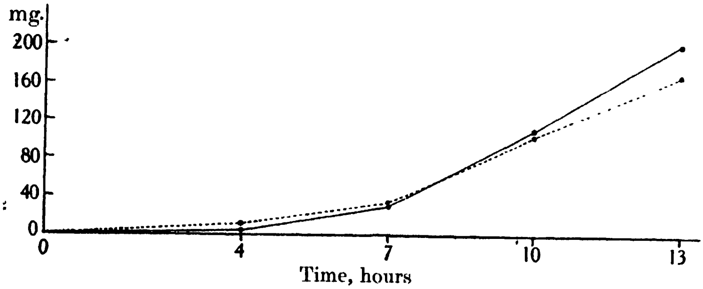

Fig. 2. Cholesteryl ester mg./100 g. liver.
—— Without choline. ------ With choline.

From Fig. 2 and Table I a number of deductions may be made. In the first place it is clear that within four hours of taking a meal containing cholesterol, cholesterol appears in increased amount in the liver of the rat. The whole of the increase in liver cholesterol throughout this experiment is due to an increase in cholesteryl esters (Table I). This result therefore illustrates the initial stage of the production of the "cholesterol" fatty liver, which is characterised by the appearance in the liver of excessive amounts of cholesteryl esters with a large but varying increase in the amount of neutral fat [Okey, 1933, 1, 2; Chanutin and Ludewig, 1933; Best *et al.* 1934; Channon and Wilkinson, 1934]. The latter authors discuss the conditions which influence the degree to which each of these two constituents is increased, for it is clearly an important point to determine why cholesterol appears in the liver exclusively in ester form, with a greater or lesser rise in the glyceride content. The intensity with which this process occurs when cholesterol is fed seems from the present results to depend on the relative inability of the animal to metabolise the substance sufficiently rapidly. After a meal containing it accumulation in the liver begins at once and hence the intensity of the final result of prolonged cholesterol feeding. Determinations of the cholesterol left in the alimentary tracts of the control group and of groups D 3 and D 4 showed that the latter had absorbed 489 and 425 mg. respectively in 9 and 11½ hours. Calculation from the liver weights and the percentages recorded in Table I shows that at these times the amounts of cholesteryl oleate present in the livers of groups D 3 and D 4 were 74 and 94·5 mg. respectively, which correspond to 43 and 58 mg. of cholesterol. Clearly therefore the increase in liver cholesterol represents only part of the cholesterol absorbed.

One further observation which may be made is that, in the twelve hours following a fatty meal containing cholesterol, choline administration has had no marked effect in preventing cholesterol accumulation in the liver, a result which seems concordant with those of Best *et al.* [1934] and Channon and Wilkinson [1934]. It suggests that whereas the amounts of phosphatide and glyceride in the liver are mutually interdependent, the amount of cholesteryl ester is not directly involved in the same mechanism of control.

SUMMARY.

1. A study has been made of the variations in the liver lipoids of rats (*a*) receiving a meal of a diet consisting of sucrose 40, caseinogen 20, fat 40 and cholesterol 2 parts, but free from choline, and (*b*) receiving a meal as under (*a*) with the addition of choline chloride, 2 parts. The changes in the liver lipoids were studied over a period of 13 hours.

2. The significant findings were as follows:

(*a*) *The phosphatide fraction.* For a period of four hours little change occurred in the percentage of phosphatide. There was then a fall to a minimum value at the seventh hour, followed by a return to normal at 13 hours. In the corresponding animals which received choline these phosphatide decreases were less than one-third as great. The evidence produced thus indicated that choline prevented at least in part the fall in the amount of liver phosphatide which took place in its absence.

(*b*) *The glyceride fraction.* The livers in both series of animals showed no change in neutral fat content for about four hours. There was then a rapid increase to the tenth hour, followed by a return towards normal at the end of thirteen hours. The effect of choline appears consistently in these curves, for the glyceride percentages in the livers of animals which received choline were uniformly lower than that of the control series.

(*c*) *The iodine values of the liver fatty acids.* The iodine values of the total fatty acids decreased in both groups during the first ten hours. The results under 2 (*a*), 2 (*b*) and 2 (*d*) are discussed in detail in relation to the rôle of the liver in fat metabolism and to the effect of choline in the prevention and cure of fatty livers.

(*d*) *Cholesterol.* The livers of animals in both series showed no change in the free cholesterol content. On the other hand, striking increases in the amount of cholesteryl esters in the livers began to appear within seven hours of feeding and the increases continued in linear fashion to the end of the experiment. This change therefore represents the first stage in the production of the cholesterol fatty liver by cholesterol feeding. Choline had no marked effect in preventing this increase.

We wish to express our thanks to the Medical Research Council for a grant from which the expenses of this work were defrayed.

XXIII. LABILE GLUTAMINE PEPTIDES, AND THEIR BEARING ON THE ORIGIN OF THE AMMONIA SET FREE DURING THE ENZYMIC DIGESTION OF PROTEINS.

By JAMES MELVILLE.

From the Biochemical Department, Imperial College of Science and Technology, South Kensington.

(*Received November 30th, 1934.*)

That the ammonia (amide-N) given by proteins on acid hydrolysis comes in part from acid amides present in the molecule has been recently proved by the isolation after enzymic digestion of *l*-asparagine from edestin [Damodaran, 1932] and of *d*-glutamine from gliadin [Damodaran *et al.*, 1932]. In the latter research the amount of *d*-glutamine present at various stages was estimated by the indirect method of Chibnall and Westall [1932]. At the end of the digestion of the gliadin the amount present was equivalent to 43 % of the total amide-N. More than half of this was lost during precipitation of bases with phosphotungstic acid and the final yield of crystalline *d*-glutamine was equivalent to only about 5 % of the total amide-N. Damodaran *et al.* [1932] concluded that the low yield was due in large part to the unstable nature of *d*-glutamine in aqueous solution. They pointed out however that the indirect determination of glutamine amide-N might include labile peptides of *d*-glutamine as well as this amide. Since Chibnall and Westall [1932] had shown that *l*-leucyl-*d*-glutamine was stable under the hydrolytic conditions employed it was suggested that these labile peptides might be those resembling *d*-glutamine itself in having a free amino-group in the γ-position with respect to the amide group.

That relatively large amounts of labile glutamine peptides might indeed be present under certain conditions in the enzymic digests of proteins followed from the unpublished work of Dr Jaaback carried out in this laboratory during 1932–33. Caseinogen was digested with trypsin, the products extracted with butyl alcohol and the distribution of glutamine amide-N determined by the indirect method of Chibnall and Westall. The monoamino-acid fraction, which would include both asparagine and glutamine, contained only one third of the glutamine amide-N present in the original digest. The other two thirds remained in the aqueous phase and if the validity of the amide hypothesis be assumed they must have represented labile peptides of glutamine of predominantly acidic or basic character.

Synthesis of glutamine peptides of the second type mentioned above and a comprehensive study of their properties were therefore clearly desirable, but on account of the probably labile nature of the γ-amide group the problem was not easy of solution by the older methods of peptide synthesis. By a fortunate coincidence however Bergmann and Zervas [1932] published about this time a new method which offered some likelihood of success. In practice this has been found excellent for the purpose and a neutral dipeptide *d*-glutaminylglycine, an acidic dipeptide *d*-glutaminyl-*d*-glutamic acid and a neutral tripeptide *d*-glutaminylglycylglycine have been prepared. In all three the amide group is as labile as in *d*-glutamine itself and all exhibit to a lesser degree the abnormal reaction of this substance with nitrous acid during a determination of amino-N by the method of Van Slyke.

Since the method of Bergmann and Zervas [1932] permits the ready synthesis of *d*-glutamine from *d*-glutamic acid a sufficient amount of this amide has also been prepared to investigate for the first time a conclusion that can be drawn from the work of Damodaran *et al.* [1932] and of Jaaback (unpublished), that the ammonia which slowly accumulates during the enzymic digestion of proteins is due to the secondary decomposition of *d*-glutamine and *d*-glutaminyl peptides under the conditions employed and not to the presence of any specific amidase in the enzyme preparations. Opportunity has also been taken to investigate the hydrolysis of *d*-glutaminyl peptides by the yeast peptidases used in the digestion experiments, so that optimum conditions may be employed in future work.

Synthesis of glutamine peptides.

Treatment of *N*-benzylcarbonatoglutamic anhydride (I) with glycine ester on the lines of the synthesis of *d*-*iso*glutamine by Bergmann and Zervas [1932] gave analogously *N*-benzylcarbonato-*d*-α-glutamylglycine ethyl ester (II). Phosphorus pentachloride converted this into the γ-acid chloride (III) which reacted with ethereal ammonia to give *N*-benzylcarbonato-*d*-glutaminylglycine ethyl ester (IV). *N*-Benzylcarbonato-*d*-glutaminylglycine (V), obtained by hydrolysis of (IV), on hydrogenation in the presence of palladium yielded *d*-glutaminylglycine (VI). By substituting *d*-glutamic acid diethyl ester and glycylglycine ethyl ester for glycine ethyl ester in the above synthesis *d*-glutaminyl-*d*-glutamic acid[1] (VII) and *d*-glutaminylglycylglycine (VIII) were also prepared.

d-Glutamine was synthesised by a similar method. *N*-Benzylcarbonatoglutamic anhydride with sodium ethoxide gave *N*-benzylcarbonato-*d*-glutamic acid α-ethyl ester which was converted *via* the acid chloride to the γ-amide. Mild hydrolysis removed the ester group and the resulting *N*-benzylcarbonato-*d*-glutamine was catalytically reduced to *d*-glutamine. Experimental details of this synthesis are omitted, as one giving a better yield has since been described by Bergmann *et al.* [1933].

N-Benzylcarbonato-d-*α-glutamylglycine ethyl ester.* 10 g. of *N*-benzylcarbonato-*d*-glutamic anhydride [Bergmann and Zervas, 1932] were dissolved in dry chloroform and 10 g. of glycine ethyl ester added. After 5 hours the solution was washed with dilute hydrochloric acid, dried with anhydrous sodium sulphate and the chloroform removed *in vacuo*. The residue was taken up in 10 ml. of absolute alcohol and left overnight in the ice-chest, when 6·5 g. of material crystallised out (47 % on the anhydride taken). Recrystallised from a small volume of alcohol it melted at 124°. (Found: N, 7·5 %. $C_{17}H_{22}O_7N_2$ requires N, 7·65 %. 0·174 g. required 4·75 ml. of 0·1 *N* NaOH; calculated, 4·75 ml.)

---

[1] It is unfortunate that Bergmann and Zervas [1932] refer to glutamylglutamic acid as "Glutaminylglutaminsäure" instead of "Glutamylglutaminsäure" (*cf.* Chem. Zentr. 1923, III, 1084) as it will lead to confusion in German with the glutamine peptide glutaminylglutamic acid described in the present paper.

N-*Benzylcarbonato*-d-*glutaminylglycine ethyl ester.* 1·5 g. of the above ester in 30 ml. of dry chloroform were treated at $-5°$ with 1 g. of pulverised phosphorus pentachloride. After 5 mins. of vigorous shaking the chloroform solution was decanted and evaporated at the pump for 10 mins. to remove free hydrochloric acid. It was then added to a cold saturated ethereal solution of ammonia. After allowing to stand for about an hour the precipitate was filtered off and after removal of the solvent was thoroughly triturated with water. The insoluble residue crystallised well from alcohol. Yield 0·9 g.; M.P. 167°. (Found: N, 11·5; amide-N (Sachsse) 3·8 %. $C_{17}H_{23}O_6N_3$ requires N, 11·5; amide-N, 3·8 %.)

N-*Benzylcarbonato*-d-*glutaminylglycine.* 2·9 g. of the above half amide half ester were dissolved in 100 ml. of alcohol, aqueous sodium hydroxide was added to the first blue colour of thymolphthalein, the solution cooled to 20° and 8 ml. of *N* NaOH added. After standing for 90 mins. a slight excess of acid was added, the solution filtered and the filtrate evaporated to 40 ml. at the pump. This was kept at 0° overnight when 2·1 g. of crystalline *N*-benzylcarbonatoglutaminylglycine were obtained, corresponding to a 78 % yield. The material was not further purified. (Found: N, 12·4; amide-N, 4·0 %. $C_{15}H_{19}O_6N_3$ requires N, 12·5; amide-N, 4·1 %.)

d-*Glutaminylglycine.* 2 g. of the above compound dissolved in 70 ml. of aqueous methyl alcohol were hydrogenated in the presence of palladium. The evolution of CO_2 stopped after 20 mins., when the solution was filtered from the catalyst, brought to neutrality with ammonia and evaporated at a temperature not exceeding 40° to 10 ml. The dipeptide crystallised out on addition of alcohol and was purified by recrystallisation from aqueous alcohol. Yield 0·7 g. (Found: C, 41·3; H, 6·4; N, 20·7; amide-N, 6·9 %. $C_7H_{13}O_4N_3$ requires C, 41·4; H, 6·4; N, 20·7; amide-N, 6·9 %.) For a 4·8 % solution in water the observed rotation was $\alpha_D^{18°} + 3{\cdot}65°$, whence $[\alpha]_D^{18°} = +76°$.

d-*Glutaminyl*-d-*glutamic acid.* *N*-Benzylcarbonato-*d*-α-glutamyl-*d*-glutamic acid diethyl ester was prepared by the method of Bergmann and Zervas [1932], the yield being 65 % as against the quoted yield of 37 %. Following the procedure outlined above this was converted in 80 % yield into *N*-benzylcarbonato-*d*-glutaminyl-*d*-glutamic acid diethyl ester. Recrystallised from alcohol this melted at 181°. (Found: N, 9·1; amide-N, 3·0 %. $C_{22}H_{31}O_8N_3$ requires N, 9·0; amide-N, 3·0 %.) 2 g. of this amide ester were dissolved in 80 ml. of alcohol, a few drops of thymolphthalein solution added and then 4·6 ml. of *N* NaOH. The mixture was kept at 37° until an aliquot showed by back-titration with acid that the hydrolysis was complete (5–10 hours). 1·1 g. of *N*-benzylcarbonato-*d*-glutaminyl-*d*-glutamic acid were obtained. (Found: N, 10·1; amide-N, 3·3 %. $C_{18}H_{23}O_8N_3$ requires N, 10·3; amide-N, 3·4 %.) Reduction was carried out in the usual way. The dipeptide crystallised during the reduction and was separated from the catalyst by washing with a considerable volume of warm water. On evaporating the solution and washings *in vacuo* to a small volume, *d*-glutaminyl-*d*-glutamic acid crystallised out in 80 % yield. Purification was effected by dissolving in the smallest possible volume of water at 50°, evaporating *in vacuo* till the peptide began to crystallise and leaving overnight in the ice-chest. (Found: C, 43·6; H, 6·2; N, 15·5; amide-N, 5·1 %. $C_{10}H_{17}O_6N_3$ requires C, 43·7; H, 6·2; N, 15·5; amide-N, 5·2 %.) For a 4·8 % solution in *N* HCl the observed rotation was $\alpha_D^{18°} + 0{\cdot}63°$, whence $[\alpha]_D^{18°} = +15°$.

d-*Glutaminylglycylglycine*. Glycylglycine ethyl ester, prepared from glycine ethyl ester by the method of Fischer and Fourneau [1901] reacted with *N*-benzylcarbonato-*d*-glutamic anhydride to give *N*-benzylcarbonato-*d*-α-glutamylglycylglycine ethyl ester, M.P. 136°, in 54 % yield. (Found: N, 9·9 %. $C_{19}H_{25}O_8N_3$ requires N 9·9 %. 0·0198 g. required 3·15 ml. *N*/70 NaOH; calculated 3·30 ml.) The ester did not dissolve readily in chloroform but it was possible to prepare a supersaturated solution for the reaction with phosphorus pentachloride. Treatment with ammonia gave *N*-benzylcarbonato-*d*-glutaminylglycylglycine ethyl ester in 57 % yield. Recrystallised from alcohol this melted at 150–152°. (Found: N, 13·0; amide-N, 3·0 %. $C_{19}H_{26}O_7N_4$ requires N, 13·3; amide-N, 3·3 %). No crystalline product could be isolated after hydrolysis of the ester grouping, so methyl alcohol was added and the reduction carried out forthwith. The yield of the tripeptide was poor and there was insufficient material to effect complete purification. The best sample gave the following analysis. (Found: C, 40·8; H, 6·2; N, 19·3 %. $C_9H_{16}O_5N_4$ requires C, 41·5; H, 6·15; N, 21·5 %.)

d-iso*Glutamine*. A sample of this prepared by the method of Bergmann and Zervas [1932] gave correct analytical figures for N and amide-N but did not give satisfactory results when titrated electrometrically [*cf*. Melville and Richardson, 1935], and it was necessary to purify the material by recrystallisation three times from aqueous acetone before sufficiently good constants could be obtained. Since the original sample gave an abnormally high amino-N (Van Slyke) value and yielded a considerable amount of ammonia on hydrolysis at p_H 4 it was suspected that the product was considerably contaminated with *d*-glutamine, *i.e.* the anhydride ring had opened to give both the α- and γ-amides, recalling the unexpected results obtained by Bergmann *et al.* [1934], who found that the condensation of benzylcarbonato-*l*-aspartic anhydride and *l*-tyrosine methyl ester gave the β- and not the expected α-dipeptide. Since the point is of importance in any synthesis utilising either of these anhydrides as starting material, further information as to the composition of Bergmann and Zervas' *iso*glutamine was desirable. The anhydride was treated with ammonia according to their directions and the product (5·8 g.) catalytically reduced. This material was crystallised from aqueous alcohol, two crops being obtained, weighing 2·1 g. and 0·5 g. respectively, a total yield of 89 %. The first crop on analysis gave a glutamine amide-N value of 10 % and the second of 35 % of the total amide-N. It was found that the *iso*glutamine could be purified either by heating its aqueous solution at 100° for an hour or by recrystallisation from aqueous acetone. Thus 1·4 g. of the first crop mentioned above were dissolved in water and heated in a boiling water-bath for one hour. On the addition of alcohol 1·1 g. of material which gave only 2 % of its total amide-N as glutamine amide-N were recovered. (Found: N, 19·2 %. $C_5H_{10}O_3N_2$ requires 19·2 %.) For a 5·4 % solution in water the observed rotation was $\alpha_D^{18°}$ +1·05° whence $[\alpha]_D^{18°} = +19·1°$. Bergmann and Zervas give $[\alpha]_D^{20°} = +21·1°$, so that heating with water may have brought about slight racemisation.

One recrystallisation of another sample from aqueous acetone reduced the glutamine amide-N value from 12 % to 3 % of the total amide-N. From these results it is clear that a substance containing labile amide-N, undoubtedly *d*-glutamine, was present in the original *iso*glutamine preparations, and that when the anhydride ring of *N*-benzylcarbonato-*d*-glutamic anhydride was opened by ammonia both α- and γ-amides were formed in the proportion of about six to one.

It is reasonable to assume both from the figures given in the last column of Table I and from the data given in Table IV that in the case of the glutaminyl peptides described if any of the γ-peptide derivatives were formed during the opening of the anhydride ring they were successfully removed during the crystallisations at subsequent stages. But the possibility that the condensation between anhydride and amino-acid ester does not always go completely in one direction should not be overlooked in future work.

The properties of d-*glutamine and* d-*glutaminyl peptides.*

As was expected the three peptides whose synthesis has just been described showed in lesser degree the abnormalities which distinguish *d*-glutamine from all other amino-acids. The results of an investigation are given in Table I. *d*-Glutaminylglycine and *d*-glutaminyl-*d*-glutamic acid both yield about 90 % of their amide-N as ammonia on hydrolysis at p_H 4, and although the abnormal reaction with nitrous acid is not so marked as with *d*-glutamine itself the values obtained are 35–50 % higher than calculated.

Table I. *Properties of* d-*glutamine and related compounds.*

	Amino-N (% total N)		Ammonia-N given on hydrolysis at p_H 4 (% total amide-N)
	Van Slyke	Calculated	
d-Glutamine	95	50·0	86·0
d-*iso*Glutamine	55	50·0	2·0
l-Asparagine*	50	50·0	1·0
l-Leucyl-*d*-glutamine*	33	33·3	2·8
d-Glutaminylglycine	49	33·3	91·0
d-Glutaminyl-*d*-glutamic acid	45	33·3	87·0
d-Glutaminylglycylglycine	32	25·0	65·0

* Values from Chibnall and Westall [1932].

These results emphasise the inaccuracy of the Van Slyke amino-N values obtained during the course of an enzymic digestion of proteins such as gliadin which yield relatively large amounts of ammonia and glutamic acid on acid hydrolysis. Further, the abnormalities due to glutamine and glutaminyl peptides cannot, as was assumed by Damodaran *et al.* [1932], be corrected by a determination of glutamine amide-N, since from the data available there appears to be no correlation between this value and the amino-N (Van Slyke) value. The abnormal Van Slyke values of these compounds may however explain a point raised by Calvery [1933]. When comparing amino-N (Van Slyke) with an alcohol (NaOH) titration he finds that in a digest of egg-albumin there is equivalence to within 3 % of amino- and carboxyl groups liberated and assumes that proline peptide bonds are not split to any marked degree. Egg-albumin contains, in terms of total N, 8·5 % glutamic acid-N and 7·3 % ammonia-N so that it is reasonable to assume that considerable amounts of glutamine and glutaminyl peptides are present in the later stages of digestion, whose effect on the Van Slyke values would compensate for the hydrolysis of proline peptides.

The stability of d-*glutamine and glutamine peptides in aqueous solution at* 37°.

The stability of *d*-glutamine at p_H values of 1·8, 7·0, 7·8 and 8·3, the optimum reactions for pepsin, aminopolypeptidase, dipeptidase and trypsin respectively, has been studied both in the presence and absence of these enzymes. (Tables II and III.) In aqueous solution at p_H 1·8 and 37° the breakdown was quite rapid, over 80 % of the total amide-N being liberated as ammonia in two days. At p_H 7·8 and p_H 8·3 approximately 40 % breakdown had occurred in two days, while at p_H 7·0 this degree of splitting was attained after about 3 days. Similar experiments with *l*-asparagine and *l*-leucyl-*d*-glutamine showed that they were almost completely stable under these conditions. Insufficient material was available to determine the stability of the labile glutamine peptides at different p_H values, but an experiment at p_H 8·3 showed that *d*-glutaminyl-*d*-glutamic acid was split at approximately the same rate as *d*-glutamine itself. No appreciable glutaminase activity was present in commercial preparations of pepsin and trypsin, or in a week-old preparation of yeast peptidase. It will be seen that these results offer strong presumptive evidence for the theory that the ammonia formed during the digestion of proteins by the above-mentioned enzymes comes from the spontaneous breakdown of *d*-glutamine and labile glutamine peptides.

It is to be noted that Grassmann and Mayr [1932] found that a fresh yeast autolysate exhibited glutaminase activity. None was observed in the week-old preparation used in the present case, owing either to the fact that this enzyme is rapidly inactivated in ice-cold solution or to the different strains of yeast employed in English and German breweries.

Chibnall and Westall [1932] showed that when *d*-glutamine in aqueous solution was heated at 100° for 3 hours at p_H 4 not only was there a large liberation of ammonia from the amide group but also a fall in the amino-N (Van Slyke) from 190 to 10–20 % of the theoretical value, suggesting that the liberated glutamic acid had been rapidly transformed into pyrrolidonecarboxylic acid. Since breakdown of *d*-glutamine in aqueous solution also takes place at 37° it was necessary to find out what effect this might have on the titrimetric technique used to follow the enzymic hydrolysis of the glutaminyl peptides, for the production of glutamic acid would lead to an increase in the acetone (NaOH) titre whereas its transformation into pyrrolidonecarboxylic acid, with no free amino-group, would leave matters undisturbed.

Actually an experiment at p_H 7·0 in which aliquots were taken at the same time intervals for estimation of ammonia and for acetone titration showed that there is no appreciable increase in titre (Table III). This is confirmed by the results of Grassmann and Mayr [1932] who studied the action of asparaginase on *d*-glutamine at p_H 8·2 and found no significant difference in titre after 48 hours, during which time, as can be seen from Table II, nearly 40 % of the *d*-glutamine

Table II. *Stability of* d-*glutamine at* p_H *values of 1·85, 7·83 and 8·3.*

The *d*-glutamine used contained 18·7 % N. p_H values were checked at the hydrogen electrode. All solutions were made up to 25 ml. and 5 ml. aliquots taken for analysis. Temperature 37°. The ammonia liberated was estimated by means of the micro-apparatus of Parnas and Heller [1924] and is expressed in ml. of *N*/70 HCl.

At p_H 1·85 Solution A contained 0·0493 g. of *d*-glutamine and Solution B 0·0497 g. of *d*-glutamine +0·05 g. of pepsin. Buffer solution *M*/10 glycine—HCl.

At p_H 7·83 Solution C contained 0·0468 g. of *d*-glutamine in *M*/20 phosphate buffer.

At p_H 8·3 Solution D contained 0·0506 g. of *d*-glutamine and Solution E 0·0505 g. of *d*-glutamine +0·05 g. trypsin in *M*/20 barbitone (veronal) buffer.

At p_H 1·85			At p_H 7·83		At p_H 8·3		
	NH_3 liberated			NH_3 liberated		NH_3 liberated

49	4·14	4·14	68	2·27	66	2·41	2·42
100 % splitting	4·70	4 73	—	4·46	—	4·85	4·84

Table III. *Stability of* d-*glutamine at* p_H *7·05.*

Solution A contained 0·0518 g. of *d*-glutamine made up to 15 ml. with *M*/40 phosphate buffer. 2 ml. aliquots were used for titration in acetone with 0·022 *N* alcoholic NaOH and for the estimation of free ammonia. Solution B contained 0·0396 g. of *d*-glutamine, Solution C 0·0402 g. of *d*-glutamine + 2 ml. of a week-old neutral autolysate of yeast in *M*/20 phosphate buffer. 5 ml. aliquots were used for analysis. Ammonia liberated is expressed in ml. of *N*/70 HCl.

Solution A				NH$_3$ liberated	
Time in hours	Acetone titre	NH$_3$ liberated	Time in hours	Solution B	Solution C
0	5·20	0·02	24	0·52	0·47
23	5·15	0·53	90	1·62	1·58
71	5·15	1·38	142	2·23	2·19
100 % splitting	—	3·3	—	3·8	3·87

must have been decomposed. It appears therefore that during the breakdown the glutamic acid must have been rapidly transformed into pyrrolidonecarboxylic acid.

Action of yeast peptidases on glutamine peptides.

Insufficient glutaminyl peptides were available to work out accurately a full p_H-activity curve with the mixture of peptidases obtained by plasmolysis of yeast with ethyl acetate and autolysis at p_H 6·5 [Grassmann, 1927]. Comparative studies have been made at p_H 6·3, 7·0 and 7·8 on the peptides *d*-glutaminylglycine, *d*-glutaminyl-*d*-glutamic acid and *l*-leucyl-*d*-glutamine with *dl*-leucylglycine as control. About 0·125 millimol. of the peptide was dissolved in 0·025 *M* phosphate buffer (at p_H 7·8, 0·05 *M* *iso*glutamine buffer solution was used [*cf.* Melville and Richardson, 1935]) and the calculated volume of 0·2 *N* NaOH added to bring the peptides to the same p_H. The requisite amount of enzyme solution, about 0·4 ml. which had previously been brought to the buffer p_H, was added and the solution made up to 10 ml. with buffer. All p_H values were checked at the hydrogen electrode. The hydrolyses were carried out at 37° and were followed by titration in 90 % acetone [*cf.* Willstätter and Waldschmidt-Leitz, 1921], using 0·022 *N* alcoholic NaOH as titrating agent and thymolphthalein as indicator. An experiment with the crude tripeptide *d*-glutaminylglycylglycine at p_H 7·0 showed that it was split at least as rapidly as *dl*-leucylglycylglycine.

Table IV. *Action of yeast peptidases on peptides of glutamine.*

				Increase in titre				
Dipeptide	p_H	Wt. in g.-millimols	ml. of 0·2 *N* NaOH	30 mins.	75 mins.	135 mins.	195 mins.	100 % splitting
d-Glutaminyl-glycine	6·3	0·126	—	0·60	0·90	1·00	—	1·14
	7·05	0·144	0·24	1·0	1·1	1·15	—	1·31
	7·8	0·119	0·40	0·20	0·70	1·0	—	1·08
d-Glutaminyl-*d*-glutamic acid	6·3*	0·131	0·65	0·75	0·90	1·10	—	1·19
	7·05	0·131	0·80	0·25	0·65	0·95	—	1·19
	7·8	0·124	1·0	0·10	0·35	0·50	—	1·08
l-Leucyl-*d*-glutamine	6·3	0·138	—	0·30	0·80	1·15	—	1·25
	7·05	0·133	—	0·20	0·55	0·95	—	1·21
	7·8	0·141	0·18	0·25	0·70	1·10	—	1·28
dl-Leucylglycine	6·3	0·259	—	0·10	—	—	0·95	1·18
	7·05	0·256	—	0·15	0·40	—	1·10	1·16
	7·8	0·253	0·30	0·20	0·70	1·05	—	1·10

*** 1 ml. of enzyme was used instead of 0·4 as in the other cases.**

The results given in Table IV show that all the peptides are rapidly split and suggest that p_H 7·0 or a little lower is the best reaction for the scission of peptides of *d*-glutamine with yeast peptidase, particularly as at this p_H the breakdown of *d*-glutamine itself is considerably retarded.

SUMMARY.

The three peptides *d*-glutaminylglycine, *d*-glutaminyl-*d*-glutamic acid and *d*-glutaminylglycylglycine have been synthesised by the method of Bergmann and Zervas [1932]. They are readily hydrolysed by yeast peptidases.

As was expected, they exhibit the labile characters of *d*-glutamine itself, *i.e.* they give abnormally high amino-N (Van Slyke) values and are unstable in aqueous solution at 100°. A determination of glutamine amide-N on an enzymic digest of a protein by the method of Chibnall and Westall [1932] therefore may include glutaminyl peptides as well as glutamine itself.

The stability of *d*-glutamine and glutaminyl peptides in aqueous solution at 37° and various p_H values has been determined. All the amide-N is hydrolysed to ammonia in 4–9 days, and the glutamic acid set free is transformed into pyrrolidonecarboxylic acid. The bearing that these observations have on the origin of the ammonia liberated during the enzymic digestion of proteins and also on the titrimetric technique generally used to follow the course of the digestion is briefly discussed.

I am indebted to Prof. A. C. Chibnall for suggesting this work and for constant advice and criticism. My thanks are also due to Dr J. M. Gulland for samples of *dl*-leucylglycine and *dl*-leucylglycylglycine and to the University of New Zealand for a Travelling Scholarship.

XXIV. THE TITRATION CONSTANTS OF SOME AMIDES AND DIPEPTIDES IN RELATION TO ALCOHOL AND FORMALDEHYDE TITRATIONS OF AMINO-N.

BY JAMES MELVILLE AND GEORGE MAXWELL RICHARDSON.

From the Biochemical Department, Imperial College of Science and Technology, South Kensington.

(*Received November 30th, 1934.*)

MEASUREMENT of the titration constants of simple peptides is of biochemical interest for two reasons. Firstly, it provides information necessary for careful titrimetric estimation of amino-N in biological fluids or enzymic proteolysates [Richardson, 1934, 1, 2]. Secondly, it facilitates interpretation of protein titration curves by helping to define the change of titration constant which results from peptide formation [Cohn, 1931].

For gelatin hydrolysates and various synthetic dipeptides, suitable data are already available [Cannan and Muntwyler, 1930; Greenstein, 1933; and others]. There is therefore no difficulty in deducing the extent of error due to these substances in alkalimetric formaldehyde or alcohol titrations of amino-N [Richardson, 1934, 2]. Yet there exists an important group of substances containing amino-N about which there has been insufficient information hitherto. These, the amino-acid amides, may be quite plentiful in certain plant extracts and probably of enzymic proteolysates [*cf.* Melville, 1935]. Titration constants for certain typical derivatives have therefore been examined, together with data for some peptides of possibly distinctive behaviour. In addition, the usefulness of *iso*-glutamine as a readily synthesised buffer of value in peptidase experiments is described.

EXPERIMENTAL.

The glutamic acid derivatives were synthesised from *d*-glutamic acid by Bergmann's benzylchlorocarbonate method [Melville, 1935], while for other materials we are deeply indebted to Prof. Max Bergmann [Bergmann *et al.*, 1929; 1932]. In our experience, all materials required several recrystallisations to free them from traces of titratable contaminants, primarily affecting the alkaline curves. The glutamic acid derivatives, which showed this effect initially, yielded admirable data on recrystallisation [Melville, 1935, p. 182]. Other materials were not further recrystallised, and one of these, *d*-tyrosyl-*d*-arginine, has required suitable allowance for a titrated impurity (5 % of the group titre). Similar contaminants in *l*-*iso*asparagine and *d*-alanyl-*l*-proline had a sufficiently alkaline range (about 9·6, suggestive of free amino-acids) to give no serious interference in the constants.

Titration from a micro-burette was carried out with hydrogenated 0·1 *M* NaOH or HCl with the recognised precautions, the reagents being standardised against Na_2CO_3, potassium hydrogen phthalate and constant-boiling HCl as ultimate standards. Separate solutions were used for acid and alkaline curves except in the cases of *d*-glutaminyl-*d*-glutamic acid and *d*-tyrosyl-*d*-arginine. Where a preparation was not originally isoelectric, a suitable correction (not exceeding 2 %) has been applied to both curves. Attempts to titrate the benzylcarbonato intermediaries at a hydrogen electrode were naturally abortive, owing to catalytic reduction with characteristic decay of electrode potential.

The apparatus has been described elsewhere [Melville and Richardson, 1934]; for titration at considerable acidity, however, a constricted vessel of 2 ml. minimum capacity was used. Junction with saturated KCl solution was made smoothly *in situ* about 10 min. before titration, and wandering potentials in acid solution were minimised by careful selection of bridges. Occasional renewal of the KCl surface was effected, in prolonged titration at acid extremes, by discharging small measured volumes of KCl from the bridge, the small salt increments being included in the estimated ionic strength. Electrodes were freshly palladised, gold-plated platinum wires, and working temperature was $25 \pm 0{\cdot}02^\circ$. The reference potential assumed for a hydrogen electrode in 0·05 *M* potassium hydrogen phthalate was 0·2347 v. at this temperature [Clark, 1928]. Duplicate electrodes seldom disagreed by more than 0·0001 v.

As usual, observed titres were corrected for free acid and alkali at the p_H extremes, the simple Debye-Hückel relation modified by Simms [1926] being used to calculate hydrion concentrations from p_H; thus, $p_H = \log \frac{1}{[H^+]} - \log \gamma$, where $-\log \gamma = 0{\cdot}3\sqrt{\mu}$ (Simms quotes $0{\cdot}2\sqrt{2\mu}$). μ, the ionic strength, was estimated without inclusion of the zwitterion. Hydroxyl ion concentrations were obtained correspondingly, the ionic (activity) product of water being accepted as $10^{-13{\cdot}995}$ at 25° [Clark, 1928]. The calculated constants, G′ *etc.*, are titration constants [von Muralt, 1930] uncorrected for activity of the ions concerned. Thus since ionic strength was not constant during titration, a titre which provides the best carboxyl constant may differ slightly from that providing the best amino constant. Carboxyl and amino constants are both expressed as hydrion dissociation constants (Brønsted-Lowry) using the Sørensen logarithmic nomenclature, $p_{G'}$ *etc.*

Results.

In Table I, full data for *d*-glutamine and *d*-*iso*glutamine are quoted, data for other materials being suitably abbreviated. The possibility that the amides would suffer hydrolysis during titration has fortunately not been realised. Thus *d*-glutamine and its peptides are sufficiently stable even at 37° [Melville, 1935] to permit a reasonable titration; at 25°, steady titration produced the consistent data of Table I. Measurements on glycyl-*l*-proline and *d*-tyrosyl-*d*-arginine had been completed before Greenstein's paper [1933] appeared. Glycyl-*l*-proline gave good constants in accord with Greenstein's on an identical sample, so that further detail is not required (Table II). The samples of *d*-tyrosyl-*d*-arginine were apparently not identical, however, and results are more fully detailed as there is considerable divergence. The source of disparity is difficult to ascertain in the absence of more particulars than are given in his paper, but our constants seem consistent enough to be accepted (except that the fourth constant (guanidine) is impaired by the large free alkali correction and by a necessary assumption of 5 % of impurity of $p_{G'}$ 10·1).

In Table II, the mean constants of Table I are collected and compared with accepted constants for related compounds (expressed on a zwitterionic basis).

Table I. *Calculation of titration constants.*

Titrated solutions were all prepared by weight.

(*a*) *d*-Glutamine (mol. wt. 146) —COOH 3 ml. 0·25 *M* titrated with 0·197 *M* HCl.

Discussion.

Effect of structure on $p_{K'}$[1]. Many factors, not solely structural, take part in promoting hydrion dissociation. It is, however, a commonplace that kationoid groups in a molecule (—C_6H_5, —I, —COOH, —$COOC_2H_5$, —$CONH_2$, —NH_4^+) will favour hydrion dissociation (displace $p_{K'}$ to more acid regions), while anionoid groups (—CH_3, —COO^-, —NH_2) will retard it, the effect varying with the number, the potency and especially the proximity of the groups [see Allan *et al.*, 1926; Cohn, 1931]. Upon this basis, ample explanation of the major displacements of $p_{K'}$ in Table II is provided.

Thus, *glutamine* differs structurally from α-amino-*n*-butyric acid by a kationoid group, —$CONH_2$, in the γ-position, this distant group effecting a small decrease of both $p_{K'}$ (Table II); an enhanced effect with asparagine illustrates

---

[1] For purposes of discussion, $p_{G'}$ is accepted as equivalent to $p_{K'}$. The approximation is small compared with the magnitudes discussed and the unspecified effects of salt concentration. Existence of optical isomerism is ignored as this is presumably without influence on $p_{K'}$.

the result of structural proximity. The comparable behaviour of a kationoid —COOH group is shown in the first carboxyl constant of *glutamic acid*. The second carboxyl constant, however, is under the opposing influences of the anion, $—COO^-$, and a kation $—NH_3^+$, and is not greatly removed from the constants of fatty acids ($p_{K'}$ 4·7), while the amino constant of glutamic acid is increased over that of glutamine owing to the replacement of the kationoid $—CONH_2$ group by the anion $—COO^-$. In the case of iso*glutamine*, the carboxyl group is rather distant from the kationoid $—CONH_2$ group and the kation $—NH_3^+$ and is consequently not so much stronger than a fatty acid; but in *iso*asparagine there is considerable enhancement. The amino-group of *iso*glutamine is in the α-position to a kationoid $—CONH_2$ group (as compared with the α-$—COO^-$ anion of glutamine) and far removed from a $—COO^-$ anion; hence its $p_{K'}$ is displaced considerably in an acid direction. In *iso*asparagine, a corresponding displacement is retarded by the greater proximity of the $—COO^-$ anion. In the *hydroxyasparagines* similar considerations, including an effect of kationoid hydroxy-groups, are involved [Chibnall and Cannan, 1930].

There is no need for a detailed extension of the argument, but a few points require mention:

(*a*) A *dipeptide* may be regarded as a substituted amide R.CONH (CHR'. COO^-), the substituent carrying an α-$—COO^-$ anion (or kationoid —COOH) with perhaps further complicating groups. As a simple case, α-aspartylaspartic acid, $p_{K'_{NH_2}}$ 8·26 (from aspartylaspartic anhydride [Greenstein 1931]) is a substituted α-asparagine (8·02); whereas aspartylglycine, $p_{K'_{NH_2}}$ 9·07 [Simms, 1928][1], and β-aspartyltyrosine, $p_{K'_{NH_2}}$ 8·92 [Greenstein, 1933; Bergmann *et al.*, 1934] are substituted β-asparagines (8·80). Compared with the amides, each peptide shows a slight increase of $p_{K'_{NH_2}}$ due to substituent $—COO^-$ anions. At the same time, however, it is the position of the —CONH— group which is most powerful in determining the magnitude of the peptide $p_{K'_{NH_2}}$.

(*b*) Therefore, a peptide carrying a $—CONH_2$ group in addition to its typical —CONHR group must be expected to show an abnormally low $p_{K'_{NH_2}}$. Indeed the displacement of $p_{K'_{NH_2}}$ in the glutaminyl peptides is not exceeded in any amino-N compound of important biological distribution and has been equalled only when both residues of a dipeptide have contained kationoid groups (phenylalanylarginine, 7·57, tyrosyltyrosine 7·68 *etc.*, also cystine 7·5, 9·0). The possibilities of further depression by coupling such residues to glutamine, or particularly by preparing derivatives of α-hydroxyasparagine ($p_{K'_{NH_2}}$ 7·17) or β-hydroxyglutamine, should not be overlooked. In the meantime, it is likely that the mean $p_{K'_{NH_2}}$ for pepsin proteolysates at 7·9 [Cannan and Muntwyler, 1930] will be lower for proteolysates from other sources than gelatin which contains a minimum of kationoid groups. Of course, complexity of the polypeptides also operates to decrease the $p_{K'}$ (as in glycine hexapeptide, $p_{K'}$ 7·6 [Stiasny and Scotti, 1930]).

---

[1] The exact structure of this peptide was not described, though Fischer's indeterminate synthesis from fumaryldiglycine was presumably employed. A paper from the same laboratory describes the preparation as stable to erepsin [Levene *et al.*, 1926], affording presumptive evidence of β-linkage [Bergmann *et al.*, 1934].

(*c*) It is noteworthy that introduction of a *p*-hydroxy-group into phenylalanine produces a negligible fall of $p_{K'_{NH_2}}$ in the resulting tyrosine (9·23 becomes 9·15). As it is unlikely that a different situation exists in their peptides (particularly after ionisation of the hydroxyl group), the analogy between our constants for tyrosylarginine and those for phenylalanylarginine (Table II) is satisfying. Again the hydroxyl constant of tyrosine (10·2) is not greatly decreased in the peptide, and resembles that of the similarly placed group in tyrosyltyrosine (9·80 [Greenstein, 1932]). Thus our new data show a uniformity previously lacking.

(*d*) There seems no essential difference between the acylproline and ordinary peptide linkages in their effect on $p_{K'}$.

Influence on the estimation of biological amino-N. In a detailed discussion of alcohol and formaldehyde titrations of biological fluids, it was shown [Richardson, 1934, 2] that a satisfactory and convenient indicator-point in the case of amino-acids (mean $p_{K'}$ 9·6) was the first visible colour of phenolphthalein (p_H 8·4). Now this discussion assumed a working temperature of 25°; at 15° the mean $p_{K'_{NH_2}}$ is more truly given at 9·9 with no accompanying change in the indicator range, so that the end-point could even be a little more alkaline than p_H 8·4. The more acid end-point favoured by Brown [1923] for his formaldehyde titration by a comparator method (phenol red, p_H 8·0) was due to the undue proportion of peptides or of amino-acids with kationoid groups which he investigated (*e.g.* asparagine, see below).

Now, the discussion quoted was concerned primarily with the single-indicator titration of simple amino-acids. It follows from the argument therein developed that where glutamine and asparagine may be present as bulk constituents, as in certain plant extracts, a lowered indicator-point is desirable to accommodate these lower values of $p_{K'}$ (9·13 and 8·80). Thus p_H 7·6 (phenol red) would be a likely point (Brown places it even lower for asparagine); yet at the same time the original indicator-points would not exclude any considerable portion of these amides from titration. A more important defect of the methods is that peptides (mean $p_{K'}$ 8·3) would largely escape estimation, as was noted in the discussion. A particularly serious example is presented by the peptides of glutamine and asparagine, or other peptides of abnormally low $p_{K'}$ (see previous section); in such cases the amino-groups would be 75 to 90 % titrated in the preliminary p_H adjustment and only the remaining 10 to 25 % would be included in the titration proper. The use of a lower indicator-point (p_H 6·5) to include peptide-N would automatically exclude the simpler amino-N. Conversely, a two-indicator method would include the desired groups but also various other unspecified substances.

Indeed, there is no titration method which can be safely applied without some foreknowledge of the chemical composition of the extract to be tested. Where such foreknowledge is lacking, a two-indicator titration of lead-treated extracts by the Lüers formaldehyde method merits further development [Richardson, 1934, 2], or, as a temporary expedient, parallel titration of aliquots to different indicator end-points may be used to find the optimum conditions (as with peptones [Brown, 1923]). The other common method for amino-N (Van Slyke) is unfortunately liable to other error [Richardson, 1934; Melville, 1935] and its use requires similar foreknowledge of the composition of the extract.

Influence on the study of peptic scission. An unusually low $p_{K'_{\mathrm{NH}_2}}$ in the dipeptides which result from protein scission will not adversely affect the customary Willstätter titrimetric estimation of the extent of hydrolysis [Richardson, 1934, 1]. On the other hand, the use of dipeptides with a low $p_{K'_{\mathrm{NH}_2}}$ as substrates in dipeptidase studies raises a novel problem as to effective buffering capacity. Thus for a scission experiment at the customary p_{H} of 7·4 to 7·8, it is clear that such a dipeptide ($p_{K'}$ 7·6) must first be brought to the appropriate p_{H} by addition of 0·4 to 0·6 equivalent of NaOH. When this is followed by scission of the peptide, this one group ($p_{K'}$ 7·6) will be progressively replaced by two groups of $p_{K'}$ 9 to 9·6, these groups sharing the added NaOH. This leads, in the absence of buffering, directly to an increase of p_{H} to 8·5 to 9. Conversely, with buffers present, these must be sufficiently effective to engage without great p_{H} change almost the whole of the NaOH previously held by the peptide.

In such cases it is necessary to modify the current procedure of Grassmann [1927] to allow greater constancy of p_{H} during hydrolysis. Indeed, much of the present evidence of p_{H} constancy seems to depend on the use of dipeptides ($p_{K'}$ 8·3) requiring little p_{H} adjustment, the buffering capacity of the enzyme preparation itself being partly responsible for the preservation of p_{H}. Certainly, Grassmann's early use [1927] of only 0·8 equivalent of NH_3– NH_4Cl buffer ($p_{K'}$ 9·3) at a p_{H} outside its effective buffering range (p_{H} 7·8) was grossly inadequate. At the same time, the subsequent general practice of using 0·03 *M* phosphate at p_{H} 7·4 to 7·8 to buffer peptides in 0·05 *M* to 0·1 *M* concentration [Bergmann *et al.*, 1934] is scarcely a sufficient improvement for critical p_{H} studies. Adequate buffering would need at least three equivalents of a buffer, whose $p_{K'}$ should be just alkaline to the experimental p_{H} in order to offer the maximum obstruction to the alkaline drift.

It is an added advantage if such a buffer is soluble in 90 % alcohol (or acetone), and is composed of some base or basic group and its salt (briefly because, in titration, the buffering range of a base is displaced by alcohol addition with respect to the phthalein indicator, so that encroachment of the buffer on the titration end-point is avoided [*cf.* Richardson, 1934, 1]; moreover, the temperature effects on the $p_{K'}$ of a basic buffer and of the titrated groups are comparable). In *iso*glutamine ($p_{K'}$ 7·9) these desirable properties are all combined and join with the convenient synthesis and stability of the material to mark it out for further study.

iso*Glutamine as a buffer for study of peptide scission.* Since the above criteria for buffering dipeptidase experiments are so admirably combined in *iso*glutamine, a few more details may be presented. *iso*Glutamine (α-glutamine) may be easily prepared from glutamic acid (for purity see Melville [1935, p. 182]) and has ample, though not great aqueous solubility. Used as a 0·03 *M* buffer for 0·01 *M* dipeptides, it does not interfere with alkalimetric acetone titration of amino-N, either by precipitating from solution or by encroaching on the end-point. In contrast the usual phosphate buffer is an acid substance with a $p_{K'}$ too low for adequate buffering against alkaline drifts and with insufficient solubility at the end-point. Barbitone, as an alternative, has a suitable $p_{K'}$ (8·2) and acetone solubility, but insufficient aqueous solubility (0·023 *M*) and being an acid is liable to interfere at the end-point.

Table III. *Stability of* d-iso*glutamine at 37°.*

0·124 g. *iso*glutamine adjusted to given p_H and made to 25 ml. (0·034 *M*) with phosphate or barbitone buffer. At intervals, 2 ml. were removed for NH_3 determination [*cf.* Melville, 1935, Tables II and III].

	NH₃ liberated (as ml. *M*/70 HCl)		
Time in hours	p_H 6·8	p_H 7·8	p_H 8·8
24	0·04	0·11	0·18
48	0·11	0·18	0·34
72	—	—	0·48
96	0·14	0·35	—
100 % scission	4·75	4·75	4·75

These features of *iso*glutamine would, of course, be valueless in presence of a latent tendency to hydrolysis of the α-amide group. Fortunately, Table III shows that this tendency is negligible under the conditions of ordinary experiment (it was interesting that simultaneous amino-N titrations showed no important increase in amino-N + NH_3 during liberation of NH_3, virtual evidence of ring closure). Moreover, as *d-iso*glutamine showed no hydrolysis whatever during two hours with mixed yeast peptidases under conditions giving 60 % scission of *d*-glutaminylglycine, no fear of hydrolytic scission of the buffer need normally be entertained in experiments of the usual duration.

Finally, data for the preparation of 0·03 *M* *iso*glutamine buffers are interpolated from the data of Table I and presented in Table IV. Similar data for *iso*asparagine ($p_{K'}$ 8·0) may be readily prepared from Table I, should *iso*glutamine prove unsuitable in unusual circumstances.

Table IV. *Preparation of* iso*glutamine buffers* (*for immediate use*).

SUMMARY.

Titration constants at 25° have been determined for *d*-glutamine, *d-iso*-glutamine, *l-iso*asparagine, *d*-glutaminylglycine, *d*-glutaminyl-*d*-glutamic acid and *d*-alanyl-*l*-proline, and re-determined for *d*-tyrosyl-*d*-arginine and glycyl-*l*-proline. Factors influencing the magnitude of the respective $p_{K'}$ values are discussed. α-Amides and α-peptides possess constants characteristically different from their β- or γ-analogues.

In certain peptides the constants attributable to the amino-group are unusually low, and the influence of this fact on the titrimetric estimation of biological amino-N and on the study of peptidase action is discussed.

Advantages attending the use of *iso*glutamine as a buffer in peptidase studies are outlined, and the necessary data as to the composition and stability of the buffer mixtures are presented.

The authors are indebted to Prof. A. C. Chibnall for providing facilities for this work, to the Department of Scientific and Industrial Research for a research award to one of us (G. M. R.), and to the New Zealand University for a travelling scholarship to the other (J. M.).

XXV. OBSERVATIONS ON THE NATURE, DISTRIBUTION AND DEVELOPMENT OF CERTAIN CELL-WALL CONSTITUENTS OF PLANTS.

By HAROLD WILLIAM BUSTON.

From the Biochemical Department, Imperial College of Science and Technology, South Kensington.

(*Received December 1st, 1934.*)

The view has frequently been advanced that the pectic substances of plants, whatever their precise chemical nature, are not to be regarded as fixed and permanent constituents of the cell-wall, but rather as labile substances that may undergo further changes, possibly of very profound nature, leading to their almost complete disappearance from the older tissues. By such transformations of pectin, two classes of substances have been supposed to arise, (i) lignin, (ii) the hemicelluloses. It has in fact been suggested [O'Dwyer, 1926; 1928; 1932] that all three types of compound are interrelated, the passage from pectin to lignin taking place through certain hemicelluloses.

With regard to the former, Fuchs [1927] has advanced a theory of lignification in which he emphasises the fact that pectin and cellulose disappear as lignification sets in—a point previously made by von Fellenberg [1918]. Fuchs sees further a parallel to this development in the individual plant in the apparent development of a more and more modified cell-wall as one passes from the Algae to the higher plants; thus the algal cell-wall (he states) consists of pure cellulose, while in the mosses, incrusting substances (pectins) are present, lignins only appearing at a higher evolutionary level. As conceived by Fuchs, lignification involves the oxidation of the primitive cell-wall to "acid saccharides," and especially to pectin, with subsequent transformation of these, by unknown stages, into lignin. Ehrlich also [1930] considers that the acid polysaccharides form the chief cell-wall material, and that the formation of lignin represents a process involving enzymic dehydration and reduction of these bodies and affecting particularly the pectins. He claims that from flax stems (*i.e.* a partly lignified tissue) it is possible to isolate an "altered pectin," giving rise on hydrolysis to less galacturonic acid than normal pectin and containing also xylose residues in the molecule; with this is associated a brown substance having many of the properties of lignin, giving the characteristic colour tests of the latter, having almost the same empirical composition and containing a similar proportion of methoxyl [Ehrlich and Schubert, 1926; 1928]. This brown substance he regards as a substance derived from the pectin and intermediate between it and lignin.

It has been claimed also that microchemical staining tests show that there is a replacement of pectin by lignin in older tissues [Mehta, 1925], while Ritter [1925] states that 0·5 % ammonium oxalate, a recognised reagent for extraction of pectins, does not remove any pectic substance from basswood, red alder or pinewood (age of wood not stated), and he infers therefore the absence of pectin from woody tissues.

Finally the common possession of a high methoxyl content, both by soluble pectin and insoluble lignin (at least, as isolated), has been regarded as evidence of their interrelation. Ehrlich [1930] also considers that the hydroxyl and acetyl groups of the lignin molecule represent those present in the parent polysaccharide.

No complete scheme representing the course of the supposed transformation of pectin into lignin seems to have been formulated—indeed, in view of the lack of understanding of the structure of lignin, none is possible as yet—but such changes if taking place must necessarily be of the most profound nature.

A relationship between the pectins and the bodies known as structural hemicelluloses is much more readily understood. The acid saccharides or polyuronides in general comprise three groups of structural units, *viz.* the anhydrides of hexoses, hexuronic acids and pentoses, combined in widely varying proportions. Chemically, the hexoses are considered to represent the parent substances forming the cell-wall material as originally laid down. By oxidation of their free primary alcoholic groups, after condensation of the sugars themselves to hexosans, there would be formed uronic anhydride units, and by subsequent decarboxylation of these, pentosan units—the whole process taking place actually within the cell-wall. Stereochemical considerations show that, by such a process, arabans would arise from galactans, while glucosans would pass through glucuronic anhydrides to xylans. It is evident that from a parent hexosan, even if based on a single sugar, a very wide variety of intermediate products could arise as the result of such transformations; it is thus not surprising that very different substances, all legitimately classed as hemicelluloses or acid saccharides, have been obtained. Among these substances the pectins represent a type of unusually highly oxidised hexosan, with but little of the unchanged parent hexose and little of the ultimate pentose constituent. Pectins thus are mainly distinguished from the hemicelluloses in that they contain some 70 % of uronic anhydride, whereas in the hemicelluloses the figure rarely exceeds 25 %.

Support has been found for the suggestion that the pectins are the precursors of the hemicelluloses in the frequently-repeated observation that the former predominate in young, fleshy or unlignified tissues, while in older lignified tissues, of lower moisture content, the position is reversed. From the more purely chemical side, the *in vitro* transformation of pectins into hemicellulose-like bodies has been reported by Candlin and Schryver [1928] and Linggood [1930] who used a method involving decarboxylation by heating under pressure; and by Norman and Norris [1930] who employed a process of mild oxidation.

It is evident therefore that, taken as a whole, the evidence for the existence of a relationship between the three groups of substances is considerable. All these suggestions, however, need some further examination. In the first place there seems to be no record of any investigation dealing with the distribution of pectin, hemicelluloses and lignin, and possibly other allied carbohydrates, in a given plant or tissue during its life-period, the statements concerning the relative amounts of these substances present in young or old material being based rather upon isolated observations on different types of material. Thus speculation has been founded upon data concerning the relative proportions of the different groups of constituents, rather than concerning the absolute amounts of the substances present in a plant from time to time. It is by no means impossible that observations which have been interpreted as indicating the transformation of one substance into another really indicate a changing course of metabolism in the plant, giving rise to increasing amounts of a new type of product, while formation of the original type ceases—that already present remaining intact, however. Preece [1930], for instance, records the presence of 0·4 % of pectin in boxwood, while O'Dwyer [1925] actually isolated a small amount of pectin from beechwood 80 years old. Although these relative proportions are low, the total weight of pectin in the whole plant must have been considerable. If pectin were formed only in the early stages of growth, while subsequent thickening of the cell-wall involved the laying down of large amounts of non-pectin material, the low concentration of the pectin would be accounted for, without the necessity for postulating any extensive subsequent alteration of pectin.

Concerning the chemical work mentioned above, the products obtained by the various investigators certainly had a much lower uronic anhydride content than the original pectins, but still considerably higher than met with in any of the hemicelluloses extracted from plant materials, with the sole exception of O'Dwyer's beech hemicellulose B [1926] which contained some 60 % of uronic anhydride, a figure not approached in any other hemicellulose recorded. Again the yields of the products were generally very low (Candlin and Schryver [1928] report a yield of some 15 %), and in some cases may have consisted in part at least of hemicelluloses present as impurity in the original pectin. The nature of the sugar residues in these products is not recorded.

As regards the evidence based upon microchemical staining tests this must be accepted with caution. The extremely complex nature of the cell-wall, the constituents of which may be present in the form of an intricate mosaic, and not differentiated into sharply divided layers, and the admitted lack of specificity of many of the stains used render the evidence from this direction of doubtful value, at least when taken alone.

Thus it will be seen that the evidence for the transformation of pectin into hemicellulose and/or lignin *in vivo* is by no means conclusive, although perhaps, in the mass, impressive. It seemed therefore appropriate to attempt experiments which would yield more direct evidence of the occurrence or possibility of the transformations suggested. Since the ready lability of the pectins is assumed in all the theories outlined above, attention was in the first place directed to these substances, and experiments were made with the object of ascertaining whether such assumptions are justified. At the same time, the investigations furnished much useful information in other directions. For instance, a search through the literature revealed the paucity of direct information concerning the cell-wall constituents of the leaf, and certain particulars concerning these bodies came to light during the course of the work. Again, observations were made concerning the availability of some of the supposed cell-wall materials as reserve carbohydrate for purposes of metabolism.

Concerning the methods of investigation which seemed suitable, the most obvious consisted in following out the distribution of the various substances under consideration in a given plant during its full period of development. To carry out thoroughly such an investigation on a typical woody plant would obviously be a matter of considerable difficulty. On the other hand, it is possible to select a part of a plant which in the course of a season's growth will show an alteration in character somewhat resembling that met with in the development of woody tissues as a whole. Data of this type may be found in the rather isolated observations published by Schulze and Pfenniger [1910] regarding the hemicellulose content of the pods of garden peas and beans. In the case of beans particularly, the young pods are of fleshy nature, with a high water content, a state regarded as quite typical of tissues in which pectins predominate; while with maturity the water content decreases enormously, and the tissues become hardened and fibrous, resembling externally at least tissues in which much hemicellulose may be found. Staining tests also show that some lignin-like material has developed in the final stages of ripening. Schulze and Pfenniger found that the proportions of hemicellulose in the pods increased considerably with maturity.

No figures for pectin content are given by these authors—in fact, the methods for estimation of these substances had not then been established. Further, Schulze and Pfenniger estimated their hemicellulose by a method of difference, and therefore possibly included certain other substances under this heading. In the present work, the cell-wall constituents of runner bean pods and the pods of sweet peas were investigated.

Although as regards steadily diminishing water content these tissues resemble to some extent those parts of the plant undergoing lignification, yet they cannot be considered as typical lignified materials, and at the most the changes taking place during their ripening could only be expected to simulate the very early stages of lignification. It was therefore desirable to carry out a similar investigation dealing with the growth of a true woody tissue. Suitable material may be found in the hard-wooded shrubs. For instance, roses normally throw up, in the spring, strong growths from the base of the plant, whose early growth is extremely rapid, and which are very definitely of a fleshy nature. During the summer and autumn these shoots become "ripened," *i.e.* lose their water slowly and undergo true lignification. Opportunity arose to conduct a (single) controlled experiment upon such growths, as described below.

Apart from such direct studies as those outlined above, artificial conditions may be set up which will tend to promote transformation of cell-wall materials where such is possible. To this end examination was made of detached leaves, (i) after a period of "starvation" in darkness, (ii) after allowing the leaves to undergo a process of slow drying in sunlight. The first-mentioned process was carried out by allowing the detached leaves to remain, with their petioles in water, in darkness for varying periods of time (7 days and upwards) until, in extreme cases, visible wilting had taken place. Under these circumstances, photosynthesis ceases, respiration continues, and there is an ample water supply. Thus it is to be expected that, after exhaustion (by respiration) of the readily available sugars, there might be some oxidation of reserve polysaccharides, either directly or after hydrolysis to simple sugars. On these lines, if decarboxylation of uronides is a process of mild oxidation, as suggested by Norman and Norris [1930], then prolonged starvation might possibly lead to such decarboxylation, the pectins with their high uronic anhydride content reflecting this process. Some early experiments on these lines were recorded by Deleano [1912] and by Ahrns [1924]. The former subjected leaves of *Vitis* to starvation for periods up to 21 days, but observed breakdown only of simple sugars and of starch; no figures for pectin were recorded. Ahrns, using much less drastic methods, obtained somewhat corresponding results.

The second process, that of slow drying, may be regarded as somewhat analogous to the conversion of grass into hay. In this case, both photosynthesis and respiration might be expected to continue during the earliest stages of the process, but would rapidly be terminated by depletion of water-supply. Thus respiration would probably be too short-lived to occasion any mobilisation of possible reserve carbohydrate; the diminished water supply would, in fact, be the most important factor altering the course of metabolism. As Spoehr and McDougal [1918] and McDougal *et al.* [1919] have shown, a depleted water supply induces a conversion of saccharides into anhydrides and leads to an accumulation of pentosans. The thickening of tissues (*e.g.* during lignification) is accompanied by a progressive decrease in their water content, a factor which may well influence the building up of the cell-wall or the modification of its constituents. If the pectins become converted with increasing age into hemicelluloses, and possibly lignin, then it might be expected that the same process would be encouraged by the gradual withdrawal of water from the tissue by slow drying.

Apart from the above-discussed suggestion, regarding interconversion of cell-wall constituents, the statement has frequently been made that pectins are formed in tissues during periods of rapid growth, hemicelluloses arising with less rapid development. It seemed therefore appropriate to examine the distribution of these cell-wall constituents in plants of the same variety grown under conditions that would produce different rates of growth, *i.e.* plants grown normally and "forced." A brief experiment of this type is recorded.

The various lines of attack outlined would in the sum be expected to yield information of the kind sought and at the same time to furnish useful data in the other connections mentioned. The isolation of the different types of hemicellulose from leaves has not been recorded hitherto. Some of these substances were of necessity handled in the present research, and information regarding their chemical nature is recorded.

Apart from the difficulty of providing suitable material (*e.g.* for any prolonged series of investigations on the development of lignin in a typical woody plant), there are considerable difficulties of analysis to contend with. While for instance the calcium pectate method for determination of pectin may be regarded as satisfactory for fruits *etc.*, where extraction is easy, the physical nature of wood might make thorough extraction much more difficult, although pectins existed in the tissue. Again the methods of estimation of the hemicelluloses so far available are far from satisfactory. The term, as usually applied, and as used in the present work, indicates those constituents not extracted by water, but removed by extraction with 4 % hydroxide solution. (Their solubility after extraction frequently alters). Thus certain substances, whose chemical nature would warrant their inclusion in the group, would be excluded; among such would be the water-soluble galactans of wood [Schorger and Smith, 1916], of fruits [Widdowson, 1931] and the unextracted xylan found in close association with cellulose and called by Hawley and Norman [1932] "cellulosan."

EXPERIMENTAL.

1. *General analytical methods.*

Since the investigation involved a very large number of routine analyses, it will save repetition if the methods usually employed are summarised in the first place, reference to any special modifications being made in dealing with the individual experiments.

(*a*) *Preparation of material.* In the case of leaves, these were dried in a large steam-heated oven through which a current of air was drawn; drying was carried out as soon after picking the leaves, and as rapidly, as possible. The material was usually allowed to remain in the oven for 4–5 hours and was then transferred to stoppered glass jars, cooled, weighed and ground finely. Before using, the material was passed through a sieve, and the portion of 30–60 mesh size (per inch) taken for experiment; this was dried overnight in an oven before being weighed out for extraction.

In some cases (noted below) drying was carried out by dropping the material into six times its weight of boiling 95 % alcohol; after boiling for a sufficient time, the material was transferred to the steam-oven and the process completed as described.

(*b*) *Estimation of pectin.* Suitable samples (1–5 g.) of the dried material were extracted with 0·5 % ammonium oxalate solution in a water-bath at 95° for

6 hours; the residues were treated twice more in the same manner. In the extract, pectin was estimated as calcium pectate, following a preliminary precipitation with acidified alcohol, according to the method of Emmett and Carré [1926]. An amount of extract was taken sufficient to provide 0·02–0·04 g. of calcium pectate for weighing.

(*c*) *Estimation of hemicelluloses.* Hemicelluloses were estimated by a method similar to that of Preece [1930], and already described in detail by the present author [1934]. According to this method, the material, after removal of pectin, was treated once with dilute alcoholic sodium hydroxide (1 % NaOH in 50 % alcohol), and then exhaustively extracted with 4 % sodium hydroxide. The hemicellulose precipitated by acidification and addition of excess of alcohol was, after suitable washing, weighed directly on a Gooch crucible. Differentiation into "hemicellulose A" (pptd. on acidification only) and "hemicellulose B *plus* C" (requiring excess of alcohol for pptn.) was made where desirable. No separation of the fractions B and C was attempted. In all cases corrections for ash and for protein present were made, as suggested by Preece. Amounts of material were chosen to give 0·15–0·30 g. of hemicellulose for weighing.

(*d*) *Other estimations.* Lignin was estimated by the method of digestion with 72 % sulphuric acid, according to the details given by Dorée [1933]. Cellulose was estimated by the Cross and Bevan chlorination technique. Estimations of furfuraldehyde were made by the usual distillation method, the furfuraldehyde being weighed as phloroglucide, while uronic anhydride was determined where necessary by the method of Nanji *et al.* [1925].

In the cases of the pectin and hemicellulose estimations, duplicate estimations were in all cases performed upon aliquot parts of the extracts and, except in a few cases where lack of material prevented, duplicate extractions were carried out. The other estimations were normally carried out in duplicate.

2. *The distribution of cell-wall materials in pods of beans and sweet peas during development.*

The material used was obtained from the open garden during the summers of 1933 and 1934, no special cultivation being made. In the case of the bean pods, all were picked at the same time and graded according to size in five or six batches, this being regarded as sufficient guide to their stage of development. In the case of the sweet pea pods, dated labels were attached to the separate flowers as the petals faded, so that the actual age of the pods themselves, from the time of forming, was recorded.

Drying of the material was carried out by the alcohol method, after removal of the seeds, only the shells being used for experiment. The figures given in Table I for percentage content of pectin *etc.* are calculated on the dry weight of material after alcohol treatment; values are also given for actual weight of the constituents per 100 pods.

The results in all cases showed a steady development of both pectin and hemicellulose throughout the whole period of the experiment. The very young pods contained relatively less pectin than the older, in which both pectins and hemicelluloses remained at a fairly constant level; both types of substance seemed therefore to be produced throughout the whole period of development. It was of interest to note the very different ratios of pectin to hemicellulose in the two types of tissue; the pods of the sweet pea are relatively of a much drier nature than those of the bean, especially in their earlier stages, and the preponderance of hemicellulose therein is in accordance with common experience.

Table I. *Distribution of pectins* etc. *in pods of* Phaseolus *and* Lathyrus.

Series I. *Phaseolus.* Tall variety, grown at Chelsea, 1933.
Picked 15. viii. 1933.

Batch No.	1	2	3	4	5	6
Average length of pods when picked (cm.)	2·5	5·0	7·5	10·0	15·0	21·0
Wt. of alcohol-dry residues per 100 pods (g.)	3·82	7·55	17·9	27·7	69·0	99·2
Pectin, as calcium pectate, % of dry weight	9·8	9·5	10·3	14·1	—	15·0
Hemicellulose, % of dry wt.	(17·2*)		18·9	16·3	19·0	18·3
Pectin, g. per 100 pods	0·37	0·72	1·68	3·52	—	14·9
Hemicellulose, g. per 100 pods	(0·98*)		3·35	4·50	13·1	18·2

Series II. *Phaseolus.* Dwarf variety, "Little Gem"; grown at Outwood, Surrey, 1934.
Picked 19. x. 1934.

Batch No.	1	2	3	4	5
Average length of pods (cm.)	4	7	9	11	13
Wt. of alcohol-dry residues per 100 pods (g.)	4·55	7·84	29·8	35·6	71·0
Pectin, as calcium pectate, % of dry wt.	11·1	11·4	14·4	15·4	13·1
Hemicellulose, % of dry wt.	14·0	13·8	13·1	16·4	17·3
Pectin, g. per 100 pods	0·50	0·89	4·29	5·49	9·3
Hemicellulose, g. per 100 pods	0·64	1·07	3·90	5·84	12·3

Series III. *Lathyrus.* Grown at Outwood, Surrey, 1933.

Batch No.	1	2	3	4
Age when picked (days)	3	8	16	23
Wt. per 100 pods (g.)	2·2	7·4	12·1	23·2
Pectin, as Ca pectate, % of dry wt.	2·63	3·75	4·26	4·31
Hemicellulose, % dry wt.	29·2†	26·0	27·7	22·25
Pectin, g. per 100 pods	0·06	0·28	0·52	0·99
Hemicellulose, g. per 100 pods	0·64†	1·94	3·35	5·11

* Average of batches 1 and 2; insufficient material for separate determinations.
† One extraction only.

The values for hemicellulose content of the bean pods are in fairly good agreement with those of Schulze and Pfenniger [1910].

This investigation was extended to include examination of fully grown bean pods in both the green and the brown (fully ripened) conditions, in order to see whether the pectin content was altered in the final stages of development. Micro-chemical examination of brown pods showed that they contained some amount of thickened tissue, giving the reactions of lignin; in this state the pods were almost completely "air-dry." Green and brown pods of the same size were chosen, assuming that equivalent development had taken place in each case.

In the 1934 series, the "brown" pods were of two types, (i) allowed to remain on the plants while ripening, and (ii) detached when fully grown, but still green, and allowed to become brown by remaining in sunlight under glass (*cf.* the process of slow drying described below, p. 207). After removal of the seeds, drying, sampling *etc.* were carried out as usual (see Table II).

From these figures it seemed evident that the pectins remained unaffected even at the end of tissue development; in the 1933 series there was even a small increase of pectin at the end of the period—possibly owing to the "green" pods having been gathered rather before they had fully developed. Complete ripening resulted in a small loss of total dry matter in each case and in a definite loss of hemicellulose. It may be pointed out that in the case of the sweet peas, batch no. 4, the pods were turning brown, and a relative decrease in hemicellulose was to be observed there also. According to Schulze and Pfenniger, part of the hemicellulose is withdrawn from the pods during the later stages of ripening and translocated to the seeds themselves. It is interesting to compare certain of the

Table II. *Distribution of pectins* etc. *in mature bean pods.*

Material	Outwood, 1933 (Dwarf type, short pods)		Chelsea, 1934 (Tall type, long pods)		
Ripened	— Green	On plant Brown	— Green	On plant Brown	Detached Brown
Dry wt. of material insol. 80 % alc., per 100 pods (g.)	62·5	56·6	109·0	132·0*	92·0
Pectin, as Ca pectate, % of dry material	12·6	15·0	17·8	14·5*	21·2
Hemicellulose, % of dry material	14·7	13·2	21·4	12·5*	17·9
Lignin, % of dry material	13·2	14·9	8·5	9·4*	—
Pectin, g. per 100 pods	7·99	8·49	19·4	19·1	19·5
Hemicellulose, g. per 100 pods	9·17	7·60	21·1	16·5	18·0
Lignin, g. per 100 pods	8·25	8·43	9·26	12·4	—

* Material not dried by alcohol. (See also Table V, p. 206.)

figures for corresponding batches grown in the two seasons, 1933 and 1934, *viz.* Series II, batch 5, of Table I, with "Outwood, 1933, green" (Table II); and Series I, batch 6, Table I, with "Chelsea, 1934, green" (Table II). In each case, total growth is greater in the 1934 batch, probably owing to the greater rainfall during the growing season; and at the same time, the relative proportions of both pectins and hemicellulose are higher. This point is further commented upon below (p. 214).

Among the other figures given, attention may be called to the small increase in lignin in the 1933 series and the very definite increase in the pods ripened on the plant in 1934.

3. *Changes in the cell-wall constituents of wood of rose during lignification.*

A vigorous hybrid tea rose ("Leni Neuss") was pruned severely in April 1934; it was noted that within a few weeks two new shoots had appeared from a dormant bud on one stem, and were making rapid growth. Their rates of growth were similar, and a terminal bud appeared on each at the end of June. On July 4th the length of each was 53 cm., with 13 internodes; it seemed therefore that the two shoots might be regarded as identical at this stage. From each shoot the apical bud and side leaves were removed. One shoot was cut off, 5 cm. from its base (*i.e.* at the lowest node) on that date. The second shoot was allowed to remain on the plant, any fresh growths from axillary buds being removed immediately, until October 24th. Shoot no. I when removed was mainly of fleshy growth, although the lower part had already become considerably hardened. During the warm dry summer of 1934 the second shoot had become thoroughly "ripened," and was hard and woody throughout its length. A small increase in length (measured from the first node) had occurred, and the water content of the shoot was much less (Table III).

Each shoot on removal was sliced thinly and dried by the alcohol method, and the necessary analyses were performed, the results of which are shown in Table III. In the calculations of the percentage composition, allowance was made for the quantity of material removed in the alcoholic extracts. From shoot no. I only single extractions were possible; the cellulose determination was carried out on the residues from the extraction of hemicellulose.

From these results it appeared that formation of pectin continued throughout the whole period of development, the percentage showing however a decrease in the older shoot. In contrast, there was a much greater development of hemicelluloses, and still more so of lignin, the total amount of which in the shoot increased six times. The significance of these results is further considered below (pp. 212, 216).

Table III. *Distribution of cell-wall constituents in woody shoots of rose.*

	Shoot I	Shoot II
Age when cut (weeks)	12	28
Length (cm.) when cut	48	55
Fresh wt. when cut (g.)	27·0	27·5
Total dry wt. (g.)	4·06	10·51
Pectin, % dry wt.	5·03	4·77
Hemicellulose, % dry wt.	13·46	18·93
Cellulose (C and B), % dry wt.	24·0	26·3
Lignin, % dry wt.	7·94	18·36
Total pectin in shoot (g.)	0·204	0·49
Total hemicellulose in shoot (g.)	0·55	0·99
Total cellulose in shoot (g.)	0·97	2·76
Total lignin in shoot (g.)	0·33	1·93

4. *Changes in cell-wall constituents of leaves during "starvation*[1]."

Three types of material were used in these experiments: (*a*) leaves of runner-bean, (*b*) leaves of vine, (*c*) laminae of maize. Picking was in all cases carried out in the early morning, when but little starch was present. The batches of leaves were divided into "control" and "experimental" lots, care being taken to obtain fair average samples in every case. The control leaves were dried immediately in the oven, after removal of their petioles; the experimental leaves were placed with their petioles in jars of water and kept in darkness throughout the experimental period. The water in the jars was changed daily, and on each occasion it was found desirable to remove a small portion of the tip of the petiole. At the end of the period, the petioles were removed, and the laminae dried under the same conditions as the controls. In the case of the maize plants, a somewhat different procedure was necessary; whole plants of as nearly the same size as possible, were chosen, and were usually found to be of almost the same fresh weight (within 5 g. on a weight of 75–100 g.). The lower ends of the stalks were sufficiently trimmed to equalise the weights of control and experimental batches (4 whole plants in each batch), and the complete plants were treated, *i.e.* starved, dried *etc.* It was noted that both vine and maize were far more resistant to the starvation process than was the bean; in one experiment maize plants remained for 45 days without any appreciable wilting. Further, in the case of maize, the loss of dry matter during starvation was comparatively little. Table IV summarises the results of these experiments.

It was evident from these figures that the pectins remained practically unaffected by the process of starvation. In only one case was any appreciable loss of pectin noticed; in one experiment on the bean leaves. The loss of 3·6 % of the total pectin, here recorded, was probably outside the limits of experimental error; and it is perhaps noteworthy that in this case, the only one in which loss of pectin could be suspected, there was an extreme loss of total material. (In the case of maize, 1933, the total pectin was so low that the differences in amount between the two batches are of doubtful significance.) The leaves used in this test were younger than in the other cases, and contained more water-soluble matter, a fact which may have accounted for the unusually great loss of material.

---

[1] Many of the analyses recorded in this section were carried out by Dr V. H. Chambers, who was responsible also for the preparation of the material (bean, 1932 batches, and vine).

Table IV. *Effect of starvation on cell-wall constituents of leaves.*

All values (pectin *etc.*) are given as % on dry weight of original tissue.

Material	% loss of solids	Pectin (as Ca pectate)	% change of pectin	Hemi-cellulose "A"	% change	Hemi-celluloses "B"-"C"	% change	Hemi-cellulose total	% loss
Bean, 1932, I									
Control	—	6·55	—	1·09	—	2·14	—	3·23*	—
Starved 7 days	31	6·31	−3·6	0·97	−11·0	1·32	−38	2·29*	−29
Bean, 1932, II

Control	—	0·90	—		—		—	25·5	—
Starved 46 days	6	1·04	(+15)	—		—	—	24·5	− 4
Maize, 1934									
Control	—	1·39	—	10·9*	—	14·7	—	25·6	—
Starved 19 days	10	1·43	+2·8	11·4*	+1·6	11·9	−19	23·3	− 9

* Values calculated, by sum or difference; other values by direct estimation.

Turning to the figures for the hemicelluloses, these in all cases showed distinct losses during the starvation period, but, except in the case of the younger bean leaves, the loss was invariably confined to the water-soluble hemicelluloses (fractions "B" and "C"), where the loss in one case reached 66 % of the total fraction.

The nature of the individual hemicellulose fractions was examined in most cases (see p. 211) and determinations of pentosan and uronic anhydride were carried out. The insoluble hemicelluloses ("A") of the bean and vine leaves proved to be hexosans, no more than a trace of furfuraldehyde being evolved on boiling with 12 % HCl. On the other hand, the soluble ("B"-"C") fractions were found to contain units of pentosan and uronic anhydride. The only other recorded examples of hemicelluloses from leaf material were those of grass [Buston, 1934]. Of these, "A" was found to be composed almost entirely of xylan, giving a furfuraldehyde yield of 55 % approximately, while the "B" and "C" fractions contained a variety of pentosans, hexosans and uronic anhydrides. From maize, the "A" fraction again contained much pentosan, while the other fractions also closely resembled those of grass. Further details of these products are recorded in Table IX.

The soluble hemicelluloses isolated from the leaves after starvation were found to differ considerably from those of the control groups, as judged by furfuraldehyde determinations, the results of which are summarised in Table V. In general there was a very considerable loss of hexosan, together with some increase of uronic anhydride. Some net loss of pentosan also seemed to have occurred, so that the difference was perhaps not due simply to loss of hexose sugar by respiration. In Table V are also included some observations on the changes shown by the hemicelluloses of the bean pods during the final stages of ripening. Here again there is a striking decrease in the hexosan content, probably owing, as suggested by Schulze and Pfenniger, to translocation to the seeds, although possibly partly due also to respiration.

The stability of hemicellulose "A" in the bean and the vine leaves seemed curious. This substance, as stated above, was of hexosan type, so that it might

have been expected to be open to metabolic change. It was found to yield on hydrolysis, galactose only—not a readily oxidised sugar. On the other hand, no hexose other than galactose could be detected in any of the hemicelluloses, even those which had undoubtedly undergone some change.

It was observed that the hemicelluloses isolated from the leaves of the bean and the vine (fraction "A"), but not of the maize, were always contaminated with considerable amounts of protein, as much as 30 % of the fraction in some cases being of protein nature (as judged by its nitrogen content). The contamination was much less in the case of the starved leaves, and the other hemicelluloses ("B"-"C") were free from protein. It will be recalled that Chibnall [1924] has shown the disappearance of protein from leaves subjected to the starvation process.

Some difficulty was experienced in dealing with the vine hemicelluloses. All the vine extracts were extremely dark in colour and inclined to be viscous, and attempts to estimate the "A" and "B"-"C" fractions separately by the ordinary method were unsuccessful. An estimate of the relative amount of each present was obtained by determining the furfuraldehyde yield of the whole fraction (mixed), and of a small portion of the "B"-"C" fraction isolated from a further batch of material; from these values, knowing that fraction "A" gave no furfuraldehyde, it was possible to calculate the relative amounts of the two types. The vine leaf is known to contain large quantities of organic acids, and the presence of these substances, or some of their degradation products, may have led to an alteration in the physical nature of the hemicelluloses, causing the difficulty. It may be mentioned further that although no difficulty was met with as a rule in identifying the sugars in the hydrolysis mixtures, with the vine products it is possible that some sugars have escaped identification, as the yields of the different derivatives were poor and crystallisation thereof always slow.

In the case of maize, the loss of material was apparently confined to the water-soluble hemicelluloses. Since however in this case the "A" fraction was mainly xylan, it was hardly to be expected that this would show any alteration. Some change in its physical condition had occurred, since it was much less readily precipitated on acidification of the extracts from the starved leaves.

5. *Changes in the cell-wall constituents of leaves during a process of slow drying.*

Leaves of the bean and the vine were again used, the method of sampling being identical with that adopted in the starvation experiments. Controls were dried in the oven, while the experimental leaves were spread on paper in an ordinary garden frame, the lights of which were removed during fine weather but replaced at night. The leaves were allowed to dry in this manner for 7–10 days, after which they were shaken to remove dust, and drying was completed as usual. Estimations of pectin and of hemicelluloses were carried out as in the previous experiment (see Table VI). Again the pectin remained unchanged by the treatment. The hemicelluloses had undergone modification, but in a manner different from that met with in the starvation experiments. In each case there

was a considerable increase in the insoluble fraction ("A"). Its furfuraldehyde yield however remained *nil*, so that there was no evidence of any production of pentosan. Definite loss had occurred in the soluble hemicelluloses, and again an increase in the proportion of pentosan was observed (see Table VI*a*). Total hemicellulose increased in some cases, and the increase was probably due to anhydride formation from hexoses, or simpler soluble hexosans, during the gradual withdrawal of water. Whether the disappearance of some of the soluble hemicelluloses was due to loss by respiration during the early stages of the treatment (which seems hardly likely) or to some alteration in their physical condition could not be judged.

No experiment was made with maize in this case, but examination was made of a sample of hay prepared from a grass previously examined. Some analyses of this grass have already been recorded [Buston, 1934]. The grass (cocksfoot) was fully grown when cut, but still green. The crop from one half of the plot was oven-dried as soon after cutting as possible; the remainder was cut at the same time, spread and raked in the usual manner until quite brown and then oven-dried. This process of hay-making was thus somewhat similar to the slow drying process carried out with the bean and vine leaves. In view of the economic importance of hay-making, it is strange that so little attention has been paid to the chemistry of the process. Fleischmann [1912] records the observation that "crude fibre" remains unchanged, and that there may be a small increase in total dry matter, but little further information seems to have been published. A rather more extended study was therefore made of the cocksfoot hay, the results of which are summarised in Table VII. Unfortunately the figures obtained could not be calculated to "dry weight of original grass," since the relative weights of grass and hay were not determined; values are given as % of dry material, grass or hay. Thus any loss or gain in dry weight by respiration or assimilation is unaccounted for; it may be pointed out, however, that the ash

contents of the two samples were almost identical, so that any considerable loss or gain of dry matter during conversion into hay was not indicated. The methods of analysis (*e.g.* for soluble carbohydrates *etc.*) were those given in the previous paper [1934]. The results showed that the cell-wall material remained practically unchanged, any variation having been confined to the simpler saccharides.

In hay-making, as carried out according to tradition, considerable variations may be expected in the product, depending mainly upon weather conditions during the harvest. It is evident that the rapid drying during hot weather would give a product very different from that obtained when hay-making is carried out under cool or wet conditions. In the present case not only was the weather extremely hot (summer 1933), but the grass crop itself was of unusually low moisture content when cut. Complete drying must therefore have been very rapid, leaving but little opportunity for alteration in the more stable cell-wall components.

6. *Relative distribution of pectins and hemicelluloses in the radish under varying conditions of growth*[1].

In order to examine the relative distribution of the pectins and hemicelluloses in plant tissues of the same type grown under conditions resulting in different rates of development, the radish was chosen on account of its short period of growth and ease of handling. The seed was sown in rows, one foot apart, and in 8–10 days the seedlings were thinned to 3 in. apart. After thinning, alternate rows in the bed were covered with cloches and the plants grown on for 25 days. At the end of this time the plants were carefully pulled and the roots washed free from soil. The "root" portion, including the swollen hypocotyl, was detached and treated separately from the shoot. A second sowing was made somewhat later in the year and grown in the same manner. It was found actually in each case that the total weight of the plants grown in the open was greater than that of the cloche-grown plants; possibly the latter suffered from lack of moisture, or the temperature inside the cloches was too high. The shoots were oven-dried and the usual estimations performed; the fleshy roots were dried by the alcohol method, and allowance was made for loss of alcohol-soluble material in calculating the results of the determinations of the pectin *etc.* (Table VIII). In considering these figures it is to be noted that the data for the batches cannot be compared directly, since the definitely higher temperature during the growth period of the second batch would no doubt have influenced the type of growth.

Broadly speaking, it seemed that a more rapid growth, as measured by the formation of dry matter over a definite period and taking the plant as a whole, favoured the formation of pectin in an increased ratio to hemicellulose, although in absolute quantities both classes of substance showed an increase with more rapid growth. In batch I the total dry solid formed was almost the same with both normal and cloche-grown plants, and little variation in the pectin/hemicellulose ratio was observed. A wide difference was found, however, in the growth rates of batch II, and here the pectin/hemicellulose ratio showed a distinct difference. The shoots, considered separately, showed a similar result. With the roots, considered alone, the greatest discrepancies were to be observed. The formation of polysaccharides in the root, however, differs from that in the leaf in that the process is dependent upon a supply of sugars translocated downward from the shoot, and therefore only represents the final stage of a process having its earlier stages in another part of the plant. Polysaccharide formation actually observed in the root will therefore be influenced by conditions obtaining

elsewhere. It seemed therefore best to consider the plants as a whole and to compare the relative formation of the cell-wall constituents in the complete plants. When this is done, the results give support to the suggestion that pectin is formed preferentially during more rapid growth.

7. *Notes on the nature of the hemicelluloses of leaves* etc.

Reference has already been made to the apparent hexose and pentose contents of certain of the hemicelluloses isolated in the course of these experiments. Since these leaf-hemicelluloses do not appear to have been described hitherto, it was thought desirable to identify their constituents where possible. The usual methods for identification of the sugars *etc.* in the hydrolysis mixtures, as given by Browne [1912], van der Haar [1920] and others in the literature, were employed, and the results are tabulated for the sake of brevity. An important difference, as mentioned above, was noted between the hemicellulose "A" of bean, vine *etc.* and that of grass and maize, the former apparently consisting mainly of galactose units, the latter mainly of xylose. Since it seemed possible that the difference was between typical dicotyledon leaves and monocotyledon leaves (which may be flattened stems rather than true leaves), other monocotyledon leaves, hyacinth and narcissus, were examined; these however gave hemicelluloses resembling those of the bean.

Apart from the leaf products, hemicelluloses from other non-lignified tissues were also examined. Schulze and Pfenniger had already reported that the products isolated from bean and pea pods consisted of galacto-arabans; determination of carbon dioxide in the products showed the presence of considerable amounts of uronic anhydride, identified as that of galacturonic acid.

It was noted, finally, that the hemicelluloses of the radish root (or swollen hypocotyl) were markedly different from those of the leaves, in that fraction "A" contained proportions of pentosan (or uronic anhydride).

The presence of an insoluble hexosan in the insoluble hemicellulose fraction was unexpected, the previously recorded insoluble hemicelluloses having consisted mainly of xylans, with but small amounts of uronic anhydride and no hexosan. It may be suggested that insolubility is characteristic of true sugar anhydrides of high molecular weight (polysaccharides), whether hexosans or pentosans; such a grouping would include the starches and celluloses, as well as the xylans and the galactans here described. On the other hand, the soluble hemicelluloses may comprise those substances containing a sufficient proportion of uronic acid groups (*i.e.* the acid saccharides or polyuronides) and their solubility may be dependent on the presence of these (polar) carboxyl groups in the molecule. In this connection, it may be observed that the oxycelluloses, which undoubtedly contain glycuronic anhydride units [Kalb, 1927], are much less insoluble than true cellulose. If this conception holds, then the water-soluble ϵ-galactan of Schorger and Smith [1916] should be an acid saccharide, and the fact that Schorger found therein some 6 % of furfuraldehyde but was unable to isolate any pentose sugar may thus be explained. The insolubility of pectic acid, however, with its very high proportion of carboxyl groups, remains unexplained.

* *Cf.* figures given by Nanji and Norman [1928].

A summary of the observations on the constituents of these leaf and other hemicelluloses appears in Table IX, while in Table X are given some collected data, arrived at in the course of the present work, concerning the little known subject of the distribution of pectin in leaves.

DISCUSSION.

Dealing in the first place with the observations on pectins and hemicelluloses only, it is evident that the frequently-made statement, that the two classes are complementary, needs some modification, for in some tissues (*e.g.* bean pod) both groups are present in very large amount, the quantities of each being in fact very similar. In this tissue, development of the two classes has been shown to proceed throughout the whole of the period of growth, and it is only at the final stages of ripening that the proportion of the two becomes altered, some of the hemicellulose being lost. In non-lignified tissues in general it seems that pectins and hemicelluloses of the galacto-araban type may exist together in any proportions; for instance, comparing the figures given for pods of beans and sweet peas, the total combined content of the two groups is roughly 30–35 % in each tissue, but whereas the pectin/hemicellulose ratio in the bean is roughly 1/1, in the sweet pea it is approximately 1/9. In lignified tissue, on the other hand, pectin certainly is usually present in but small amounts, and this statement is true both for material of considerable age (timber) and for comparatively young growths (grass, maize), the hemicelluloses greatly predominating, according to the usual conception.

There seems however to be a further distinction between lignified and non-lignified tissues in the nature of their hemicelluloses. The analyses here recorded as well as others given in the literature show that lignified tissues are characterised by the presence of xylan and allied hexo-pentosans of the same series (glucosan—glycuronic anhydride—xylan) while in the non-lignified material galacto-arabans constitute the main bulk of the hemicelluloses. The information to be found in the literature is somewhat indefinite, but in the cases examined this generalisation is found to hold. The distinction is of course not rigid but is sufficiently evident. A brief summary of the available data is given in Table XI.

It would seem best therefore to look upon pectins as comprising a limited number of galacto-arabans of a rather special type, arising in certain circumstances during the course of the transformation of galactans into arabans. With regard to the possible conversion of pectins into bodies of the hemicellulose type, it is evident that from the former only substances of the araban type are likely to arise; this follows from the structural relationships of the various sugars entering into the composition of these substances, if the usually accepted view of the oxidation—decarboxylation mechanism already outlined (p. 197) be followed. Thus the typical major hemicellulose component of lignified tissues, xylan, would not be formed as the result of pectin decarboxylation. Suggestions that hemicelluloses in general may arise thus from pectin have therefore been based on the unfortunate lack of conciseness in the application of the term "hemicellulose," which has been adopted to include a widely differing collection of substances, with often only certain physical properties in common.

Moreover, from the results of the experiments here recorded, it would seem that the conversion of pectin *in vivo* into other substances of whatever nature is by no means so easy as has been suggested. The persistence of the pectins during the period of development of tissues (bean pods, shoot of rose *etc.*) and under the artificial conditions of starvation and of slow drying points to a marked degree

of stability; pectin transformation, where it occurs, must therefore normally be a process taking place during a prolonged period. Some interesting figures in this connection are quoted by Schorger [1926, p. 113], which, although the assumptions upon which they are based are open to question, tend to indicate again the comparatively great stability of the pectins.

As the pectic substances in the tissues are considered to be present within the cell-walls, partly as middle lamella substance and partly in definite combination with cellulose, they are to a large extent not readily exposed to the oxidising mechanism of the cell. Alternatively, the stability of the pectins may be due to the fact that, as Sucharipa [1924] has shown, in the case of *Citrus* fruits, the pectins in the cell-wall are esterified, through their carboxyl groups, with cellulose residues, and this association may render the carboxyl groups resistant to attack, although as Norman and Norris [1930] have shown free pectin molecules are extremely easily oxidised *in vitro*.

In contrast to the apparent stability of the pectins, some at least of the hemicelluloses seem open to chemical action, shown partly in intramolecular changes of the substances themselves (as evidenced by the alteration of their apparent pentosan content *etc.*) and partly in their disappearance from the tissues under certain conditions. This disappearance may be due to their mobilisation for purposes of oxidation (respiration) as in the bean leaves during starvation; or to their translocation to another part of the plant, as suggested by Schulze and Pfenniger in the case of bean and pea pods and again indicated in the present work. The changes in structure of the hemicelluloses have been shown to affect mainly the hexosan part of the molecule, although in some cases there also appeared to be a net loss of pentosan (Table V*a*). The fact that the hemicelluloses of maize, in contrast to those of bean and vine leaves, remained but little affected by the starvation process was perhaps to be expected in view of their much smaller content of hexosan; their chief component, xylan, being unaffected by the experimental conditions.

Returning to the consideration of the relation between pectins and the other galacto-arabans found in the plant tissues, it would be expected that, if all such compounds are the derivatives of a parent galactan (or series of galactans of different molecular weights), the pectins would be formed under conditions conducive to extreme oxidation, without subsequent decarboxylation. That these conditions may be produced during rapid growth in the presence of an abundant water supply (as already suggested by various authors) would seem to be indicated by the known relative distribution of the pectins and of the other galacto-arabans. Examples may be seen, in the present work, in the results of the experiments on radishes, and also in comparing the distribution of the types of compound in the pods of beans and sweet peas respectively—the former having a much more rapid growth rate, together with a greater water supply, than the latter.

More detailed suggestions as to the exact course and nature of the oxidation-decarboxylation process are not possible. Norman and Norris suggest that the latter process is actually a prolonged mild oxidation, but it is difficult to see, if such were the case, why decarboxylation should occur when but a small proportion of galactan units, in some types of molecule, have undergone the primary oxidation; one would rather expect this first type of oxidation to have reached its limit before the presumably slower type of oxidation, leading to decarboxylation, became evident.

With more knowledge of the chemistry of the hemicelluloses and polyuronides generally, it would seem that the time is approaching when the designation of hemicellulose fractions as "A," "B" *etc.* on a solubility basis should be modified. Members of the insoluble ("A") type hitherto described have proved to be mainly pentosans, with at most a low uronic anhydride content. From leaves, another type of substance, which on grounds of solubility would be classed as "hemicellulose A," has now been isolated; chemically, however, it is quite unlike the various hemicelluloses "A" previously recorded. A more satisfactory basis of classification, if it could be applied, would recognise the following types: (I) compounds predominantly hexosan; (II) intermediate compounds comprising hexosan-uronides, pentosan-uronides *etc.*; these might be of any degree of oxidation, from the but slightly oxidised compounds of the type isolated from lichens by Buston and Chambers [1933] to the more complex bodies in which a considerable amount of pentosan formation has occurred; and (III) compounds predominantly pentosan, such as the xylans of maize-cobs, straws *etc.* Further, examples of each of the three types could arise from glucose, galactose or other parent hexoses. Thus pectin would become a particular member of type II of the galactose series. Pectin itself seems to be widely regarded as an entity, the definite formula of Nanji *et al.* [1925] having found acceptance, although there is evidence that pectins from various sources may differ somewhat in their structure. It is agreed however that they are members of the galactose-uronide series and that their characteristic is a high state of oxidation, as evidenced by their high content of galacturonic anhydride; and perhaps it is best to regard them as comprising a sharply defined group of highly oxidised galacto-arabans.

In order to pass from a galactan (type I) to an araban (type III) it would not be necessary to pass through pectin as an intermediate—indeed, direct observations on these compounds *in vivo* suggests that passage into pentosans is actually more easy *via* intermediate compounds of a lower state of oxidation than *via* pectin. Thus the araban isolated by Ehrlich [1930] from beet-pulp is not necessarily derived from the pectin with which it is associated (see also Colin and Chaudin [1934]).

It would seem that the ability to form stable compounds with a very high uronic anhydride content such as the pectins is confined to the galactose series, for no glucose or mannose polyuronides have been isolated having a similar constitution. In the xylan series, in fact, the process seems to tend to pass rapidly through to the pentosan stage, glycuronic anhydrides being of comparatively rare occurrence among plant products and the glucosan-hemicelluloses still more so. The parent hexosan of the xylans is possibly cellulose itself, but this seems hardly likely, for xylan is frequently found in very close association with cellulose and is in fact almost certainly derived from it *via* glycuronic anhydride units; this xylan differs from the xylans isolated as "hemicelluloses" in its extreme resistance to extraction.

Turning to the question of lignin development, in view of the relative lack of knowledge of lignin itself, speculation must necessarily be more tentative. As has been pointed out, the evidence in favour of the theory that lignin arises by a transformation of pectin cannot be ignored. The microchemical evidence put forward by Ritter [1925], that pectin is absent from woody tissues in general and especially from the middle lamella, does not however prove that it is replaced by lignin. The actual isolation of pectins from wood does not altogether accord with the conclusions of Ritter.

It is admitted that, although pectin is remarkably stable in the tissues, over comparatively short periods, there is no reason to suppose that it is completely exempt from the general process of decarboxylation. Its final state is probably to be sought in the small amounts of arabans which are to be found in all woods, and which microchemical tests are not adequate to identify.

The observed possession by pectin and by lignin in common of hydroxyl and methoxyl groups is still less evidence of the supposed transformation, even though the latter constitute similar proportions of the molecule in the two cases. For the methoxyl of pectin is readily removed, *e.g.* by enzyme action, and yet it is supposed to persist in the molecule throughout the admittedly profound changes involved in lignification. In any event, it seems that the first step in pectin transformation consists of a demethylation (as indicated by the relative proportions of pectate-pectin in grass and hay respectively and by the methoxyl contents of the grass and hay pectins as isolated). Further, in his experiments on the extraction of pectin from lemon albedo, Sucharipa [1924] found that only a small amount of pectin was present in the fully esterified form (11·7 % OMe) and that only in the most easily extracted portion. The main bulk of the pectin was present in a form in which much of the methoxyl was apparently replaced by cellulose residues. It seems more likely that the methyl groups are split off from the pectins during the period of transformation and subsequently become combined with the unknown lignin precursor.

With regard to the arguments of Ehrlich [1930] based upon his observations on flax pectins, the reputed presence of xylose in the pectin molecule seems remarkable. No other example of a xylose-containing pectin has been reported elsewhere, so far as can be ascertained. It is true that flax pectin has been considered to be of abnormal type [Henderson, 1928] but the abnormality reported has suggested a simpler structure than usual, and not one more complex as would be required by the inclusion of xylose in the molecule. The question of the constitution of flax pectin has been examined also by Norris [1929] who failed to detect any abnormality. It would seem more likely that the xylan in Ehrlich's product is an accompanying impurity, extracted simultaneously from the tissues —xylans, as already pointed out, being typical of lignified material such as flax stems. The methods of separation of pectins, excluding that of conversion into calcium pectate, which is not favoured by Ehrlich, are mainly of physical type (based on solubilities *etc.*), and some of the xylans might well have solubilities similar to that of pectin. The lignin-like body separated by Ehrlich may also be but physically associated with pectin, or, if actually in chemical combination, not necessarily derived from pectin. Ehrlich emphasises the facts of its solubility when present in association with the pectin and its loss of solubility on separation and sees in these evidence for its derivation from pectin. The soluble form of cellulose described by Bailey and Norris [1932] and others, which is present in seed mucilages, shows a similar phenomenon in losing its solubility on isolation. There is however no suggestion that it is derived from the other constituents of the mucilage—indeed since the latter consist mainly of pentosans, such an origin is evidently out of the question. Nor has the fact that pectin appears chemically combined with cellulose in protopectin [Sucharipa, 1924] been used as evidence that pectin is a cellulose derivative. Had Ehrlich's product been a link between pectin and lignin, it would probably have been met with elsewhere, in view of the large number of examinations of woods at all stages of growth that have been made.

The experiments recorded in the present paper do not suggest that pectin is the precursor of lignin in the tissues examined. In the case of the rose, considerable formation of lignin occurred with no corresponding loss of pectin, the amount of which indeed increased, though at a slower rate. The main change observed in the rose shoot consisted in a fairly rapid growth, not in the sense of an elongation of the shoot, but in the sense of formation of dry matter, that is, by laying down of fresh material on to the cell-wall structure already present. Of the materials so laid down, lignin accounted for 1·6 g., while the pectin content rose by 0·3 g. It may be argued that the pectin was in a state of continual formation and transformation, while maintaining a fairly constant balance. This would involve a marked lability on the part of the pectin molecule, such as does not appear from the experiments on detached leaves.

It may be pointed out that lignification must be a more rapid process, at least in its first stages, than is sometimes realised; for Mehta [1925] has shown the presence of lignin in quite young pine needles, and there is evidence of its presence in grasses at an early stage. On the other hand, pectin breakdown or alteration, though not excluded, is slow.

While therefore the evidence is not satisfactory in support of the view that pectin is the precursor of lignin, it is evident that the latter must be derived finally from some sugar, and probably through a polysaccharide. The experiments of Hawley and Wiertelak [1931], although possibly of a rather artificial type, suggested that the source of the lignin was to be found in certain pentosans. The amount of pectin and galacto-arabans present in their original ashwood was almost certainly insufficient to account for the amount of "lignin" they obtained.

In view of the predominance of xylans in lignified tissues, these, or closely related bodies, seem more likely to be the precursors of lignin. It has been pointed out that xylan formation seems to take place more rapidly than the corresponding change to araban; this suggests a degree of lability in the precursors of xylan which may bear upon the comparatively rapid rate (in some cases, at least) of lignification. The view that xylan is the main precursor of lignin has been advanced by Klason [1930]. However, as no attempt has been made in the present work to examine these suggestions, it is not appropriate to discuss them here.

Summarising the views here expressed, the following suggestions may be put forward.

(i) If glucose be regarded as the primary sugar formed in the plant, part of this becomes converted into galactose, the two sugars thus becoming severally the precursors of the glucosan—xylan and galactan—araban series of polysaccharides. Since the latter are more characteristic of non-lignified tissues, it would seem that there is some connection between formation of galactose or galactans and development of a non-lignified structure. Nevertheless, increasing age, or an alteration in the conditions of the tissue, may result in decreasing galactose formation, together with increasing predominance of xylan production.

(ii) Of the galactan series, the pectins arise under rather exceptional conditions, involving rapid growth, combined with a copious water supply; while the other galacto-arabans, of a lower degree of oxidation, are formed when metabolism is at a different, lower level. Finally, all these bodies may pass into true arabans, but the pectins, either by reason of some innate stability of the molecule (alone or in combination with cellulose), or by reason of their location in the cell-wall, are only slowly transformed. In this limited sense, pectins are the precursors of hemicelluloses, but only of a small range of these substances, *viz.* the arabans.

(iii) The glucosan-xylan series is not apparently typical of rapidly growing tissues, or of tissues with a high water content. The intermediate members of the series are to be found in a less highly oxidised state than the corresponding galactans and much more readily pass into the final products of decarboxylation, the xylans.

(iv) Lignin does not arise from pectin, but more probably from some carbohydrate related to the glucosan-xylan series, with members of which series it is usually associated in the plant.

SUMMARY.

1. The distribution of pectin and of the hemicelluloses in developing pods of beans and sweet peas has been investigated. The proportion of each remains almost constant throughout the greater part of the growth period, but there is a falling off in the content of the latter towards the close of the period. This is possibly due to a translocation of some of the sugar constituents to the seeds.

2. Similar experiments have been made on the distribution of these and other cell-wall constituents during the development of a woody stem (rose). Here, the increase in lignin was found to run parallel with an increase in hemicellulose, but there was no loss of pectin. It is considered that pectin does not constitute the source of lignin during the primary lignification.

3. Detached leaves, submitted to a process of starvation, or of slow drying, showed no appreciable change in their pectin content, but the amount of hemicellulose showed a significant variation; hemicelluloses are therefore considered to be more labile than the pectins. It is possible that they may be in part available for respiration under certain circumstances. The main change during starvation was shown to consist in loss of hexose units, together with some decrease in pentosan.

4. Rapid growth of the plant is conducive to the formation of galacto-arabans, but especially of pectins.

5. The nature of the hemicelluloses of certain leaves has been examined. The "A" type has been shown to differ from those of lignified tissues in consisting almost entirely of hexosan units based on galactose. A modified classification of these bodies is tentatively suggested.

6. The bearing of these experiments on the possible transformation of pectins into hemicelluloses and lignin in the plant, and on certain theories of lignification, is discussed.

The author wishes to record his great gratitude to Dr V. H. Chambers and to Mr H. Thring, for their assistance in the experiments described in sections 4 and 6; and to Mr W. Hales and his staff at the Chelsea Physic Garden for providing much of the material used in the work.

XXVI. STUDIES ON THE ORIGIN OF SULPHUR IN WOOL.

II. A CUPROUS MERCAPTIDE METHOD FOR THE DETERMINATION OF CYSTINE OR CYSTEINE.

By SAREL DANIEL ROSSOUW
AND TOBIAS JOHANNES WILKEN-JORDEN.

From the Department of Agriculture, Veterinary Research Institution, Onderstepoort, South Africa.

(*Received September 7th, 1934.*)

Having established the value of the Sullivan method, as modified by the authors [1934], as a specific and quantitative reaction for the determination of cysteine or cystine, it became necessary to study its possible application to the analysis of animal and vegetable materials. The first step in such an analytical procedure would obviously include some process such as acid hydrolysis whereby the cystine or cysteine of the raw material is totally liberated and quantitatively brought into solution. In such processes the intensity of acid treatment must be sufficient to liberate all the cystine or cysteine from its protein or protein-like complex, but not so intense as to destroy the cystine thus liberated. It is not the purpose of the present paper to consider this phase of the problem, since investigations in this direction are still under way. On the contrary, it has been considered advisable to assume, for the time being, that the hydrolysis of the raw material can be effected quantitatively. What has been aimed at in the present work is to find a method whereby the cystine or cysteine actually present in such hydrolysates may be determined successfully.

In a few cases of high cystine content, *e.g.* wool and some pure proteins rich in cystine, the colour of the hydrolysate causes very little interference, and the modified Sullivan technique can be applied directly and with satisfactory results. With low cystine content and a dark-coloured hydrolysate, the problem becomes rather involved. It is obviously quite impossible to apply directly a colour reaction to a hydrolysate obtained from grass or some animal tissue low in cystine, as anyone who has handled such solutions will readily appreciate. To overcome this difficulty it has been suggested by Henrici [1932] that the cystine should first be precipitated from such a solution. Even after much manipulation it is still difficult however to obtain a solution sufficiently light in colour for colorimetric methods to be applied with any degree of satisfaction. Certain workers [Sullivan, 1929; Sullivan and Hess, 1930] have suggested the use of active and animal charcoal and other decolorising agents. None of these substances however appears suitable, since the cystine in solution is either adsorbed along with the colouring matter, or it is catalytically decomposed and destroyed [Baur and Wunderly, 1933]. Other workers [Lugg, 1933] have tried to inhibit colour development during hydrolysis by adding such reducing agents as stannous or titanous chloride with equally unsuccessful results.

On the other hand it has been shown by Vickery and White [1932], amongst others, that cysteine, in quantities of about 20 mg., can be precipitated quantitatively from solution as the insoluble cysteine cuprous mercaptide. Vickery and White used cuprous oxide, and determined the cystine in the solution from the sulphur content of the cuprous mercaptide precipitate. Hopkins [1929] precipitated glutathione in a similar way and found the compound to be $C_{10}H_{16}O_6N_3SCu$. Preliminary experiments on the behaviour of this cuprous mercaptide soon led to the conviction that it embodied a reaction sufficiently sensitive to enable the separation of quantities of cystine or cysteine much smaller than that postulated by Vickery and White.

The addition of cuprous oxide in the solid form appeared somewhat cumbersome and unsuited for micro-work. Since cuprous chloride is only very slightly soluble in water, initial attempts were made with cuprous chloride dissolved in potassium acetate and acetic acid mixtures. Although promising results were sometimes obtained with quantities as low as 1 mg. of cystine reduced to cysteine by means of a few mg. of zinc dust, the results were somewhat irregular. At this stage it was resolved to study the precipitation of cystine by making use of the well-known solubility of cuprous chloride in potassium chloride solutions. A very interesting fact was soon discovered. Working on 2 mg. quantities of cystine per aliquot volume, the preliminary reduction to cysteine was omitted by mere accident; however, on adding the solution of cuprous chloride in potassium chloride, the cysteine cuprous mercaptide was observed to form as readily as if all the cystine had been present as cysteine. In all subsequent experiments the preliminary reduction of cystine to cysteine was therefore omitted. The cuprous chloride solution was prepared from Merck's Reagent cuprous chloride. About 0·5 g. of the salt was shaken up with 1 % HCl to remove most of the cupric chloride present, the insoluble cuprous chloride allowed to settle, and the supernatant liquid poured off. This perfectly white residue was then dissolved in a minimum quantity of 25 % KCl containing 0·2 % HCl. The reagent should, preferably be prepared freshly before use, although, if left in a well-stoppered bottle it may be kept for a few days.

On studying the precipitation of cystine with this reagent, it was found that the cysteine could be quantitatively precipitated at room temperature at hydrogen ion concentrations between p_H 3·0 and 5·5, although the rate of precipitation appeared to be greatest at p_H 4·5. It was therefore decided to work at a hydrogen ion concentration of approximately p_H 4·5. Aliquot portions of 2 mg. cystine dissolved in very dilute HCl were measured into 50 ml. centrifuge-tubes and a few drops of glacial acetic acid added to each. These solutions were then brought to p_H 4·5 by adding carefully 10 % KOH using bromocresol green (B.D.H.) as an external indicator. To the buffered solution cooled to room temperature 5–10 drops of the cuprous chloride solution were added with constant stirring. A fine precipitate was observed to form almost immediately and coagulated gradually to a flocculent mass. After 40 minutes this precipitate was centrifuged and the supernatant liquid poured off. The precipitate was washed with alcohol, again centrifuged and the alcoholic liquid poured off. After draining, the precipitate was dissolved in 5 ml. 1–2 % HCl, and transferred to a 25 ml. measuring cylinder of good accuracy, using about 15 ml. of wash water. 2·5 ml. of a 5 % acetic acid solution were then added, and after mixing 1 ml. of 10 % KCNS was added in order to precipitate the cuprous copper. To remove the varying amounts of cupric copper always present at this stage, use was made of the reaction of Biazzo [1926] by precipitating the cupric copper as the green sulphocyanide-copper-pyridine complex. At this stage pyridine was therefore added until p_H 4·5 was reached. Under these conditions no measurable adsorption of cystine by the precipitate could be detected. After mixing thoroughly and making up to 25 ml., the precipitates were filtered off. To overcome the buffering action of the acetic acid in solution, 1 ml. of 10 % KOH was added to a suitable aliquot (usually 5 ml.) of the clear filtrate, and the cystine was determined by the modified Sullivan method [Rossouw and Wilken-Jorden, 1934].

Using this method, the effect of varying amounts of potassium chloride on the precipitation of the cysteine cuprous mercaptide was studied, since with actual hydrochloric acid hydrolysates the amount of potassium chloride in the aliquot solution must vary with the amount of cystine present in the material. This consideration is most important, since, as the curves reproduced below readily show, the cuprous mercaptide will partly or totally dissolve in an excess of potassium chloride, unless a correspondingly large excess of cuprous chloride reagent is added. However, considering the fact that the presence of potassium acetate in relatively large quantities has been found to depress the solubility of the mercaptide in potassium chloride, the curves show that it is perfectly practicable to determine the cystine in such solutions as a hydrochloric acid hydrolysate of sheep's blood. In dealing with grasses however the position is somewhat different, since in a hydrochloric acid hydrolysate a suitable aliquot containing a determinable amount of cystine would inevitably contain such a large quantity of hydrochloric acid that the amount of cuprous chloride reagent necessary would become unwieldy and impracticable.

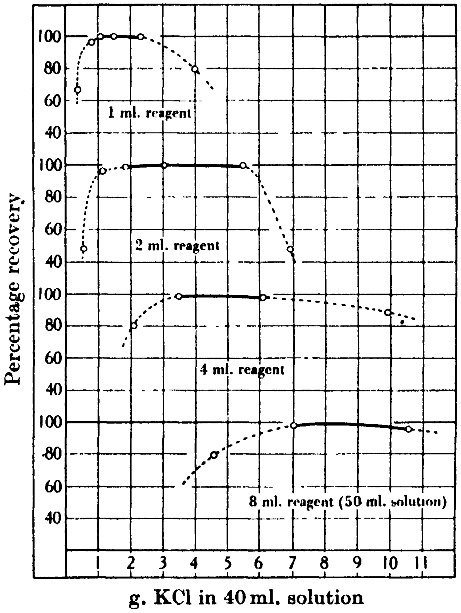

Fig. 1.

To overcome this difficulty when working with material very low in cystine, the hydrochloric acid was replaced by sulphuric acid. In testing this modification of the method 2 mg. of cystine were added to 5 ml. of 40 % H_2SO_4, 2·5 ml. glacial acetic acid were added, and the solution was brought to p_H 4·5 by neutralising with 10 % KOH. After cooling to room temperature, 5–10 drops of the cuprous chloride solution were stirred in. Precipitation and flocculation were rapid, and

100 % recovery was obtained repeatedly, even after leaving the precipitate to stand for 24 hours.

This procedure of first precipitating the cystine as the cysteine cuprous mercaptide soon proved most successful in the treatment of hydrolysates, especially those highly contaminated with excessive quantities of dark colouring and other matter. On bringing such hydrolysates to p_H 4·5 by means of acetic acid and potassium hydroxide, a large amount of objectionable colouring material was precipitated and centrifuged off. That the material thus precipitated could occlude or contain no measurable amount of cystine can be safely accepted, since neither could cystine be found in such precipitates nor could any loss be demonstrated on adding a known amount of cystine to the hydrolysate. On adding the cuprous chloride reagent to the centrifuged and decanted solution, a further quantity of dark-coloured material was precipitated along with the cuprous mercaptide. On dissolving the mercaptide in dilute hydrochloric acid, the accompanying dark material was also brought into solution, but was removed practically completely in the precipitation of the copper with sulphocyanide and pyridine. The final solutions were either perfectly colourless or exhibited only the faintest straw-yellow which has no measurable influence on the cystine determination. As an example of the applicability of the method, the following analytical figures may be given:

Merino wool	12·5 %
Dried sheep's blood	450 mg./100 g.
Yellow mealies	104 „
Lucerne hay	80 „
Veld grass...	20–80 mg./100 g.

In the successful execution of the method, some experience is undoubtedly necessary. If too large an excess of the cuprous chloride reagent be added to the sulphuric acid hydrolysates, some cuprous chloride may be precipitated along with the mercaptide. Excessive quantities of this cuprous chloride make the dissolution of the mercaptide in the dilute hydrochloric acid more difficult to control and may further result in some cystine being retained by the cuprous chloride. In such cases the difficulty may be remedied by adding a few mg. of zinc dust to the hydrochloric acid solution and thus converting the cuprous chloride into metallic copper. In such cases however the filtrate, after adding sulphocyanide and pyridine, must be left to stand overnight to allow any cysteine formed to be reoxidised to cystine. Any zinc in solution is practically completely removed by pyridine at p_H 4·5; the residual traces that may remain in solution have no effect on the determination by the Sullivan method, as also shown by Prunty [1933].

Method.

The method, employing sulphuric acid, may be summarised as follows.

A suitable quantity of dried material *plus* 8 times its weight of 40 % H_2SO_4 hydrolysed for 24 hours at 125° (oil-bath temperature).

Hydrolysate filtered hot and made up to volume.

A suitable aliquot measured into a 50 ml. centrifuge-tube. 2·5 ml. glacial acetic acid added to this and brought to p_H 4·5 with 10 % KOH.

If precipitate is shown here, centrifuge and wash with acetic acid-KOH mixture of p_H 4·5 (final volume to be approximately 40 ml.).

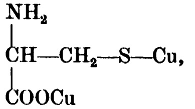
Stir in a few drops of cuprous chloride reagent.

Leave until flocculation sets in (a few minutes to 1 hour).

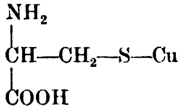
Centrifuge and wash with alcohol.
Dissolve in 5 ml. 1 % HCl.
Transfer, with washings, to a 25 ml. measuring cylinder.
Add 2·5 ml. 5 % acetic acid, and mix.
Add 1 ml. 10 % KCNS and mix.
Add pyridine to p_H 4·5 and make up to volume.
Filter.
Determine cystine in suitable aliquot (0·4 mg. cystine), by method of Sullivan as modified by the authors, adding 1 ml. of 10 % KOH to counteract buffering effect of acetic acid.

Discussion of mechanism.

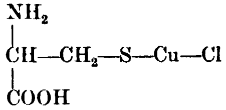
The exact nature of the cuprous mercaptide precipitate has not been determined. Indications [Preisler and Preisler, 1932] have been obtained that the mercaptide which is either



$\underset{\displaystyle COOCu}{\overset{\displaystyle NH_2}{CH}}-CH_2-S-Cu,$

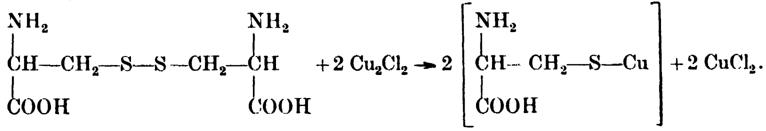


$\underset{\displaystyle COOH}{\overset{\displaystyle NH_2}{CH}}-CH_2-S-Cu$ or



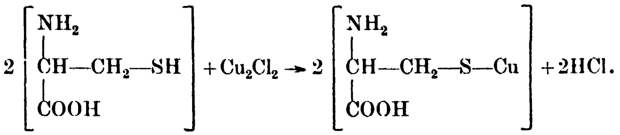
$\underset{\displaystyle COOH}{\overset{\displaystyle NH_2}{CH}}-CH_2-S-Cu-Cl$

is apparently associated with either cuprous or cupric chloride, or both. Whatever the composition of the precipitate, it is generally accepted that all the cystine is present in the reduced form as the copper salt of the mercaptan cysteine. It therefore appears that the cystine reacts with the cuprous chloride according to the following reaction:



$$(1)\quad \underset{\displaystyle COOH}{\overset{\displaystyle NH_2}{CH}}-CH_2-S-S-CH_2-\underset{\displaystyle COOH}{\overset{\displaystyle NH_2}{CH}} + 2\,Cu_2Cl_2 \rightarrow 2\left[\underset{\displaystyle COOH}{\overset{\displaystyle NH_2}{CH}}-CH_2-S-Cu\right] + 2\,CuCl_2.$$

In the case of the preformed cysteine, the reaction would naturally be:



$$(2)\quad 2\left[\underset{\displaystyle COOH}{\overset{\displaystyle NH_2}{CH}}-CH_2-SH\right] + Cu_2Cl_2 \rightarrow 2\left[\underset{\displaystyle COOH}{\overset{\displaystyle NH_2}{CH}}-CH_2-S-Cu\right] + 2HCl.$$

These reactions seem to proceed quantitatively in feebly acid solutions (p_H 3·0–5·5) in the presence of an excess of cuprous chloride. In dissolving the precipitates in dilute hydrochloric acid, the initial state of the cystine should be the reduced form. Experimental data can be adduced however to show that its conversion into the oxidised form is extremely rapid in such acid solutions. In the normal course of analysis all the cysteine is quantitatively converted into cystine by the time the copper is precipitated with sulphocyanide and pyridine, even when operations are speeded up to the maximum limit with the object of detecting any unoxidised cysteine. It appears that the transformation to cystine already occurs during the process of dissolution in hydrochloric acid, since, even after adding small quantities of zinc powder no cysteine could be detected. This behaviour of the mercaptide suggests that it is precipitated as a complex containing cupric chloride. In the presence of hydrochloric acid, and in the absence of excess cuprous chloride, the first reaction is therefore reversed, the reaction being forced to completeness by the precipitation of the cuprous copper as sulphocyanide. The observation of Andrews [1933] on the catalytic oxidation of cysteine by copper must probably be explained in a similar way.

In the case where a relatively large excess of zinc dust is added to the solution of the mercaptide in dilute hydrochloric acid, it was found possible, by rapid work, to obtain practically all the cystine in the reduced form. Since in the Sullivan method the treatment with cyanide results in the formation of only one molecule of cysteine from one molecule of cystine, and since, for all practical purposes one part by weight of cystine is theoretically equivalent to one part by weight of cysteine, the Sullivan method in reality determines only half of the cystine when present as cystine. When present as cysteine therefore, a colour intensity double that of the standard should be obtained. In actual experiment colour intensities round about 192 were obtained with the standard at 100. On allowing the solution from which the copper had been precipitated to stand for a further 4 hours, the intensity of the Sullivan colour dropped to 150, while after 20 hours it had dropped further to 100, showing that by that time all the cysteine had been converted into cystine. Since some extractions with chloroform according to Biazzo still revealed minute quantities of copper in the solution, the conversion seems to have been effected catalytically.

The rapid conversion of the cysteine in the mercaptide into cystine was further demonstrated by precipitating the cysteine from a standard cysteine hydrochloride solution with cuprous chloride, and comparing the colour intensity of the cysteine treated in this way with that of the cysteine hydrochloride standard directly treated by the Sullivan method. The cysteine from the mercaptide was found to be only half that of the cysteine treated directly.

The fact however that in the hydrochloric acid solution of the mercaptide the cystine can be quantitatively reduced by means of zinc dust and the modified Sullivan method applied to this cysteine solution, is considered to be of some practical importance, since double the normal colour intensity is obtained. Along these lines it has been found possible to determine the cystine contents of grasses and other material extremely low in cystine. These and other results will be reported in a following paper.

SUMMARY.

1. A method for the micro-determination of cystine in biological or plant material has been described. The dried material is hydrolysed with 40 % sulphuric acid and the cystine precipitated by cuprous chloride as the cysteine cuprous mercaptide. The cystine content of this is determined by the modified Sullivan method.

2. The interfering colouring matter is automatically eliminated.

3. The method is quick and comparatively easy.

XXVII. THE MECHANISM OF THE INTERCONVERSION OF THE HEXOSE SUGARS IN LIVING ORGANISMS.

By KAMEL MIKHAIL DAÓUD and WADEI TADROS.

From the Biochemical Laboratory, Physiology Department, Faculty of Medicine, Cairo, Egypt.

(*Received October 9th, 1934.*)

The transformation of one hexose sugar into another is a process which takes place in both kingdoms of living matter. Thus in animals, fructose, mannose and galactose when slowly introduced into the circulation form glycogen which is supposed to be a result of an intermediate formation of glucose. When lactose is administered to diabetics two molecules of glucose for each molecule of lactose may be recovered in the urine. This indicates that the tissues can under certain conditions transform galactose into glucose. The reverse process, that is the transformation of glucose into galactose, has been observed by Rohmann [1919], who shows that the galactose constituent of milk sugar is formed from *d*-glucose.

In plants, Daoud [1932], working on the germination of fenugreek seeds, found that while the reserve polysaccharide of these seeds is composed of mannose and galactose, the radicles of the germinated seeds contain glucose, fructose and sucrose, this last sugar being entirely absent from the ungerminated seeds. The reverse process undoubtedly takes place during the development of the seed, *i.e.* the galactose and the mannose constituents of the reserve polysaccharide must arise from the photosynthetic sugars.

The mechanism of the transformation of one hexose into another is the subject of the present investigation. The transformation of a sugar such as mannose into its epimeride (glucose) may to some extent be explained by the ease with which the reversal of the stereochemical configuration of carbon atom 2 takes place. This occurs *in vitro* under the action of alkalis on either of these two sugars; but as a result of this reaction a mixture of these three and fructose together with other sugars is formed. The fact that the mannose constituent of the reserve polysaccharide of fenugreek seeds is not found in the free state among the other hexoses during germination suggests that the mechanism *in vivo* is different from that *in vitro*. Still more difficult to understand is the transformation of a sugar like galactose into glucose or *vice versa*.

Robinson [1927, 1], bearing in mind the common occurrence of hexosephosphates in nature, suggests that the transformation of glucose into galactose takes place through the reversal of the stereochemical configuration of carbon atom 4 on the hydrolysis of glucose-4-phosphate; the reverse change will have the same mechanism.

The view of Robinson was opposed by Levene [1927] who observed that glucose-3-phosphoric acid ferments at the same rate as glucose. Should glucose-3-phosphoric acid on hydrolysis pass into allose, then the rate of fermentation would be lower than that of glucose. Furthermore, Raymond and Levene found that on hydrolysis of glucose-3-phosphoric acid, only one sugar, namely glucose, is obtained.

Robinson [1927, 2] brings into consideration firstly, that even if his hypothesis of inversion in the hydrolysis of sugar phosphate in nature is correct it may well be difficult to find the conditions for the imitation of the process in the laboratory, and secondly, that the glucose-galactose change involves position 4 where the stereochemical conditions are different from those in the glucose-3-phosphoric acid used by Levene.

Levene *et al.* [1929] found, in favour of Robinson's suggestion, that the hydrolysis of the phosphoric group in fructose-3-phosphoric acid during osazone formation is accompanied by a Walden inversion.

It may be remarked that the reserve polysaccharide of fenugreek seeds, a detailed study of the behaviour of which is provided in this communication, is a mannogalactan which is also esterified by phosphoric and silicic acids. On germination it gives rise to glucose and fructose, while, apart from the seeds, hydrolysis by different means results only in the production of galactose and mannose. A hydrolysis of the original ester takes place in all cases.

Mathers and Robertson [1933], working on the hydrolysis of *p*-toluenesulphonyl esters of glucose, were able to convert a derivative of glucose into a derivative of altrose. Cognate researches by Robertson and Oldham [1934] provided evidence that the hydrolytic reactions fall into two main groups, normal and abnormal, according as the original substance contains one or two *p*-toluenesulphonyl residues in neighbouring positions. They have also shown that in cases in which Walden inversion has been proved to occur, such inversion is accompanied by anhydro-formation. According to them the anhydro-formation may be a necessary precursor of this type of inversion, which follows as a consequence of the opening of the anhydro-ring.

Lohmann [1933] has shown that in yeast and animal cellular extracts there is an agent which converts both ketohexose- (Neuberg ester) and aldohexosemonophosphoric ester into Embden ester which is an equilibrium mixture composed of aldo- and keto-hexosemonophosphoric esters in which the former are present to a predominant extent. It may be noted that this investigation applies only to the transformation of an aldose into its ketose analogue or *vice versa.*

Robison [1932] and Macleod and Robison [1933], working on the products of yeast fermentation and on the hydrolysis of hexosediphosphate produced during the fermentation, suggest schemes which may possibly apply to the transformation of one hexose into another. According to these schemes an enolic compound common to glucose, fructose and mannose is formed, which reacts with phosphoric acid and the resulting enolic phosphate passes into a mixture of esters of the three above sugars. But, again, these schemes suggest only the mechanism of the interconversion of a sugar with its epimeride and its ketose analogue and, if applied to the problem under investigation as a whole, they give no clue to the transformation of a sugar like galactose into glucose or fructose as happens during the germination of seeds.

EXPERIMENTAL.

It has already been mentioned that the sugars entering into the constitution of the reserve polysaccharide of fenugreek seeds are mannose and galactose, which are transformed during germination into glucose, fructose and sucrose. It is natural to attribute such transformations to the influence of enzymes elaborated by the seeds. As the transformation may be brought about by the co-operation of more than one enzyme, it was decided to study the action of the enzymic mixture of the germinated seeds on the polysaccharide *in vitro.*

The enzyme preparations.

Fenugreek seeds, in different stages of germination, were used for the preparation of the enzyme mixture. The seeds were first minced in a meat mincer and ground up in a mechanical mortar into a fine paste, which was then extracted either with chloroform water or with glycerol. The proportion of solvent in each case was 1 ml. per g. of paste. The paste was allowed to stand with either solvent for different intervals of time varying from 6 hours to 10 days and was shaken from time to time. For some experiments the paste was treated with distilled water and was mechanically shaken for 2½ hours after which it was prepared for immediate use. For use the mixture of paste and any of the solvents used was placed in a calico bag and pressed out by hand, followed by a press. The liquid obtained by centrifuging the fluid was used in the experiments. In some experiments the enzyme mixture used was prepared by treating the paste with a small amount of water and a little toluene and then allowing to stand for a few days in an incubator in order to allow the cells to autolyse and to liberate their enzymes. Water was then added to the mass which was subsequently treated as above.

Action of the mixture of enzymes on the polysaccharide in vitro.

It should be remembered that the mixture of enzymes prepared by any of the above methods contains, in case of short extractions, glucose, fructose and sucrose. After prolonged extraction the amount of sucrose diminishes, finally leaving only the two former sugars. This is due to the sucrose undergoing hydrolysis by the invertase which is present in the extract. The preparations also contain the polysaccharide which had not been utilised during germination, and also, in the case of long extractions, its hydrolytic products.

The quantity of the enzymic solution employed was usually 2–3 ml. for every 40 ml. of the polysaccharide solution; thus the amount of the sugars originally present in the reaction mixture due to the enzymic preparations was too small to influence the identification of the sugars resulting from the hydrolysis of the polysaccharide. Nevertheless, controls with the same quantity of enzyme solution added to a quantity of water equivalent to the volume of the polysaccharide solution used were performed at the same time and treated in a similar manner.

The purified polysaccharide of fenugreek seeds, which is a silicophosphoric ester of mannogalactan, was prepared by the method of Daoud [1932]. Different antiseptics (toluene, camphor, thymol, chloroform and sodium fluoride) were used in the different experiments.

When the mixture of enzymes, prepared by any of the above-mentioned methods, was added to the polysaccharide solution together with one of the antiseptics and incubated at 37°, it was noticed that the opalescence as well as the viscosity of the solution gradually diminished with simultaneous deposition of an insoluble residue, while the reducing power gradually increased. The insoluble residue was found to be composed mostly of inorganic constituents including silica, phosphates, iron, calcium and magnesium. Portions of the reaction mixture, removed at different intervals of time, were treated with an equal volume of 95 % alcohol; the precipitate of polysaccharide obtained showed a gradual diminution in quantity and gradual changes in property as the reaction proceeded. The precipitate obtained as soon as the enzyme was added was a white filamentous mass, while that obtained at advanced stages of the reaction was white and pulverulent and dissolved in water with greater ease.

The changes taking place during the action of the mixture of enzymes appear to be as follows: firstly, there is a hydrolytic removal of the silicic and phosphoric acids, which is most probably brought about by esterases with the production of a more soluble substance, and secondly, a simultaneous or subsequent hydrolysis of the de-esterified substance into sugars. There is also the possibility that the more soluble substance includes degradation products of the original polysaccharide. The de-esterification proceeds at a greater rate than the hydrolysis into sugars since the precipitate of silica and phosphates produced during the enzymic action ceases to increase after a certain period while the reducing power continues to increase further.

To investigate the nature of the sugars produced by the action of the enzymes on the polysaccharide, the following procedure is adopted.

The reducing power is determined from time to time by removing portions of 25 ml. of the reaction mixture, making up to 50 ml. with 95 % alcohol, filtering, washing with 50 % alcohol, evaporating the alcohol, making up the residue to the original volume with water and determining the amount of reducing sugars by Bertrand's method.

When the reducing power shows little or no further increase, the whole of the reaction mixture is removed from the incubator, filtered from the insoluble residue, shaken with a small amount of calcium carbonate and refiltered. The filtrate is treated with alcohol to precipitate any traces of polysaccharide which sometimes remain unattacked, refiltered if necessary and finally concentrated in a vacuum to a smaller volume than the original. This somewhat concentrated solution is treated with normal lead acetate until maximum precipitation is reached, any excess of lead being removed by sodium carbonate; the filtrate after removal of the lead is neutralised with acetic acid and decolorised.

When portions of the solutions thus obtained are heated with phenylhydrazine hydrochloride and sodium acetate, two osazones are obtained, one of which is identical with glucosazone and the other with galactosazone. The presence of galactose is further confirmed by the production of mucic acid on oxidising a portion of the solution with nitric acid. On treating other portions of the solutions with phenylhydrazine and acetic acid in the cold a white crystalline precipitate is obtained which is identified by its crystalline form and its melting-point as mannosephenylhydrazone. The glucosazone obtained on heating, with the exception of a very small amount which is due to the glucose and fructose content of the enzyme solution, is entirely due to mannose and not to glucose or fructose which might have been formed during the breakdown of the polysaccharide. This is proved by adding an excess of phenylhydrazine dissolved in acetic acid to a portion of the cold solution and keeping the mixture in the ice-chest for 24 hours, then filtering off the mannosephenylhydrazone, heating the filtrate in a water-bath, and examining the osazone thus formed after the removal of the mannose. It is found that the main osazone present is galactosazone together with a very small amount of glucosazone which is as above-mentioned due to the sugars of the enzyme solution. Further, quantitative experiments prove beyond any doubt that the sugars produced by the enzymic action on the polysaccharide are entirely mannose and galactose. These quantitative experiments are performed as follows.

A measured volume of the polysaccharide solution is treated with a known volume of one of the enzymic preparations. At the same time a control is made by the addition of the same volume of the same enzymic preparation to a volume of water which is equal to the volume of the polysaccharide solution employed. Both solutions are incubated till no precipitate of polysaccharide is produced on the addition of alcohol to a portion of the polysaccharide solution and they are then filtered and equal volumes of the filtrates are clarified and decolorised, taking equal measured volumes of the filtrates after each process. The mannose in the final solutions is estimated as mannosephenylhydrazone. After allowing for the quantity of mannose in the control, it is found that in all cases the yield of mannose from the polysaccharide alone by the action of the enzyme almost agrees with the theoretical amount of mannose which is calculated to be present in the quantity of polysaccharide originally taken. The amount of mannose found is never less than 98·8 % of the theoretical amount.

The above solutions are also used for calculating the specific rotatory power of the mixture of sugars resulting from the enzymic hydrolysis of the polysaccharide. The percentage of reducing sugars calculated as glucose and also the rotation of the final solution in the case of the control are subtracted from those of the final solution derived from the polysaccharide. The balance of the rotation is considered to be due to the amount of sugars resulting from the enzymic action on the polysaccharide only. The specific rotatory power calculated on this assumption for the several experiments performed varies from $[\alpha]_D^{20^\circ} + 45{\cdot}9^\circ$ to $[\alpha]_D^{20^\circ} + 48{\cdot}1^\circ$. The theoretical specific rotatory power for a mixture of equal quantities of galactose and mannose is $[\alpha]_D^{20^\circ} + 47{\cdot}5^\circ$.

Since the yield of mannose from the polysaccharide, which contains equal quantities of mannose and galactose, is quantitative, and these two sugars are produced by the enzymic action in equal quantities, it follows that the only products of the enzymic action on the polysaccharide are galactose and mannose.

It was noticed that the extracts of the germinated seeds were usually slightly acid to litmus. This observation suggested that the hydrogen ion concentration might have an effect in causing the interconversion of the hexoses to take place in the germinating seeds. The polysaccharide solution was buffered at p_{H} values varying between 5·4 and 7·8. It was found that the production of galactose and mannose from the polysaccharide by the action of the enzymic mixture is independent of the hydrogen ion concentration of the medium within these limits.

The above observations lead to the conclusion that the hydrolytic products of the reserve polysaccharide of fenugreek seeds are always the same whether the hydrolysis is effected by acids or by the enzyme mixture from the germinated seeds *in vitro*.

Direct investigations on the germinating seeds.

It was noticed that while mature ungerminated fenugreek seeds are usually starch-free, the germinated ones contain starch and that this increases in amount with the progress of germination. Some specimens of fenugreek seeds were found to contain traces of starch before germination; this, however, is rare and is most probably due to an immaturity of the seeds or an imperfect drying and preservation of the harvest. It was proved by various methods that the substance formed during germination is starch. In some cases the starch appeared to have an admixture of some other substance probably of the nature of an erythrodextrin, since on the addition of iodine to the isolated substance a violet coloration instead of blue was sometimes given.

The starch formed was not the result of photosynthesis as in all cases the investigations were made before the cotyledons left the testa or showed any sign of chlorophyll formation. Furthermore the steeping and the germination were carried out in darkness.

The importance of determining the relation of the sugars, especially that of glucose, appearing during germination to the starch is apparent. An attempt was therefore made to find out which of these compounds first appears in the germinating seeds. This presents certain difficulties since in most seeds starch and sugars seem to occur practically at the same time at the beginning of the germination. On carefully following the formation of starch in starch-free fenugreek seeds, it was observed that this substance appears during steeping; usually after 10 to 18 hours of steeping. The following procedure was therefore adopted to find out which of the above substances appears first.

A weighed quantity of the seeds steeped till the starch became detectable was thrown into a small volume of vigorously boiling water to stop all enzymic action. Boiling was continued for one hour. The seeds were then drained, weighed, ground into a paste and remixed with the drained water. Alcohol was added to this mixture to a concentration of about 50 %, taking into consideration the quantity of water absorbed by the seeds during the steeping. Calcium carbonate was added to neutralise the solution which was then boiled on a water-bath under reflux for 2 hours in order to extract any sugars formed. The filtered extract was distilled *in vacuo* to a small bulk. The concentrated residue was clarified and examined for reducing sugars by the osazone test. In the great majority of the experiments no osazone could be detected. In very few exceptional cases small traces of glucosazone were found. The amount was exceedingly small if it be remembered that we dealt in each case with a concentrated extract of 100 ml. obtained from 1 kg. of the dry seeds. This result indicates that the formation of starch precedes that of glucose. It has been observed that while the reserve mannogalactan of fenugreek seeds is contained in the endosperm, the formation of starch takes place entirely in the cotyledons and radicles. The amount of starch in these organs increases with the exhaustion of the endosperm, thus indicating the formation of starch at the expense of the reserve mannogalactan.

Further support of the view that the starch formation precedes that of the glucose was gained by observations made on single germinating seeds of carob (*Ceratonia Siliqua*). The reserve polysaccharide of these seeds is also a mannogalactan which, as in the case of fenugreek seeds, gives glucose, fructose and sucrose during germination. These seeds are difficult to germinate under laboratory conditions as they possess a very hard testa and a thick hard endosperm, while the cotyledons are very thin and practically free from carbohydrates. The straight radicles of these seeds allowed easy measurement which helped in determining the beginning of germination. Germination was only possible after steeping for a long time and then carefully removing the testa and the mucilage layer round the radicle. The germination was still slow even after exposing the radicles. In order to have the cotyledons accessible for the purpose of detecting the first appearance of starch, the testa at the top of the seeds was removed. The seeds were always kept moist during germination. Every 12 hours a minute fragment of one of the cotyledons was removed at the top of the seed by means of a thin needle and tested with iodine under the microscope. It was found that starch makes its appearance in the cotyledons before the radicles show any increase in length. Elongation of the radicles was almost simultaneous with the appearance of reducing substances in them; both take place between 24 and 36 hours after the first appearance of starch. It was further noticed that some seeds failed to form starch and these never germinated.

It is, therefore, justifiable to assume that the mannogalactan of carob and fenugreek seeds gives rise to starch and that the glucose which appears during germination arises as a result of hydrolysis of the starch by an amylase which has been experimentally found to be elaborated during germination.

The experiments just described gave a clue to the probable course followed in the formation of the reducing sugars found in the radicles of the germinating seeds, sugars which are entirely different from those constituting the reserve. If the starch supplies the glucose, another compound might be expected to be responsible for the supply of fructose. Other polysaccharides were, therefore, looked for. The concentrated clarified extracts obtained from the steeped fenugreek seeds by the method described before were treated with alcohol. A precipitate began to appear when the concentration of alcohol was about 64 % and gradually increased with the addition of more alcohol till the concentration reached 75 %. The small precipitate formed was collected by centrifuging, redissolved and reprecipitated three times, treated with absolute alcohol followed by ether and dried *in vacuo*. The white powder so obtained was readily soluble in water, did not reduce Fehling's solution and was, in most cases, laevorotatory. In a few cases, however, the substance had a feeble dextrorotation. The variation in rotation suggested a non-homogeneous constitution for this substance. The product was, therefore, subjected to fractional precipitation. It was found that a portion came down when the concentration of alcohol was about 64 %. This was collected by centrifuging and proved to be a pentosan. When the concentration of alcohol in the remaining fluid was raised to 70–75 % a second minute fraction was obtained. This fraction was white when dry, tasteless, did not reduce Fehling's solution and was laevorotatory. When hydrolysed with 1 % sulphuric acid under reflux on a boiling water-bath for half an hour, the hydrolysate after neutralisation with barium carbonate and filtration reduced Fehling's solution, gave an osazone identical with glucosazone, yielded the Pinoff-Seliwanoff's reaction and had a laevorotation. The specific rotation of the hydrolysates obtained from different experiments varied from $[\alpha]_D^{20^\circ} -89{\cdot}7^\circ$ to $-91{\cdot}2^\circ$. The specific rotation of fructose is $[\alpha]_D^{20^\circ} -92{\cdot}5^\circ$.

This clearly indicates that the sugar obtained on the hydrolysis of the above fraction is fructose, and that the original substance is composed of polymerised fructose residues and is similar to, if not identical with, inulin. It will be referred to as fructosan.

After removal of the fructosan, the fluid still contained a substance of a carbohydrate nature which came down only when the concentration of alcohol was very high. This rendered its separation by this method inconvenient. This substance was found to form a precipitate with Fehling's solution which was used for its separation. The alcohol contained in the fluid after the removal of the two above-mentioned fractions was distilled and Fehling's solution added. The plastic precipitate formed was rapidly collected, dissolved in a little dilute hydrochloric acid and precipitated with acetone. The precipitate was collected, redissolved, reprecipitated with acetone three times and finally dried. The dried substance is pale-yellow in colour, readily soluble in water with frothing, it has a bitter taste and causes a slight reduction of Fehling's solution when heated or in the cold if allowed to stand for a sufficient time; it gives no osazone and is laevorotatory. When its solution is hydrolysed, it shows a dextrorotation, its reducing power greatly increases, while a considerable amount of precipitate is formed. This shows that the substance behaves in every respect like a saponin; further it gives similar colour reactions and causes haemolysis.

As this saponin was found to be present in the dry ungerminated fenugreek seeds and as it was proved to be utilised during germination, it became necessary to determine the nature of its sugar content. On hydrolysis galactose and mannose were the only two hexoses identified.

All the above experiments show that the reserve carbohydrates of fenugreek seeds are entirely constituted of mannose and galactose and that the whole glucose and fructose which appear during germination are to be regarded as transformation products.

The identification of the minute amount of fructosan in the steeped seeds necessitated the examination of the ungerminated seeds for the presence of that substance. Powdered ungerminated fenugreek seeds were extracted with 50 % alcohol following the steps already mentioned in the extraction of the steeped seeds. When the clarified solution was treated with alcohol, the precipitate obtained between 64 and 75 % concentration was in all cases dextrorotatory.

When alcohol was added to the clarified solution to a concentration of 75 % the precipitate obtained, contrary to the case of the steeped seeds, could not be fractionated into a pentosan and a laevorotatory body. Pentoses were the only products obtained on hydrolysis. This shows that the fructosan is not originally present in the ungerminated seeds, but that, similarly to starch, it is formed only during steeping.

Examination of the seeds in different conditions for the presence of an enzyme which attacks inulin has shown that while extracts of the ungerminated seeds have no action on that substance, those of the steeped and germinated feebly attack it. The secretion of an enzyme which attacks inulin simultaneously with the formation of the fructosan in the steeped or germinated seeds suggests that the fructosan formed is built up on lines similar to inulin.

Since no glucose or fructose is formed in a free state during the period of steeping, it becomes clear that both the starch and the fructosan formation from the galactose and the mannose constituting the reserve polysaccharide of the ungerminated seeds must precede the appearance of glucose and fructose of the germinated seeds. This explains the failure of the enzymic mixture of the germinated seeds to produce the interconversion of the hexoses of the reserve polysaccharide *in vitro*.

Having demonstrated that starch and fructosan appear in the steeped seeds before the appearance of reducing sugars, the behaviour of these two polysaccharides was next studied during different stages of germination of the fenugreek and other seeds. The results obtained can be summarised as follows. On germination the starch gradually increases in amount; the fructosan can be detected in fenugreek seeds during all stages of germination but always in small quantities, it seems to diminish further or to disappear on prolonged germination. In carob seeds the fructosan could not be detected at all. The following table illustrates the changes in the quantities of the starch and the fructosan during different stages of germination of fenugreek seeds. The figures are expressed in g. per 100 g. of the dry seeds.

Exp.	Time	Starch	Fructosan
I	Before steeping	0·00	0·00
	1 day germination	1·48	0·067
	2 days ,,	2·44	0·071
	4 ,, ,,	4·15	0·054
	6 ,, ,,	5·97	0·035
	8 ,, ,,	7·71	0·021
II	8 ,, ,,	8·02	Practically nil
III	8 ,, ,,	8·31	0·014

It has already been mentioned that, besides the glucose and the fructose, sucrose is also formed during the germination of fenugreek seeds. Examination of seeds similar to those of fenugreek as regards their reserve polysaccharides and of other seeds containing different forms of reserve polysaccharides, such as galacto-araban and starch, proved that sucrose is always produced during germination. Experiments to show the relation between sucrose and the reducing sugars glucose and fructose were performed by quantitatively determining the amounts of these sugars at the early stages of germination in the different seeds examined. This was done by extracting the three sugars with boiling 80 % alcohol, taking all the precautions already mentioned in investigating the relation between starch and glucose. The results of these experiments as well as the significance of sucrose and the part it possibly plays in the mechanism of the interconversion of the hexoses will be referred to in the discussion.

DISCUSSION.

It is clear from the foregoing experiments that formation of starch and a fructosan from the galactose and the mannose of the ungerminated seeds precedes the appearance of glucose and fructose in the germinated seeds. It would appear therefore that the transformation of one hexose into another occurs through an intermediate formation of a polysaccharide which gives rise to the new sugar on hydrolysis. When the radicles of dry non-starchy seeds are removed and the residual parts of the seeds are steeped and incubated at the same time with similarly treated seeds but with radicles left intact, neither starch nor sugars appear in the former while considerable amounts of both appear in the latter.

The work of Rohmann [1919] affords further evidence that in the process of interconversion there is an intermediate polysaccharide formed which gives rise to the new sugar. He found that the mammary gland contains a substance not identical with glycogen from which lactose may be obtained by ferment action. He points out that this substance is formed in the milk gland out of *d*-glucose and that on hydrolysis of this complex substance lactose is produced. It follows that the galactose constituent of the lactose molecule must arise from *d*-glucose during the polysaccharide formation.

Taking into consideration the work of the different investigators, including the present work, it can be concluded that this mechanism, if not universal amongst living organisms, plays at least a conspicuous part in the interconversion of hexoses.

Thus, according to this point of view, the actual transformation of one sugar into another takes place during the polymerisation of the hexose residues of the sugar undergoing transformation to form the polysaccharide which ultimately gives rise to the new sugar. That the process does not involve a direct transformation of one polysaccharide into another is deduced, firstly, from the presence of a powerful enzyme in the seeds which hydrolyses the original polysaccharide into its constituents and, secondly, from the fact that the starch formation in endospermic seeds takes place in the cotyledons and radicles but not in the endosperm where the original polysaccharide is present. Since the diffusion of colloidal matter through cell membranes is not likely to take place it is more probable that it is the constituent sugars of the original polysaccharide which diffuse into the embryo and polymerise to form the new polysaccharide. In order to see how this agrees with the well-known structural and other characteristics of sugars and polysaccharides, the following may be brought into consideration.

The difference between galactose and glucose lies in the configuration of carbon atom 4 and it has been shown by Haworth and Percival [1931] that in starch, the glucose residues are linked together by an α-linkage joining the fourth carbon atom of one residue with the terminal carbon atom 1 of another residue. It is seen, therefore, that it is the same carbon atom 4, the configuration of which determines the difference between galactose and glucose, which is concerned in the linkage of the hexose residues. This indicates the possibility of the stereoisomeric change taking place on the polymerisation of the residues to form a polysaccharide.

In the transformation of a sugar like mannose or glucose into fructose, one hydrogen atom on carbon atom 2 must change position with the oxide ring on carbon atom 1. In inulin, the mode of linkage of the fructose residues has been determined by Drew and Haworth [1928]. According to these authors the junction of pairs is between the reducing group 2 of one residue and the terminal group 1 of another residue, while the oxide ring connects positions 2 and 5 in each residue; thus according to this inulin is composed of γ-fructose residues. In view of the appearance of the enzyme inulase in the germinating seeds of fenugreek, the fructosan formed during germination is supposed to be built up on similar lines to inulin. Whatever the constitution of the fructosan may be, it is evident that in a non-reducing polysaccharide composed of fructose residues the reducing group 2 must be concerned in the linkage of residues. It is seen, again, that the carbon atom concerned in the linkage of the residues is the atom at which the rearrangement takes place, and it is quite possible that such a rearrangement between a hydrogen on carbon atom 2 and the oxide ring on carbon atom 1 in glucose or mannose is effected by the linkage of carbon atom 2 to another hexose residue on polymerisation of the residues for the formation of the fructosan.

It may be remarked that the fructosan formed during the steeping and the germination of fenugreek seeds is either a highly labile substance or a substance of no great importance for the mechanism of fructose formation since, contrary to starch, it is only found in small quantities at any stage of germination. Further the experiments show that on prolonged germination the fructosan diminishes considerably or even vanishes, and that in seeds of similar reserve, as well as some seeds of different forms of reserve, it could not be detected. On the other hand sucrose is formed in considerable amounts during the germination of seeds containing different forms of reserve polysaccharides. In early stages of germination of seeds in which the fructosan was not identified it has been found that when the reducing sugars just become detectable the amount of sucrose is considerably greater than that of reducing sugars. Had the sucrose been formed at the expense of the reducing sugars glucose and fructose such a result would not be expected. Further, with the production of sucrose there is also a production of a strong invertase. These observations indicate the possibility of the sucrose playing a part in the mechanism of fructose formation. The fructose residue of sucrose can arise from mannose or from glucose on condensation with another glucose residue in a manner similar to that described for the fructosan formation. Again Haworth [1920] has shown that the linkage between fructose and glucose in sucrose is through their reducing groups, the fructose residue being present in the γ-form, *i.e.* in the formation of sucrose the carbon atom 2 of one hexose residue is concerned in the condensation.

The following two possibilities of the transformation of a hexose into a polysaccharide which subsequently gives rise to another hexose suggest themselves:

(1) A stereoisomeric change which takes place at the carbon atom concerned in the linkage of the hexose residues as, for example, the transformation

of galactose into glucose through starch or *vice versa*, *i.e.* glucose into galactose through a polymeride like the reserve polysaccharide of some seeds.

(2) Intramolecular rearrangement between a hydrogen atom on carbon atom 2 and the oxide ring on carbon atom 1 in the same residue. This takes place in the transformation of an aldose into its ketose analogue as, for example, in the transformation of glucose or mannose into fructose through a polymeride of the latter or its condensation product with another hexose forming a higher sugar. The reverse rearrangement may take place in the transformation of fructose into mannose or glucose through polysaccharides like starch, glycogen or compounds containing mannose.

The possibility of the transformation of aldoses into polymerides of ketoses has been indicated by Colin [1918], who showed that inulin was formed in places of storage by condensation of the sugars synthesised by the leaf.

Evidence of the transformation of fructose into glucose through the intermediate formation of glycogen can be gained from the work of several investigators, *e.g.* Wittgenstein [1923]; Cori [1926]; Cori and Cori [1928] and Corley [1929]. The work of these authors leads to the conclusion that fructose requires transformation into glycogen before it can be utilised. In the formation of glycogen, of starch and generally of non-reducing polysaccharides composed of aldose units, the junction of pairs of units must be through the terminal reducing group of one residue and some other group in the other residue. It is, again, clear that the carbon atom 1 which is concerned in the junction of units is the atom at which the rearrangement takes place between the oxide ring on carbon atom 2 of fructose and a hydrogen atom on carbon atom 1. The transference of the hydrogen atom to carbon atom 2 may lead to the production of either glucose or mannose residues in the resultant polysaccharide. This assumption postulates that in the transformation of glucose or mannose into fructose or *vice versa* the oxide ring in either case moves to the carbon atom concerned in the linkage of pairs of units.

The consideration of the structure of the fructose residue in the natural plant products gives further support to these views. It can be concluded from recent investigations that fructose is the only sugar known to exist in the γ-form in its polymeride inulin and its condensation products like sucrose. According to the mechanism under discussion, when a sugar like glucose or mannose is transformed into a polymeride of fructose or a condensation product of it with another sugar, the ring which is an amylene oxide ring in the original sugar, *i.e.* joins positions 1 and 5, will now join positions 2 and 5, *i.e.* becomes a butylene oxide ring. This may give an explanation of the natural existence of fructose in the γ-form in its polymerides or condensation products only.

It remains to explain, on similar grounds, the transformation of mannose into glucose. During the present work evidence has been obtained that such a transformation takes place. The only carbohydrate reserve of carob seeds (*Ceratonia Siliqua*) is a polysaccharide composed of mannose and galactose similar to that of fenugreek seeds, but it has been found that the two sugars exist in the proportion of four of the former to one of the latter, while in fenugreek seeds the two exist in equal quantities. When the seeds were germinated, glucose, fructose, sucrose and starch were formed. Examination of the radicles proved that the glucose and the fructose existed in almost equivalent quantities; the sucrose also contains these two constituents in equivalent quantities and in addition to that, starch is formed which is composed entirely of glucose residues. If we consider that the glucose arises from galactose only, the glucose content of the germinated seeds would not exceed one-fifth of the total hexose content of the different above-mentioned compounds. The fact that the glucose element is in excess over the fructose one can only be explained if we assume that mannose also gives rise to glucose.

Applying the mechanism under discussion to the transformation of mannose into glucose, we must consider that starch in the higher plants and glycogen in the lower plants and animals are intermediate compounds. The difference between mannose and glucose lies in the configuration of the second group of the hexose molecule; but in the formation of a compound like starch from hexose residues the fourth carbon atom is the one concerned in the linkage of pairs. Unless we know more about the nature of the polysaccharides and the mode of polymerisation no explanation can be given with certainty, but two possibilities suggest themselves.

(1) A formation of an intermediate polysaccharide composed of glucose residues in which the junction of pairs is at the carbon atom 2 of one residue and the terminal carbon atom 1 of another residue. Such a polysaccharide has not been identified in the steeped or germinated seeds.

(2) A more probable explanation which fits to some extent with experimental facts is that the mannose is transformed into a fructosan or gives rise to a fructose residue on condensation with another hexose forming a non-reducing reserve sugar such as sucrose. These fructose-containing compounds give rise to fructose which undergoes polymerisation forming a glucose precursor such as starch or glycogen. This assumption is supported by the observation already mentioned that the fructosan found in steeped and germinated fenugreek seeds always occurs in small quantities and further diminishes or even vanishes with prolonged germination. Secondly, in all non-starchy germinated seeds the glucose element in its different forms, especially starch, is found in considerable excess over the fructose element. These observations tend to show the transformation of fructose and its compounds into starch. In this respect, it is of interest to mention that Colin and Belval [1922; 1923] working on the genesis of carbohydrates in wheat, found that a fructosan is present in the stem during the flowering season and in the seeds a little after that season. This fructosan gradually disappears with the maturity of the seeds, thus indicating the formation of starch at the expense of this compound.

SUMMARY.

1. An important mechanism of the isomeric change of one hexose sugar into another in the living organism is the formation of an intermediate polysaccharide or a condensation product such as a non-reducing sugar which gives rise to the new sugar on hydrolysis.

2. It is suggested that the actual transformation of the sugar takes place on polymerisation or condensation in one of two ways. Either a reversal of the stereochemical configuration of the carbon atom concerned in the linkage of pairs of the hexose residues, or an intramolecular rearrangement between the oxide ring and a hydrogen atom on the first and second carbon atoms of the hexose molecule. The oxide ring moves to the carbon atom concerned in the linkage of pairs of residues. The former case occurs in the transformation of a sugar into its stereoisomeride, *e.g.* galactose into glucose or *vice versa*, and the latter case during the transformation of a sugar into its ketose analogue, *e.g.* glucose or mannose into fructose or *vice versa*.

3. An explanation of the natural existence of fructose in the γ-form in its polymerides such as inulin or its condensation products such as sucrose can be

given on the basis of these views. It is assumed that such plant products originate from aldoses, such as glucose, of the photosynthetic process on polymerisation or condensation.

4. The influence of the living organism is a determining factor in the process of interconversion since the elaboration of the intermediate polysaccharides does not take place in the absence of the organism. When the enzymic extracts of germinated seeds in which interconversion of the hexoses takes place are allowed to act on the reserves of these seeds *in vitro*, the end products obtained are identical with those obtained by acid hydrolysis.

If the vitality of the seeds is destroyed by removing the radicles, then on steeping and incubating the seeds, no intermediate products or sugars are formed.

5. Together with the production of the intermediate compounds in seeds there is also a production of the specific enzymes which attack them.

6. Starch, besides playing a part in the mechanism of the interconversion of the hexoses, is usually the principal reserve carbohydrate of seeds. In starch-free seeds the different forms of carbohydrate reserves are transformed during germination mainly into starch. The other intermediate compounds playing a part in the interconversion of hexoses are formed in much smaller amounts than starch and are possibly transformed into it. The process is reversible and starch in its turn can give rise to other forms of reserves when necessary.

In starch-free endospermic seeds the starch formation takes place in the cotyledons and radicles at the onset of metabolic processes but not in the endosperm where the original reserve carbohydrates mainly exist.

We wish to express our indebtedness to Prof. G. V. Anrep and Dr A. Hassan for the encouragement and the interest they have shown in this work.

XXVIII. PROBLEMS OF NITROGEN CATABOLISM IN INVERTEBRATES.

II. CORRELATION BETWEEN URICOTELIC METABOLISM AND HABITAT IN THE PHYLUM *MOLLUSCA*.

By JOSEPH NEEDHAM.

From the Biochemical Department, Cambridge, and the Marine Biological Laboratory, Plymouth.

(*Received November 12th, 1934.*)

In the preceding paper of this series [Baldwin and Needham, 1934] some figures were reported for the uric acid content of the nephridium or kidney of the large land-snail, *Helix pomatia*. It was found that even for a considerable time after the end of the hibernation period, no less than three-quarters of the dry weight of the organ could consist of uric acid. This remarkable retention stimulated a desire to investigate whether other gastropod nephridia showed a like accumulation, and the possibility arose of studying in this way the distribution of uricotelic metabolism. We are accustomed to the view that the use of uric acid as the main vehicle of waste nitrogen excretion may in some way or other be regarded as an adaptation to terrestrial life, and the suggestion has been made [Needham, 1929; 1931; see also Hopkins, 1928] that terrestrial oviparity in particular, where development within the cleidoic egg occurs, is associated with uricotelic metabolism. Hitherto, however, such generalisations have had perforce to rest upon our knowledge of the nitrogen metabolism of vertebrates only. The urea production of fishes, amphibia and mammals has been compared with the uric acid production of reptiles and birds. But the invertebrates may perhaps provide a still more striking opportunity for the correlation of metabolism with habitat. In the insects, where the excretion of uric acid as the main end-product is widespread if not universal, such opportunities, it is true, are not promising, for the Subphylum Insecta is as a whole so typically terrestrial, and the aquatic forms are so obviously secondary, that the boundaries of habitat and metabolism will be the boundaries of the group. In the molluscs, however, we have a morphologically homogeneous population distributed through every conceivable environment; thus the gastropods are to be found in the sea and on its littoral, in brackish-water and fresh water, both rivers and lakes, and on land in surroundings showing every degree of humidity. The lamellibranchs, on the contrary, are mainly marine, with a few fresh-water species. Amphineura, Scaphopoda, and Cephalopoda are wholly marine. With the probability that terrestrial snails are uricotelic organisms now raised almost a certainty [see Baldwin and Needham, 1934] we are evidently at liberty to enquire how far this form of metabolism extends and to correlate within one group of genera the environment and the metabolism.

Strohl [1914, p. 527], in his valuable review of the excretory mechanisms of molluscs, concludes that in general the gastropods are characterised by positive findings of uric acid in their nephridia, but that in the lamellibranchs this substance is always absent, and its place seems to be taken by urea. This statement, it will be seen, is in rough agreement with the expectations which we derive from facts mentioned in the preceding paragraph. But it rests entirely on the qualitative tests scattered through the literature (which he fully cites). From these it is difficult to draw very far-reaching conclusions, if only for the reason that a positive uric acid test might imply simply the presence of a nuclein metabolism similar to that of mammals and nothing whatever regarding the excretion of the main portion of the waste nitrogen as uric acid. Moreover, it must be admitted that many of the workers reviewed by Strohl employed techniques which would not receive unqualified approval to-day. This vitiates any wide conclusions drawn from the general body of their work.

There are two main ways in which uricotelic metabolism could be proved to exist in molluscs, firstly, by the direct estimation of the various nitrogenous substances excreted by them and the drawing up of a table of nitrogen partition, secondly by the demonstration of the synthesis of uric acid from ammonia by tissue-slices *in vitro*. Unfortunately, both these methods suffer from difficulties, some of which are special to the molluscs. The direct estimation of the end-products, though straightforward enough in the case of terrestrial or fresh-water species, presents technical difficulties if the animals have to be kept in sea-water, especially if a high degree of accuracy is desired. Worse than this, however, is the very erratic nature of the excretion of many species and the possibility that others, although breaking down protein with the ultimate formation of uric acid, never excrete the latter at all. Thus experience in the cultivation of *Helix pomatia* shows us that an emptying of the nephridial contents, with the formation of clay-like granular masses, does not take place more often than once a fortnight or three weeks. Other snails probably excrete more rarely [Simroth and Hoffmann, 1928]. *Cyclostoma elegans*, the terrestrial operculate, possesses a special dermal gland (referred to later) in which uric acid is stored in extremely large amounts, and nothing is known about its excretion. In such a case, the measurement of the types of substance excreted might be very misleading indeed in the absence of other information even if carried on over very long periods. Then with regard to the demonstration of the synthesis of uric acid from ammonia by tissue-slices, difficulties arise owing to the relative slowness of the nitrogen metabolism in gastropods, leading to unduly long experiments. Here other limitations such as the tendency of the hepatopancreas, for instance, to fragmentation, and the danger of bacterial attack, are soon met with. Much further research, too, will be needed before we know the optimum requirements for invertebrate tissues *in vitro*, and there may be a poisoning of the synthesising cells by ammonia. Finally the smallness of many of the most interesting molluscs makes the study of their tissues *in vitro* for the present as good as impossible.

In view of all these considerations, it was decided to attempt a preliminary survey of the molluscs upon the assumption that the existence of uricotelic metabolism in any particular case would be reflected in the degree of retention of uric acid by the nephridium, or what might be called the average load, and to examine accordingly the nephridia of a large number of molluscs, quantitatively estimating the uric acid present. It must be emphasised at the outset that if the possibility that a gastropod could excrete uric acid just as fast as it was formed is realised anywhere in practice, the conclusions of this paper will not hold good, although the comparative data for the uric acid retention of molluscan nephridia will still possess a value. The possibility, however, is here taken to be remote. Judgment would be easier if we knew anything detailed about the rapidity of water-flow through the body of molluscs, but as reviews such as that of Adolph [1930] show, very little is known about the water turnover of the body in species other than the frog and some fishes. There is probably not much difference between a marine and a terrestrial environment with respect to the water-flow through the body, for since the osmotic pressure of the molluscan body-fluids is well-known to be approximately equal to that of the sea-water in which they live, no favouring osmotic gradient can be envisaged. Studies of the tonicity of the excretions in molluscs, similar to those of Schwabe [1933] for instance, on the nephridial fluid in crustacea, are urgently needed. On the other hand, fresh-water molluscs, such as *Anodonta*, would be expected to have a much higher water turnover and a copious excretion of hypotonic "urine" from the nephridial orifice. These considerations must be borne in mind in relation to the figures tabulated below.

Arguments in favour of the hypothesis that uricotelic metabolism will reveal itself in high uric acid retention may be drawn from the work of Cuénot [1892; 1894; 1899] on excretion in molluscs studied by means of dyes such as indigo-carmine or safranine. If these dyes, he found, were injected into the body of a gastropod or a lamellibranch mollusc, the concrements in the nephridial cells took them up, and an idea of the rate of excretion could be gained from the time taken to lose dye from the nephridium. "For aquatic molluscs" he writes [1899, p. 77] "one can obtain sufficiently precise figures by injecting a series of animals on one day and then opening them week after week until one observes the decoloration of the kidneys, previously tinted with the injected substance. It seems that in general the nephridial cells accumulate for a very long time within themselves the products which they make, and only excrete them at long intervals; thus in *Anodonta* and *Unio* it was not until 140 days after the injection that the coloured concrements with carminate began to disappear." Similar experiments have been carried out by Emeljanenko [1909] on terrestrial gastropods.

The method adopted in the present research was to dissect out the nephridia[1] from a number of animals (live and in good condition), and after grinding in a mortar with clean sand, to bring the uric acid into solution by digesting the mixed tissue for a shorter or longer time over a small flame with the phosphate mixture of Benedict and Hitchcock [1915] in which uric acid has forty times its normal solubility in water. The final volume represented approximately for each 100 ml. 1 g. wet weight of tissue, but this proportion was often departed from, depending upon the amount of uric acid shown to be present in preliminary trials. Precipitation of the proteins was accomplished by 1·5 % uranium acetate, added in the proportion of about 1 to 10 to the boiling digest, but here also the amount varied according to the quantity of protein present. The uric acid was then estimated on an aliquot part of the final solution, which was always crystal clear and usually colourless, by the colorimetric method of Folin [1933]. This method is known to be unsatisfactory in some cases, but Fujiwara and Kataoka [1933] have carefully surveyed the limits of its specificity. Reduction of phosphotungstic acid under Folin's conditions is brought about by many aromatic amines, phenols, indole derivatives, lactic acid, fructose and inulin. It may be legitimately assumed that none of these compounds would be present in the nephridial tissue to such an extent as to interfere seriously with the conclusion that the main bulk of the colour produced is due to uric acid. The analyses made on the whole body are probably more open to doubt.

In some cases the bodies of the gastropods were not removed fresh from their shells, but the attachment of the columella muscle was previously weakened by placing them for a few seconds (up to half a minute) in boiling water. It was feared that the partial coagulation of the proteins which occurred might have had the effect of rendering the uric acid more difficult to extract with the hot phosphate mixture after grinding, but experiments made in parallel to test this point on several species showed no difference of significance. In many species the small size necessitated the use of the whole body, and it was found that the shells of the organisms formed a satisfactory substitute for the sand used in grinding. In such cases separate determinations of shell weight and live weight on samples of the group permitted the calculation of the wet weight taken.

---

[1] For the morphology and cytology of gastropod nephridia see Meisenheimer [1912] and Freitag [1916].

The results are summarised in Table I and placed in order of classification and habitat in Table II. From Table I an idea can be gained of the great variation in size between the different species. The whole body of *Hydrobia* weighs but 3 mg. while the nephridium alone of *Buccinum* weighs well over 1 g., and its whole body would amount to a hundred times as much. Some of the nephridia,

Table I. *Uric acid in molluscs.*

N.B. The nomenclature adopted in this table follows Ellis [1926] for the terrestrial and fresh-water species, and the Plymouth Fauna List [Marine Biol. Assoc., 1931], as modified by Winckworth [1932; 1934], for the marine ones. Older names are bracketed. Environments are represented by T for terrestrial, (T) for moist or semi-terrestrial, FW for fresh-water, and SW for marine. Under localities M.B.L. stands for English Channel species, collected by the Marine Biological Association at Plymouth. The figures for *Helix pomatia* mostly derive from the previous paper of this series. Correlation of the above results with data on feeding habits may be attempted by consulting the lists of Hirsch [1915], Hunt [1925] and Yonge [1928], but there is no correspondence.

again, are very small; thus those of *Helicella itala* weigh only 9 mg. each, and 20 mg. is an average figure for the nephridia of Trochid marine snails. This involved the taking of large samples, such as nearly a thousand specimens of *Hydrobia* in one case, and from 50 to 100 dissected-out nephridia were a common requirement.

Not until the relation between the results and the environment is brought out, however, do we obtain a coherent picture. In Table II each systematic group is divided into sub-groups according to habitat, terrestrial preceding fresh-water and fresh-water preceding marine.

First of all, the terrestrial pulmonates may be considered. The extremely high retentions of *Helix pomatia* were not encountered in other species, but the uric acid content both of nephridium and whole body is always very high. In *Helix aspersa*[1] the average value for the nephridium would be about 100 and for the whole body 3·5 to 4·0. *H. itala* agrees closely in both ways with *H. aspersa*, but *H. virgata* may contain three times as much in the whole body, as also may *Cochlicella*. All these, as Ellis [1926] says, are typical arid-living forms. At the extreme opposite would be the marine pulmonates, but these are extremely rare, the only convenient English species being *Onchidella celtica*. This very interesting shell-less mollusc (for which see the classical paper of Joyeux-Laffuie [1882]) proved to contain almost no uric acid, its whole body giving a figure of only 0·27 mg./g. dry weight in contradistinction to the amounts from ten to one hundred times as large found in the terrestrial species. It is certain that the high degree of vascularisation of the mantle cavity and the reduction of the gills to vestiges, which characterise the pulmonates, are adaptations to terrestrial life, and *Onchidella* is therefore generally regarded as a return to the sea, *i.e.*

[1] During the dissection of these snails, it was impossible not to be impressed with the large amount of bright yellow pigment excreted by glands in the foot. This was found to be soluble in water but not in chloroform and only irreversibly reducible. Its properties were apparently not those of a flavin or a pterin. The literature is very silent on the subject of gastropod slime-pigments, but there is a reference to them in Krukenberg [1886]. They are now under investigation by my friend Dr Kurt G. Stern.

secondarily aquatic. If, therefore, we may interpret the high retentions seen in the terrestrial pulmonates as evidence of uricotelic metabolism, the condition of affairs in *Onchidella* indicates a far-reaching, if not complete, abandonment of this form of metabolism and a return to ammonia or urea production.

An interesting parallel case to this is to be found in the fresh-water elasmobranchs studied in Siam by Smith and Smith [1931]. The high urea content of elasmobranch blood is now generally believed to be adaptive in character, in that it brings the total osmotic pressure of the internal medium above the external, and so, by forming a favourable osmotic gradient, exempts the fish from the continuous drinking and complicated excretory arrangements found in the teleosts [Smith, *et al.*, 1930, 1; Smith, 1932]. The majority of elasmobranchs are marine, but secondary (or tertiary) penetration into fresh-water environment occurs in certain rather rare cases, such as the saw-fish, *Pristis*. It was accordingly of interest to study the urea content of fresh-water elasmobranch blood, for if no longer required, it might have sunk to a level similar to that of other animals, or on the other hand, if such an evolutionary retrogression were not possible, it might have remained at its usual level[1]. In actuality Smith and Smith observed a diminution of about 60 % in all the species studied. If, however, we were to apply this analogy in full to the case of the marine pulmonate, we should have to suppose that a mixed metabolism existed; true uricotelism supplying only a portion of the total excreted nitrogen, but this we may be reluctant to do in view of the all-or-none character of the cases of uricotelic metabolism hitherto known. It is clear that *Onchidella* invites much closer and more detailed attention.

The remainder of the pulmonates divide into two distinct groups (*a*) the aquatic snails of fresh-water and (*b*) the slugs. The fresh-water pulmonates are all, it is generally agreed, secondary, and correspondingly it is found that the uric acid content of some of them closely approaches that of the terrestrial snails; thus a nephridium may have in *Limnaea* 137 mg./g. dry weight and in *H. aspersa* 153. Nevertheless, there seems to be a gradation here reminiscent of what was seen in the case of *Onchidella*, for *Planorbis* nephridia are not as rich in uric acid as the land-snail nephridia, and the water-snail *L. peregra* with the river limpet *Ancylastrum* have an average body content of only 0·41 mg./g. dry weight, as against 8·75 for the land-snails. This low figure, indeed, closely approaches the 0·27 of *Onchidella*. The apparent conclusion is that some of the fresh-water species are still uricotelic while others are not, and that the difference may be associated with the length of time the species have been in fresh-water. The position of *Ancylastrum* would agree with this view, for as it is a pulmonate it must have entered the fresh waters by an overland route, and yet its completely aquatic limpet-like morphology must indicate a very long stay in fresh-water, long enough for it to diverge so widely from its nearest ally *Planorbis*. However, it is to be remembered that a fresh-water environment probably involves a faster current of water through the body than other environments, and the low values in these species may, therefore, be due to great rapidity of excretion. What has already been said, however, about the excretion of molluscs, makes this possibility only indifferently plausible.

Just as the fresh-water snails vary in uric acid content from "terrestrial" values down to very low ones, so also do the slugs. *L. maximus* gives a nephridial value equal to that of any land-snail, but the others more nearly resemble an intermediate aquatic form such as *Planorbis*. Here again there are two explanations, either that there is a real retrogression from uricotelic metabolism parallel with the loss of the shell, or that the excretory system is more vigorously flushed with water. In favour of the latter view are the recent experiments of Howes and Wells [1934], who also summarise the previous literature on water turnover of terrestrial organisms. Relatively dry and impermeable skins allow of very little loss (*e.g.* mammals 3 %/day, insects 2 %/day, lizard 5 %/day), moist skins allow more (anurans 10 %/day, urodeles 28 %/day). The earthworm may lose 240 %/day in air, but in subterranean conditions, this capacity for loss is probably not a serious deficiency. The slug, however, loses 58 %/day as a minimum in the motionless state, and if continuously creeping, loses 384 %/day. Correspondingly, although snails such as *Helix* can be kept without water for many months, since they only retire into their shells and lose very little, slugs must be supplied with ample water and must constantly drink. As there is clearly so great a current of water through the skin and the slime-glands it is at least very possible that there is also a great current of water through the nephridium and this would have the effect referred to above. On the other hand, the generalisation, which most oecologists would accept, that on the whole slugs inhabit a moister environment than snails, would be in favour of the former alternative. The work on arginase, reported in the succeeding paper of this series by Baldwin [1935], tends also in the same direction.

---

[1] The subject of evolutionary retrogression merits more attention from biochemists than it has yet received (*cf.* the papers of Nopcsa [1923] and Blagoveschenski [1929]).

We have now to consider the operculate gastropods. Two groups of them, the terrestrial and the marine, give very clear-cut results. In the first place, *Cyclostoma*, the only English representative of its class, shows an enormous retention of uric acid, exceeding even the figures for *H. pomatia*. Its whole body contains uric acid to the same extent as the nephridium alone of the other terrestrial snails. This finding is no doubt due to the presence in *Cyclostoma* of a "concrementary gland" first described by Claparède [1858] and containing dense deposits of uric acid. A lengthy examination of it was made by Meyer [1925], especially with regard to the symbiotic bacteria which it is said to contain. It is not strictly speaking a gland, but a perivascular agglomeration of large cells containing the concretions. Uric acid was first shown to be present in the gland by Barfurth [1884] and according to Meyer's figures, at least 42 % of its dry weight is uric acid (*cf.* the *H. pomatia* nephridium). Other purine bases are believed to be present also in considerable amounts. Very little is known about the actual excretions of *Cyclostoma*, but the elimination of concrements probably takes place at infrequent intervals, and urea has been recognised by the xanthydrol reaction in the nephridial fluid.

Marine operculate gastropods show, without exception, extremely small amounts of uric acid in nephridium or in whole body. The average figure for all species, 3·2 mg./g. dry weight nephridium, contrasts with the immensely high figures for *Cyclostoma* and the land pulmonates (up to 1000). In other words, it is clear that in these species, of which the whelk *Buccinum* is typical, and which possess no trace of terrestrial ancestry, uricotelic metabolism does not exist. Here the question of water turnover is not likely to affect the issue, since the concentration of the external medium allows of no rapid current through the body.

At this stage the general argument may be crystallised as shown in Table III.

The general conclusion that if uricotelic metabolism can be gauged by uric acid retention, uricotelic metabolism is especially associated with terrestrial life, seems unavoidable. And in this case the comparison is between animals all within a comparatively restricted group, the gastropods.

Table III.

Environment	Typical species		Uric acid, mg./g. dry weight: Nephridium	Uric acid, mg./g. dry weight: Whole body
Terrestrial	Pulm.	*Helix pomatia*	700	(30)
		Helicella itala	150	4
	Operc.	*Cyclostoma elegans*	(1000)	80
Fresh-water	Pulm.	*Limnaea stagnalis*	100	3
	Operc.	*Viviparus fasciatus*	35	1
Marine	Pulm.	*Onchidella celtica*	(0)	0·27
	Operc.	*Buccinum undatum*	4	(0·2)
		Gibbula umbilicalis	2	(0·2)
		Littorina littorea	1	0·2

The figures in brackets are deduced from comparison with other species.

But there remains for consideration the interesting group of fresh-water operculates. It is usually held that these animals, by reason of their gills and lack of mantle vascularisation, must have reached their present position by colonisation up the rivers. We should therefore expect that uricotelic metabolism would not occur in them and that their bodies would be nearly free of uric acid. *Hydrobia jenkinsi* gives a remarkable opportunity of testing this point, for according to Ellis [1926, pp. 31, 78] the species was entirely confined to brackish- and sea-water until near the end of the nineteenth century. Not until 1893 were the first specimens obtained from an inland situation. Subsequently it became abundant in rivers, streams and canals over all the British Isles [see also Boettger, 1931]. In accordance with expectation uric acid was found to be absent from this mollusc, not even detectable amounts being noted in samples from various parts of the country. The phenomenon was sufficiently striking, for where comparable amounts of another gastropod, *Littorina neritoides*, of about the same size (4 mg. individual body weight) would have given deep blue colours, the extract from *H. jenkinsi* was quite colourless. One catch from an Anglesea llynn included some other gastropods; 27 of these (mixed *Limnaea peregra* and *Planorbis albus*) were worked up and gave 1·6 mg./g. dry weight, *i.e.* similar to other fresh-water pulmonates. The difference cannot, therefore, be purely environmental.

On the other hand, *Paludina* and *Bithynia* did not behave as expected, for both of them contained amounts of uric acid corresponding to the fresh-water pulmonates. Recourse to an explanation based on high water turnover is here impossible, for while that would explain a case in which uric acid was expected but not found, it cannot explain a case in which uric acid is found where it was not expected. There seem to be two explanations which are available (1) that uricotelic metabolism is an adaptation not only to terrestrial but also to fresh-water life, (2) that the fresh-water operculates originated not from the sea direct but by way of a period of terrestrial or semi-terrestrial life, analogous to that which *Cyclostoma* and *Littorina neritoides* are now living.

With regard to the first of these possibilities one of the most general characteristics of the fresh-water fauna, as Carter has shown in numerous studies [*e.g.* Carter and Beadle, 1930; 1931] is the possession of adaptations for passing periods of unfavourable conditions inactively. These adaptations are particularly necessary in the fauna of the shallower and often stagnant fresh waters, for the danger of desiccation is always present. Many shallow water animals can pass through periods of drought contracted within their shells. Unfortunately for this point of view, the evidence regarding the capabilities of modern fresh-water operculate gastropods is that they possess very poor powers of withstanding periods of complete dryness. As for the parallel case of the aestivating lung-fishes, it is now definitely known that uricotelic metabolism does not occur in them, but that like the elasmobranchs they can store in their tissues great quantities of urea [Smith *et al.*, 1930, 2]. This mechanism appears to be strictly confined to the fishes.

That the fresh-water operculates originated not directly from the sea but overland in a manner analogous to the fresh-water pulmonates is a suggestion at first sight somewhat more unwelcome to the zoologist, but not by any means impossible on closer inspection. Even in *Cyclostoma* there is a vestigial gill which under suitable conditions might grow again, accompanied by a diminution in the number and size of the blood vessels in the wall of the mantle cavity. And in the periwinkles we see a series of animals the most terrestrial of which is not far removed from the condition of the fresh-water operculates.

The celebrated series of periwinkles affords a particularly good opportunity of testing the ideas here discussed, for within one single genus there is a marked zonation of habitat on the sea-shore, *Littorina littorea* being entirely marine, *L. neritoides* almost wholly terrestrial and two other species, *L. obtusata* and *L. rudis* intermediate. Corresponding with this there is a gradation of adaptations for air-breathing [Carter, 1931]. This is represented in Table II by an arrow, and from the figures accompanying it a gradation in the amount of uric acid contained both in the nephridium and in the whole body, is apparent (Table IV). This is graphically illustrated in Fig. 1. At the bottom of the figure the percentage intertidal exposure (taken from Colman [1932, 1, 2]) is given, showing that whereas *L. littorea* is never exposed for more than 65 % of the time, *L. neritoides* is never exposed for less than 85 % of the time. Moreover, these figures allow for the splash zone. Above, the uric acid in mg./g. dry weight nephridium and whole body is given. Even if the highest value for *L. neritoides* is set aside, there still remains a definite increase with increasing dryness of habitat. At the

Note. N, nephridium; WB, whole body. Of *L. neritoides* Colman [1932, 1] says it "extends up the rocks several feet above high water mark, where for weeks during a calm summer its sole source of moisture is dew, rain if any, and perhaps the dampness caused by the salt on the rocks." *L. rudis* may also live in positions much above the tide mark: Ellis [1926] lists *L. neritoides* among the terrestrial snails.

point marked *A* is shown the average figure for all the terrestrial pulmonates (excluding their two highest values), and at *B* the value for the single marine pulmonate. It would be tempting to make the preliminary assumption that *L. rudis* and *L. neritoides* are both uricotelic, while the others are not, and this would accord with the fact that the two first-named species are also ovoviviparous. This raises exceedingly interesting general problems which strongly invite much further work on the nitrogen metabolism of the *Littorinidae*. The literature [*cf.* Turchini, 1923] does not seem to contain a comparative cytological study of their nephridia.

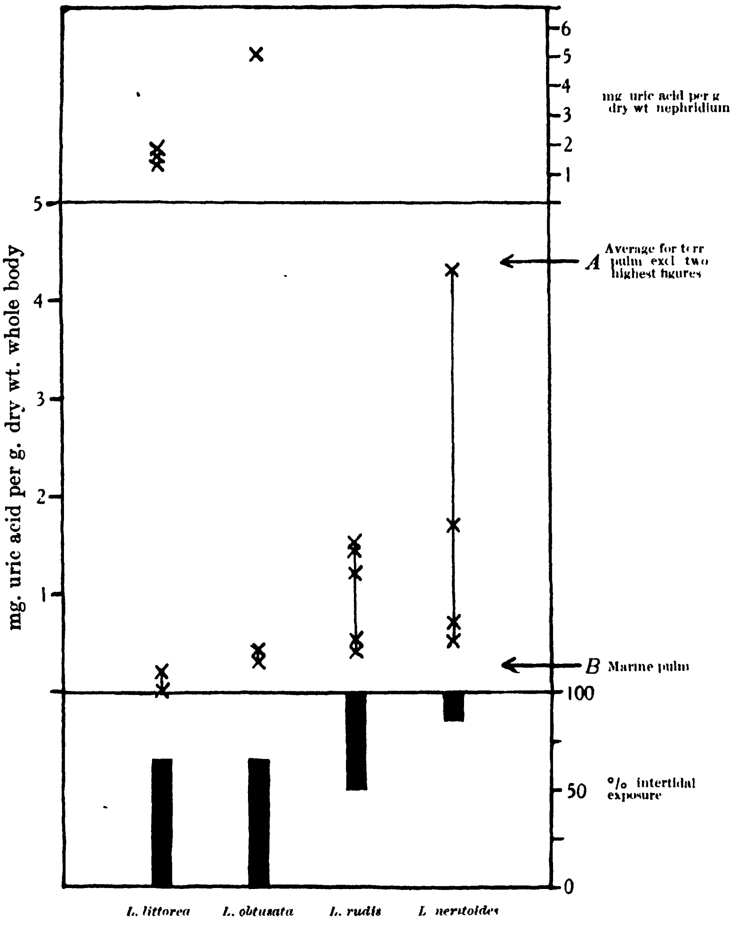

Fig. 1.

The remainder of Table II contains data about various other forms, all marine, belonging to diverse groups such as the Nudibranchs, the Solenogastres *etc.* They are at one in containing little or no uric acid, agreeing therein with their absence of terrestrial ancestry and with the marine gastropods already mentioned. The lamellibranchs were not studied in any detail, but it was curious that while the two fresh-water forms contained no detectable uric acid, the two Pectinidae had measurable amounts. A repeatable difference seems to exist between *P. maximus* and *P. opercularis*, the former having somewhat less uric acid in its nephridium than the latter. The Amphineura gave uniformly negative results.

A few observations were made upon the developing embryos of *Helix aspersa* which may be of interest in view of the absence of any similar information in the literature. The undeveloped eggs contained no uric acid whatever, but the young snails examined immediately after hatching had 2·76 mg./g. dry weight in the whole body. This is analogous to the uric acid formation which Baldwin [1934] found to go on during the development of the pond-snail, *L. stagnalis*. During the development of these *H. aspersa*, which took 23 days, the wet weight of one individual decreased from 37 to 17·5 mg.; a loss of 19·5 mg. or 53 %; while the dry weight decreased from 6·8 to 5·5 mg., *i.e.* by 1·3 mg. or 19 %. The loss of water was therefore 48 %[1]. The uric acid formed per individual was 0·007 mg. or 0·28 % of the final dry weight (excluding the weight of the shell). The comparison of these figures with those for another terrestrial cleidoic uricotelic form, the hen, is interesting. The hen's egg during its development does not lose so much water (about 15 %) probably owing to its more impermeable shell. On the other hand it loses about 18 % of its original dry weight by combustion—a figure quite close to that for the snail. During development, about 35 mg. of uric acid are formed, or 0·7 % of the final dry weight. This is again a figure of the same order as that for the development of the snail. Further work on this material would well repay the effort involved.

It is hoped that the present work may initiate a series of comparative investigations on nitrogen metabolism in molluscs. The lines of advance which most immediately present themselves are (i) the closer examination of nudibranchs, and tectibranchs such as *Aplysia*, *Philine* and *Pleurobranchus* (*Oscanius*), about which conflicting reports exist in the literature, (ii) direct determinations of the nitrogen partition of the excreta in the *Littorina* series, and in selected cases of special interest such as *Hydrobia* and *Onchidella*, (iii) nephridial determinations on the only English fresh-water Aspidobranchiate *Theodoxus* (*Neritina*) so far unobtainable, and on foreign gastropods such as *Ampullaria* which has gill and mantle-cavity of about the same size, (iv) a study of the rapidity of uric acid elimination after injection of the substance or other purines into terrestrial and aquatic species respectively, (v) a thorough examination of the nitrogen metabolism of cephalopods.

SUMMARY.

1. The uric acid retention of the nephridia and other tissues of a large number of molluscs (especially gastropods) has been studied on the assumption that uricotelic metabolism will indicate itself in this way.

2. The reliability of this assumption for molluscs is discussed in the text. If it is correct, the preliminary survey here reported demonstrates that within the homogeneous group of gastropods uricotelic metabolism is an adaptation to terrestrial life.

The author wishes to express his grateful thanks to Mr Hugh Watson, Mr A. E. Ellis, Mr C. Oldham, and Mr F. A. Potts, for their untiring help on matters connected with molluscs, as well in collecting as in identification and theory. He

---

[1] In this connection the results of Carmichael and Rivers on the dehydration of slug eggs are of interest. These eggs will still develop even if their wet weight is lowered 85 % by an environment of low humidity.

is also greatly indebted to Dr E. J. Allen for hospitality at the Plymouth laboratory, and to his staff, in particular Mr G. E. Steven and Mr L. H. N. Cooper for their kindness. The expenses of the work were partly defrayed by a grant from the Government Grant Committee of the Royal Society.

XXIX. PROBLEMS OF NITROGEN CATABOLISM IN INVERTEBRATES.

III. ARGINASE IN THE INVERTEBRATES, WITH A NEW METHOD FOR ITS DETERMINATION.

By ERNEST BALDWIN[1].

From the Biochemical Department, Cambridge.

(*Received November 12th, 1934.*)

ARGINASE was discovered in mammalian liver by Kossel and Dakin [1904, 1, 2] who showed that the products of its action are ornithine and urea. Since that time the enzyme has attracted a great deal of interest from many points of view, but for present purposes it is sufficient, without going into the history of the subject, to point out that until very recently it was generally supposed that a small proportion of the urea excreted by mammals arises by the action of the liver arginase upon ingested arginine. Krebs and Henseleit, however, brought forward convincing evidence [1932] for supposing that the whole of the urea so excreted is elaborated by means of a cyclical mechanism involving arginase. In the meantime a generalisation of the greatest comparative importance was made by Clementi [1914; 1915], who pointed out that arginase could be detected in the livers of animals having a ureotelic metabolism, but not in cases where the metabolism is uricotelic in character. Manderscheid [1933] has extended the work of Krebs and Henseleit [1932] to other vertebrates and found the same cyclical system operating in those having the ureotelic type of metabolism, thus providing an explanation for the empirical rule enunciated by Clementi.

The distribution of arginase among vertebrate tissues has been carefully studied by a number of workers [Edlbacher, 1915; Hunter and Dauphinee, 1924, 1, 2; Edlbacher and Bonem, 1925] but the invertebrates have received scant attention. Table I presents the results obtained in the few cases hitherto examined. From these results Hunter and Dauphinee [1924, 2] concluded that "arginase is an enzyme almost, if not entirely, peculiar to the vertebrates." But it is known that many and possibly all invertebrates excrete urea to some extent [Delaunay, 1927; 1931]. The facts that *Helix* excretes some 20 % of its waste nitrogen in the form of urea and that it was the only invertebrate then known to contain arginase led Baldwin and Needham [1934] to investigate the possibility of a cyclical synthesis of urea in *Helix* itself. The presence of arginase in

[1] Senior 1851 Student.

the hepatopancreas was confirmed, and the enzyme was also detected in the nephridium, but we were forced to the conclusion that the urea excreted by this snail arises, not synthetically, but from ingested arginine. This brought the snail into the same category as the bird [Clementi, 1932; 1933] and raised the question as to how far the excretion of urea by invertebrates in general can be attributed to the action of a tissue arginase upon ingested arginine. The present paper offers a partial answer to this question in the form of the results obtained for a variety of invertebrates by means of the new and very sensitive method which has been devised for the detection and estimation of arginase.

METHOD.

The essential basis of all the methods which have been employed for the detection of arginase consists in allowing the enzyme to act upon arginine and determining the amount decomposed in one or another of several ways. Of these the most suitable for quantitative purposes is that of estimating the urea which is liberated. The earliest quantitative studies of the distribution of arginase were those of Hunter and Dauphinee [1924, 2] who used a colorimetric method of their own for the estimation of urea [1924, 1]. Their method however was open to objections on theoretical grounds, as was pointed out by Edlbacher and Röthler [1925, 1], who introduced a second quantitative method and defined a new unit of arginase activity; in this case the urea determinations were carried out by a distillation method. But the most delicate method yet introduced for the estimation of urea is that of Krebs and Henseleit [1932]. Here the urea is decomposed by a urease preparation acting at p_H 5; ammonia is effectively bound at this p_H but the CO_2 is liberated and measured manometrically. The sensitivity of this method is at least 100 times that of the distillation method employed by Edlbacher and Röthler [1925, 1], and the manometric technique was therefore adopted for present purposes. It must be mentioned, however, that Weil and Russell [1934] have used the same principle in their studies of blood arginase, their method being published shortly before the present work was completed.

In the method of Edlbacher and Röthler [1925, 1] the arginase was prepared in the form of a glycerol extract of the tissue under examination. Increasing quantities of this extract were incubated for 60 minutes with 10 ml. 1 % arginine solution and 5 ml. of a glycine buffer, the p_H being 9·5 and the temperature 37°. A few drops of toluene were added as an antiseptic. At the end of the period of incubation the enzyme was destroyed by heat, the urea formed being decomposed by urease and the ammonia so set free estimated by titration after being distilled off. A standard curve was now plotted relating urea production to enzyme concentration, the latter being expressed in convenient arbitrary units. The ratio of activity to enzyme concentration was not constant, but fell off with increasing concentration of the enzyme, but the form of the curve was found to be the same for all the tissues examined, with a single exception in the case of the kidney of the bird. This curve could therefore be used as a standard for interpreting the urea production directly in terms of arginase concentration. The number of "Arginase Units" per g. of tissue could then be calculated, and hence the "Arginase Number" of the particular tissue.

This simple procedure however could not be applied at once to invertebrate materials. Different tissues did not, it was found, give superposable curves for the activity-concentration relation, and it was thought that better agreement might be obtained if the enzyme were allowed to act upon an excess of substrate and if the period of its action were reduced. Arginine was therefore used at a concentration of 2 % and an incubation period of 30 minutes only was allowed, and this, since the temperature was 28° instead of 37°, was equivalent to only one-fourth of the period used by Edlbacher and Röthler [1925, 1]. It will be remembered that those authors themselves stressed the importance of measuring the initial rate of the arginase-arginine reaction.

With these modifications it was found that the amount of urea produced was directly proportional to the enzyme concentration, provided that the total urea formed was not more than 4 mg. under the conditions adopted as standard. A number of curves are plotted in Fig. 1 and show this relation clearly. The slope of the straight part of the curve thus gave the urea production per unit weight of tissue, *i.e.* the relative richness of the tissue in arginase. All the results are here expressed in the $Q_{\rm H}$ notation of Krebs and Henseleit [1932], *i.e.* as μl. urea-CO_2 per mg. dry weight of tissue per hour, the temperature being 28°, the activities so expressed being denoted by the symbol $Q_{\rm H}^{28}$. It is possible to express the data given by Edlbacher and Röthler [1925, 2] in the same terms, and it seemed better to use Krebs and Henseleit's mode of expression than to add yet another arbitrary unit to the list already defined.

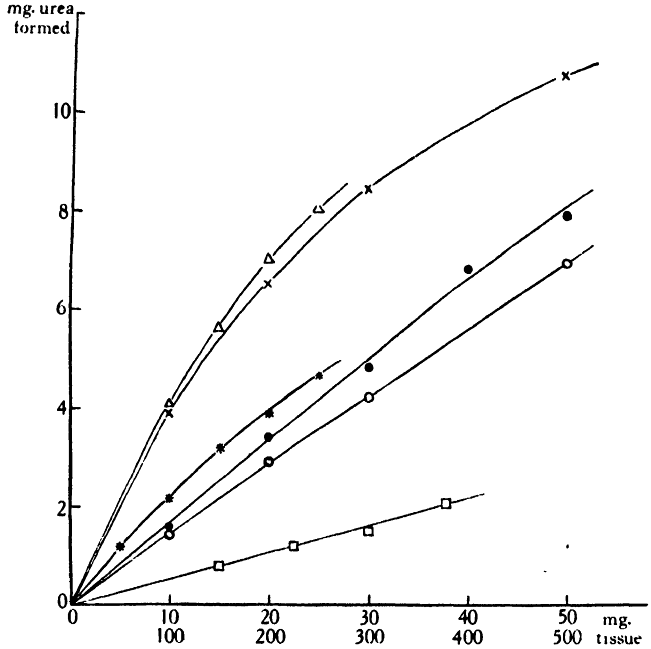

Fig. 1. See text for explanation. * Guinea-pig; • *Limnaea*; o *Viviparus*; × *H. pomatia*; △ *H. aspersa*; □ *Carcinus*. The data for *Carcinus* are plotted on the lower scale of weights.

The conditions of temperature and $p_{\rm H}$ were 28° and 9·5 respectively. Hunter and Dauphinee [1933], Hunter and Morrell [1933] and Hunter [1934] have made a thorough study of the effects of these and other factors upon the reaction and point out that although the enzyme has an optimum $p_{\rm H}$ of 9·5–9·8 under certain conditions [Hunter and Morrell, 1924; Edlbacher and Bonem, 1925] it is very labile at such a $p_{\rm H}$, the lability being much increased by rise of temperature. Consequently there is in practice an optimum neither of temperature nor of p_H but "at p_H 9·8 the optimum for most conditions will be lower than 40° and for many lower than 30°" [Hunter, 1934]. The temperature chosen was 28°; it seemed possible that the enzyme, coming from invertebrate sources, might be more labile than that from vertebrate materials, and this actually appeared to be the case. Fig. 2 shows two comparable curves obtained at p_H 7·4 and 9·5 respectively. That at 7·4 shows that the arginase of *Limnaea stagnalis* is rapidly inactivated even at 28°, whereas mammalian preparations undergo only very slow inactivation under such conditions [Hunter and Dauphinee, 1933]. At 9·5 the *Limnaea* enzyme was practically destroyed in 3 hours, a circumstance which again indicates the desirability of dealing only with the earliest stages of the reaction.

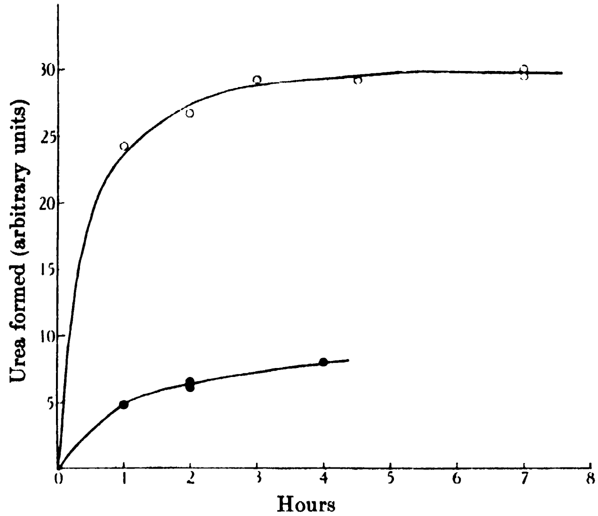

Fig. 2. Time curve of arginase-arginine reaction at 28° (*Limnaea* enzyme). ○ at p_H 9·5; ● at p_H 7·4.

The p_H was controlled by means of a glycine buffer; Weil and Russell [1934] report that such a buffer causes slight inhibition of the arginase of rat blood but no such effect was noticed here. The use of a p_H of 9·5 seems especially suitable since urease, which appears to be of frequent occurrence in invertebrate tissues [Albrecht, 1920; Przyłęcki, 1922; Baldwin and Needham, 1934], is here practically inactive and cannot interfere appreciably with the urea produced by the action of arginase. Indeed, no evidence of such interference was observed during this work.

No antiseptics were employed since the period of incubation was only 30 minutes. Quite apart from any effect it may have had upon arginase itself, the introduction of toluene resulted in vapour pressure effects in the manometers, and stationary readings could not be obtained in spite of prolonged equilibration in the bath. Chloroform was successfully tried in a few of the earlier experiments since, on account of its lower boiling-point, it could be boiled off before samples were taken into the manometric flasks.

Finally, the method of extracting tissue arginase with glycerol has not been employed. At best this is a long and somewhat cumbrous process, and Hunter and Dauphinee [1930] have obtained maximum yields of the enzyme from fresh mammalian liver by extraction with water only for 2 minutes at 60°.

The details of the method may now be described, and it should be pointed out that these details must be closely observed in order to secure comparable results with different tissues.

SOLUTIONS AND EXPERIMENTAL TECHNIQUE.

(1) *Arginine solution.* This contained 5 % of arginine in the form of its carbonate. A little of the Universal Indicator of B.D.H., Ltd. was added and the p_H brought to 9·5 by passing in CO_2.

(2) *Glycine buffer.* A stock solution containing *M* glycine *plus* *M* NaCl was prepared. For use, 7 parts of this received 3 parts of *M* NaOH; such a mixture, diluted 10 times, has a p_H of 9·5 at 28° (interpolated from the data given by Britton [1929]).

(3) *Urease solution and acetate buffer.* These solutions were prepared according to the directions of Krebs and Henseleit [1932], whose method was followed exactly except that for the sake of convenience the estimations were carried out at 28° instead of 37°.

(4) *Preparation of tissue "brei."* The organs selected for analysis were dissected from animals in good physiological condition. Adherent tissues were removed as far as possible, surplus water was absorbed by means of filter-paper, and the material dropped into a chilled dish. When enough had been collected, representative samples were removed and weighed on the torsion balance for the determination of the dry weight, the rest being weighed and transferred to a mortar. Enough sand was added to give a thin paste and the tissue then thoroughly ground. After the addition of a little water the p_H was brought to 9·5 by the addition of *N* NaOH and the mixture filtered through a loose plug of glass wool into a measuring cylinder and washed through. The volume was now made up to the desired value and the p_H finally adjusted if necessary, the Universal Indicator being employed externally.

It is essential that the preparation and neutralisation of the "brei" be carried out as rapidly as possible on account of the lability of arginase.

(5) *Experimental procedure.* A series of pyrex boiling-tubes (6 × 1 in.) were prepared and numbered. Each received 0·5 ml. of the buffer and sufficient water to bring the final volume to 5 ml. A quantity of the arginine solution having been set to warm to 28° in the bath, the "brei" was prepared, and samples were at once measured into the tubes. The latter were then promptly lowered into the bath and left for exactly 5 minutes; 2 ml. of the arginine solution were then added to the contents of each tube (except the control), the additions being made serially and at 10-second intervals. Table II shows the quantities taken in typical experiments. After 30 minutes, the interval being measured with a stop watch, each tube received 1 drop concentrated HCl to neutralise the arginine and break down the buffer, followed by sufficient glacial acetic acid (usually 3–5 drops) to bring about precipitation of the proteins. This brought the p_H to a value at which urease is still fairly active, and the tubes were therefore plunged at once into a briskly boiling water-bath, where they were allowed to remain for

Table II.

Tube		1	2	3	4	5	6 (control)
Buffer	ml.	0·5	0·5	0·5	0·5	0·5	0·5
Water	,,	0·0	0·5	1·0	1·5	2·0	2·0
"Brei"	,,	2·5	2·0	1·5	1·0	0·5	2·5
Arginine	,,	2·0	2·0	2·0	2·0	2·0	0·0

2 minutes. This inactivated the enzymes and usually sufficed to coagulate all the proteins present, which were then filtered off. Crystal clear filtrates, slightly yellow in colour, were usually obtained, and of these samples were taken into the manometric flasks for the determination of their urea contents. In addition to the control on the tissue itself (tube 6 in Table II) additional controls were run on each new lot of the arginine solution, since the arginine used was found to contain a little urea.

(6) *Calculation.* The yields of urea, expressed in terms of μl. of CO_2 and duly corrected for the tissue and solution blanks, were plotted against the amounts of tissue in the corresponding tubes. The yield per mg. of tissue was deduced from the slope of the curve in the manner already indicated, converted into μl. CO_2 per mg. dry weight of tissue and finally expressed as a Q_H^{28} value. It is proposed to refer to each such value as the "arginase index" of the particular tissue.

(7) *Preliminary tests.* Before following out the foregoing somewhat elaborate procedure it was desirable to discover approximately how much arginase, if any at all, was present in each tissue or organ examined. This was done by preparing a rather concentrated "brei," containing 100–300 mg. of tissue per ml. Of this 2·5 ml. were treated in the usual way, the two necessary controls being set up at the same time. Urea estimations were then carried out on the final filtrates, and the arginase index was approximately evaluated; fresh experiments were then set up in all cases to confirm negative results or to secure accurate values for the index where arginase was present. The data in Table II may be regarded as typical of those obtained in such preliminary experiments, but it should be pointed out that arginase was only regarded as present if the total amount of urea CO_2 exceeded 10μl. On the other hand, the disappearance of more than 10μl. CO_2 might conceivably be taken as indicating the presence of urease in the tissue, but such indications would need further confirmation.

HP, hepatopancreas.

RESULTS AND DISCUSSION.

The results of the experiments performed are presented in Table IV. The liver of the guinea-pig was examined in two cases with a view to comparing the values obtainable for Q_H by the new method and by that of Edlbacher and Röthler [1925, 1, 2]. From the data given by the latter authors it was possible to calculate an index of 930 for female guinea-pigs at 28°, the necessary temperature coefficient being obtained by interpolation from the data given by Hunter [1934][1]. The mean value found by the new method was 750 and it may be taken that the agreement between the two figures is satisfactory in view of the fact that the arginase content of the liver varies considerably from animal to animal as well as with conditions such as age and sex [Edlbacher and Röthler, 1925, 2].

---

[1] Krebs and Henseleit [1932] give an index of 4000 for the guinea-pig, but this figure refers to 37° and appears to have been calculated from Edlbacher and Röthler's data for the male animal; furthermore the dry weight was assumed to be 20 % instead of 28 % as was found here.

A glance at the table of results suffices to show that the distribution of arginase is considerably wider than has hitherto been supposed. While two marine lamellibranchs (*Mytilus* and *Pecten*) gave no evidence of containing arginase, thus confirming Hunter and Dauphinee's finding in the case of *Saxidomus*, a fresh water species, *Anodonta*, contained the enzyme. This suggests that the distribution of the enzyme may be somewhat erratic although it is possible that further work would reveal a strict correlation between the presence of arginase and a terrestrial or fresh-water habitat. It will be seen that of all the molluscs examined only the terrestrial and fresh-water species contained the enzyme. The finding of arginase in a crustacean and in an asteroid suggests that it was on account of lack of sensitivity that the enzyme was not detected in *Astacus* and

The nomenclature is that of Ellis [1926].

(*a*) Animal moribund.
(*b*) Starved and aestivating.
(*c*) Just wakened from hibernation and well fed.
(*d*) Just wakened from hibernation but no food eaten.

Pisaster by the methods of Clementi [1918] and Hunter and Dauphinee [1924, 2] respectively. On the other hand the technique of Edlbacher and Röthler [1925, 1] would probably have been sufficiently delicate to allow of the detection even of the small arginase concentrations which were found in the animals so far mentioned, although the indices did not in any case exceed a value of 20, which is less than 3 % of the mean for the guinea-pig livers.

The examination of a moribund specimen of *Asterias* brought to light the fact that arginase content is dependent upon physiological condition, and this was further demonstrated in the case of *Helix pomatia* (see Table IV). Well-fed individuals of this species gave an index of 6500 as compared with 1200 and 933 for starved specimens, while only traces of arginase could be found in the slug *Milax sowerbii* and *Helicella itala* after these had been kept for about a fortnight without food. The results listed in Table IV refer to fresh healthy specimens except in the cases indicated; the marine forms, which were obtained from Plymouth, were in all cases used within a day or two of capture.

Turning now to consider the results obtained for gastropod molluscs, it will be seen that arginase could not be detected in any of the three marine forms which were tested, *viz. Buccinum*, *Littorina* and *Patella.* Yet the hepatopancreases of the fresh-water forms, *Limnaea* and *Viviparus*, contained the enzyme in a concentration quite comparable with that found in mammalian livers. Two terrestrial species, *H. pomatia* and *H. aspersa,* even surpass the mammalia in arginase content, the former having an index of about 6500 and the latter 1200 in well-fed specimens. In a previous paper [Baldwin and Needham, 1934] a value of 20·2 for the hepatopancreas "brei" of *H. pomatia* was published. The experiments in which this value was determined involved incubation of the "brei" with arginine for several hours at p_H 8·4 and 28°. The conclusions of our previous work are not much affected by the newer values here reported, but the fact that such low values were obtained emphasises the importance of measuring only the initial velocity of the arginase-arginine reaction when the arginase index of a given material is to be determined with anything approaching accuracy.

The present finding of indices of from 1000 to 6000 for the hepatopancreases of animals which are primarily uricotelic makes it still more certain that, if there be any homology whatever between the gastropod hepatopancreas and the vertebrate liver, Clementi's rule [1914; 1915] fails in its application to the invertebrata, and all the more so when it is remembered that the nephridium, and perhaps other organs too, contains much arginase [Baldwin and Needham, 1934]. At the same time, in view of the work of Krebs and Henseleit [1932], it seemed somewhat curious that the snail, possessing as it does an arginase content of the same order as that found in mammals, should excrete only 20 % of its waste nitrogen in the form of urea [Delaunay, 1927; 1931], while the mammalia excrete about 80 % in that form.

Meanwhile Needham [1935] was examining the distribution of uric acid in the nephridia of a large number of molluscs, and on comparing our respective results it was found that there appeared to be a correlation between the arginase and uric acid contents of those forms which had been examined in common. Table V shows the average values found for Q_H and for uric acid content, the latter expressed as mg. HU per g. dry weight of nephridium, for those gastropods for which both sets of data are available. A test case of the greatest interest was found in the large black slug, *Arion ater.* As *Arion* appears at first sight to possess all the attributes of a truly terrestrial gastropod, it might have been expected to ally itself with other terrestrial forms such as *Helix* by having a high concentration of nephridial uric acid. This, however, was found not to be

Table V. *Relationship between hepatic arginase and nephridial uric acid in gastropods.*

Species	Habitat	Q_H^{28}	HU content

Limnaea stagnalis		635	114
Viviparus fasciatus		719	35
Helix aspersa	Terrestrial	1235	128
Helix pomatia		6500	744
Arion ater		11	36

Data for Q_H^{28} are the average values from Table IV.
Data for uric acid are mean values calculated from the data of Needham [1935].

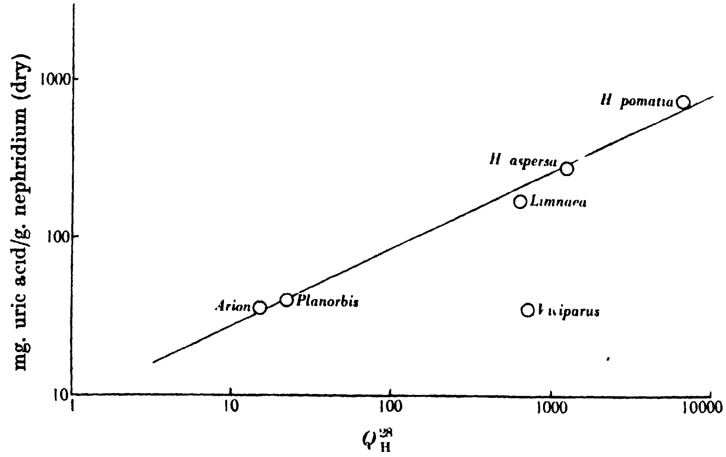

Fig. 3. Relation beween arginase and uric acid in gastropods. (See text.)

the case; the amount of uric acid which could be detected was only a fraction of that to be found in the nephridia of the terrestrial snails as a group, and correlated with this low uric acid content was an arginase index of only 11. This is of the same order as those found for *Carcinus* and *Asterias*, neither of which would be regarded on any grounds as being primarily uricotelic. The relationship between the two sets of data is more clearly shown in Fig. 3, where they have been plotted on a double logarithmic scale. The points for the various forms lie well on the curve, with the exception of that for *Viviparus*, which differs from the others represented in being operculate and not pulmonate and perhaps might therefore be expected to behave in a rather different manner.

We have already seen how Krebs and Henseleit [1932] were able to demonstrate the functional importance of arginase in the elaboration of urea by the mammalian organism, and the discovery of this new and altogether unexpected correlation between arginase content and uric acid formation suggests that the enzyme is also of importance in the elaboration of uric acid by the Gastropoda. This group, together with the Insecta, appears to have specialised more than any other invertebrate group in the production of uric acid as a nitrogenous end-product. To extend this notion to cover the birds, which are the chief producers of uric acid among the vertebrates, would plainly be difficult or impossible on account of the very small amount of arginase which is present in the avian organism [Edlbacher and Röthler, 1925, 2], but this does not detract from the possible value of the new hypothesis, since it has already been shown [Baldwin and Needham, 1934] that the bird and the snail probably make use of quite different chemical mechanisms in the formation of uric acid. Further work is therefore in progress with a view to testing the hypothesis.

A few interesting points remain to be discussed. In the first place, what is the source of the urea which plays such a large part in the nitrogenous excretion of the slug *Arion*? In our examination of the case of *Helix* we were unable to demonstrate any synthetic production of urea and came to the conclusion that the urea excreted by that animal arose almost entirely from ingested arginine under the influence of the arginase of the hepatopancreas and nephridium [Baldwin and Needham, 1934]. It was quite clear that the arginase cycle did not operate in *Helix* in spite of the high arginase index of its hepatopancreas. This must probably be true also in the case of *Arion* whose arginase index is relatively small, but in spite of this *Arion* is believed to excrete a greater proportion of urea than any other invertebrate so far examined [Delaunay, 1927; 1931]. It would be desirable to confirm Delaunay's analyses of the excreta of *Arion*, since, if they are reliable, they must point to the existence of some synthetic mechanism for the production of urea which is markedly different from that found in the vertebrates.

Summary.

1. A new and sensitive method for the detection and estimation of arginase is described, together with a suitable mode of expression of the results.

2. A series of results has been obtained with the aid of this new method, and there is reasonable agreement between the values obtained by the new method and by its predecessor.

3. The examination of a variety of invertebrates has shown that arginase is much more widely distributed than has hitherto been supposed.

4. The arginase content of a given tissue is dependent upon its physiological condition, the enzyme tending to disappear in starvation.

5. On the grounds of a correlation between the arginase and the uric acid content of the hepatopancreases and nephridia respectively in a number of gastropods, it is suggested that arginase is concerned in the production of uric acid by members of this class. Thus in the elaboration both of urea and of uric acid, which represent the principal nitrogenous end-products of the non-sauropsid vertebrates and the gastropods respectively, the same enzyme, arginase, may be involved.

The author is indebted to the Royal Commission for the Exhibition of 1851 for a Senior Studentship during the tenure of which this work was done. He also wishes to thank Dr E. J. Allen for his kind co-operation in providing the marine specimens.

XXX. BIOCHEMICAL STUDIES IN THE NITROGEN METABOLISM OF THE APPLE FRUIT.

I. THE ESTIMATION OF AMINO-NITROGEN BY THE VAN SLYKE METHOD IN PRESENCE OF TANNIN.

By ALFRED CRESSWELL HULME.

Low Temperature Research Station, Cambridge, and
Ditton Laboratory, East Malling, Kent.

(*Received December 1st, 1934.*)

Early in a study of changes in the nitrogen fractions of the peel and pulp of the apple fruit during development on the tree serious errors became apparent in the determination of the amino-nitrogen fraction of the total soluble nitrogen by the Van Slyke gasometric method. In certain cases—notably in the peel at all stages of maturity and in the pulp of young fruits—the amino-nitrogen figure obtained was considerably higher than that of the total soluble nitrogen. This fact indicated either that the total soluble nitrogen figures (determined by a modification of the micro-Kjeldahl method to be described in a later communication) were too low or that the "Van Slyke amino-nitrogen" figures were too high. On carrying the investigations further it became apparent that the latter possibility was the more probable. It appeared most likely that some substance present in the extracts, other than amino-acids, was yielding gas in the amino-nitrogen determinations. Various possibilities as to the nature of this substance were examined without success until a paper by Wasteneys and Borsook [1924] was noted in which it was shown that tannic acid, used by these investigators for the precipitation of peptones, yielded large volumes of gas in the Van Slyke apparatus.

Thus it appeared likely that tannin, present in the apple extracts, might be leading to the anomalous amino-nitrogen results [Hulme, 1932].

Support is lent to this view by the results of Overholser and Cruess [1923] who showed that there is considerably more tannin present in the peel than in the pulp of the apple fruit. Thatcher [1915] gives figures varying between 0·132 and 0·208 % of the fresh weight for the tannin content of several varieties of American apples. Wehmer [1929] gives the tannin content of apples as varying between 0·1 and 0·3 % of the fresh weight.

Using the method of Spiers [1914] the present writer found the tannin content of the Bramley's Seedling apples used in this investigation to be of the order of, peel 0·37–0·45 %, pulp 0·06–0·18 % (for criticism of the Spiers method see later). This meant that in the dilutions used (see later) in the Van Slyke amino-nitrogen estimations as much as 50 mg. of tannin might be present. It was therefore decided to investigate the possibility of removing the tannin from extracts prior to the amino-nitrogen determinations and the present paper is concerned with the attainment of this object.

A brief description only will be given of the method of preparing the apple extracts and of other details not directly concerned with the present problem since it is proposed to present such details in full in a later paper in the present series.

EXPERIMENTAL.

1. *General Methods.*

(*a*) *Preparation of the apple extracts.* The method of preparation consisted essentially of extracting the frozen (−20°) and finely ground tissue with 60–80 % alcohol at 40° in a special vacuum-extractor until all the nitrogen soluble under such conditions had been removed. The alcohol was then evaporated off from the extract at 50° under diminished pressure. The pulp extracts had a final volume of 100 ml., contained 100–150 mg. of nitrogen and represented 400 g. of fresh tissue; peel extracts had a final volume of 60 ml., contained 40–100 mg. of nitrogen and represented 100–250 g. of fresh tissue depending on the size and state of maturity of the fruit. The separation of the fruits into peel and pulp tissue was achieved by means of a household potato peeler when the material was in the hard frozen state.

(*b*) *The Van Slyke amino-nitrogen determinations.* The reaction chamber of the apparatus used was intermediate in size between the macro- and micro-forms originally suggested by Van Slyke, the burette used for the introduction of the solution under examination having a maximum capacity of 5 ml. This reaction chamber was used in conjunction with the micro-gas burette (3 ml.). The shaking time for completion of the reaction was 15 min., this time being found necessary for concordant results with apple extracts.

(*c*) *Spiers's method for the estimation of tannin.* It is necessary to outline the essential points of this method as the method of removal of tannin used was adapted to the present problem in preliminary experiments.

Briefly the method consists of titrating a known volume of the tannin-containing solutions (Spiers was chiefly interested in cider), diluted with 750 ml. of distilled water, with potassium permanganate in presence of indigo carmine (as indicator), before and after treatment with fat-free caseinogen. The caseinogen, treatment, which is supposed to remove all the tannin present, consists of shaking 50 ml. of the extract with two successive portions of 1 g. of fat-free caseinogen with intermediate and final filtration through a fine filter medium. The method was standardised by Spiers against Schering's "tannin leviss. puriss." and other commercial tannin preparations.

In the present work Merck's "Caseinum-Natrium for bacteriological purposes" was used after extraction with ether for several hours. Similar results were obtained with a sterile solution of caseinogen prepared from milk by the method of Van Slyke and Baker [1918] kindly supplied by Dr R. B. Haines of the Low Temperature Research Station, who was using such a preparation for bacteriological work. The tannic acid used was Schering-Kahlbaum "acidum tannicum pro analysi" and B.D.H. pure; both these samples gave identical volumes of gas per unit amount in the Van Slyke determinations and their 1 % solutions had approximately the same hydrogen ion concentrations (p_H *ca.* 3·5).

2. *Investigation of the amount of gas given by pure tannic acid solutions in the Van Slyke estimation.*

By "Van Slyke estimation" is meant here and elsewhere throughout the present paper a determination carried out according to the Van Slyke technique for the estimation of amino-nitrogen whether or not the solution under examination contains amino-groups.

Solutions containing various amounts of tannic acid between 5 and 100 mg.

per 5 ml. were prepared and 5 ml. of these solutions were taken for a Van Slyke estimation. Within these limits a linear relation was found to exist between the amount of gas evolved (at 750 mm. and 15°; corrected for blank value) and the amount of tannic acid present, as will be seen from Fig. 1.

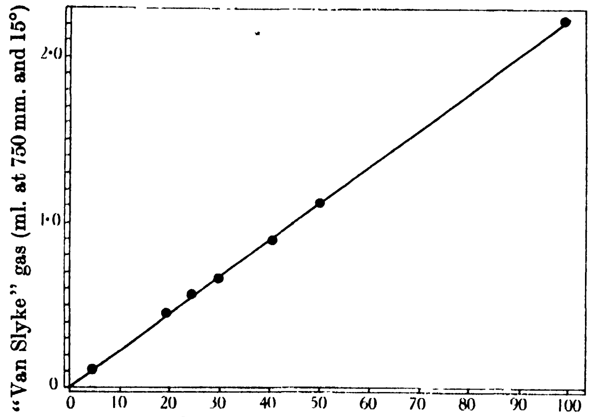

Fig. 1. Tannic acid (mg.)

Thus it is clear that the amounts of tannin likely to be present in apple extracts are sufficient to interfere to an appreciable extent with the amino-nitrogen determinations.

3. *Removal of tannin prior to the Van Slyke estimations.*

(*a*) *Preliminary investigations.* Spiers's method for the estimation of tannin suggests that the treatment of extracts with fat-free caseinogen should bring about a quantitative removal of tannin. If such a method were adopted it would, of course, be essential to remove completely any excess caseinogen before proceeding to an amino-nitrogen determination.

To examine the effect of the addition of caseinogen to pure solutions of tannic acid, two successive portions of 0·5 g. of fat-free caseinogen were added to 50 ml. lots of tannin solutions of various concentrations adjusted to various hydrogen ion concentrations by phosphate or acetate buffers. Filtration through a Whatman No. 44 filter was carried out after each addition of caseinogen and 5 ml. of the filtrates were taken for a Van Slyke determination. The results obtained may be summarised as follows:

(i) The first treatment with caseinogen at p_H 1 to 2 removed (as judged by the reduction in the volume of gas given in the Van Slyke apparatus) about 35 % of the tannin; the second treatment at the same p_H removed all but 19–20 % of the tannin. At this hydrogen ion concentration the caseinogen formed a clot as soon as it entered the tannic acid solution.

(ii) The best results were obtained by two caseinogen treatments at p_H 7 to 8 (which allowed some of the caseinogen to go into solution) followed by the addition of acid to bring the p_H value of the filtrate from the second treatment to 4·6 (to precipitate excess caseinogen), and a further filtration. By this means 96 % of the tannic acid was removed.

When, however, this latter method was applied to apple extracts alone and to extracts to which tannic acid had been added, not more than 40 % of the tannin was removed. Further modifications of the "caseinogen method," including three caseinogen treatments, gave no better results. While this work was in progress a paper by Rahn [1932] appeared in which further emphasis was laid on the serious interference of tannin with the Van Slyke method. Rahn says of tannin "Es reduzierte im Vakuum des Apparates einen Teil des bei der Reaktion entstehenden N_2O_3 zu elementaren N und verhöhte so die vom α-Amino-N stammende N Menge auf das 3–7 fache"—although no evidence was adduced in support of such a theory. Nevertheless Rahn showed that tannin could be removed from plant extracts by precipitation with potassium dichromate. In Rahn's case the tannin had been added for precipitation purposes during the nitrogen fractionation of his extracts; the potassium dichromate solution was allowed to remain in contact with the extracts for a day to bring about the precipitation of the tannin.

Preliminary results for the precipitation of small amounts of tannin from pure tannin solutions by means of dichromate were very promising, so that a more detailed examination of the method was initiated in relation to the present problem. In particular it appeared necessary to ascertain whether the prolonged contact of the dichromate with amino-acids and amides of the asparagine type caused any destruction of these compounds.

(*b*) *The precipitation of tannic acid by dichromate in solutions containing glycine and asparagine.* To 30 ml. of a 1 % solution of tannic acid 3, 4 and 6 ml. quantities of 5 % potassium dichromate were added. The liquids were brought to 50 ml., well shaken and allowed to stand for 18 hours. At the end of this time they were filtered and 5 ml. of the filtrate taken for a Van Slyke estimation. The results obtained are presented in Table I.

Table I.

ml. dichromate	Volume of "Van Slyke" gas (ml. at 750 mm. and 15°)
3	0·23
4	0·17
6	0·18

The solution containing only 3 ml. of dichromate filtered extremely slowly and the filtrate was opalescent. From Fig. 1 it is seen that the volume of gas which would have been given if no tannic acid had been removed is 0·66 ml. (equivalent to 30 mg. tannic acid). Since the water blank value was 0·16 it is clear that 4 and 6 ml. of dichromate solution were sufficient to remove all the tannic acid present.

To examine the effect of dichromate on glycine and asparagine and to ascertain whether the dichromate effected a quantitative removal of tannin in the presence of these compounds and also if such a removal were affected by the p_H of the solution, a series of experiments was carried out along the following lines.

To 5 ml. of a solution containing 0·5 g. of pure glycine and 0·5 g. of pure asparagine per 100 ml. of solution was added phosphate or acetate buffer to give the required p_H. Five ml. of a 5 % solution of tannic acid were added together with 2–4 ml. of 5 % potassium dichromate solution and distilled water to make the volume to 45 ml. The mixture was well shaken and allowed to stand for 18 to 20 hours at 1° (to minimise any effect of the dichromate on the glycine and asparagine). At the end of this time the liquid was filtered through a fine filter and 5 ml. of the filtrate were taken for a Van Slyke estimation.

Similar mixtures were prepared with distilled water in place of the tannic acid and also in the absence of dichromate. The results obtained are given in Table II. The amounts of glycine, asparagine and tannic acid present and the ml. gas obtained in the Van Slyke determination all refer to the 5 ml. of filtrate used in the

Van Slyke estimation. The dichromate volume refers to that initially present in the whole solution. The gas volumes are all corrected to 750 mm. and 15°.

Table II.

	Glycine mg.	Asparagine mg.	Tannic acid mg.	Dichromate ml.	ml. gas (theoretical)	ml. gas (observed)	p_{H}

(8)	2·767	2·767	28	4	tannic acid to be	1·48	3·4
(9)	2·767	2·767	28	4	precipitated	1·44	5·0
(10)	2·767	2·767	28	4	„	1·18	5·5
(11)	2·767	2·767	6	2	„	1·16	5·7
(12)	2·767	2·767	28	4	„	1·19	6·4
(13)	2·767	2·767	28	4	„	1·10	6·8
(14)	2·767	2·767	28	4	„	1·20	7·5

Results (1) and (2) give the "blank" value (av. 0·18 ml.) which is applied to all the subsequent results. The "theoretical" values are calculated from the amino-nitrogen content of the glycine and asparagine present, assuming glycine to give 103 % of its calculated nitrogen content in the Van Slyke apparatus [Mitchell and Hamilton, 1929]; the "theoretical" value for tannic acid is obtained from Fig. 1.

p_{H} values were measured by means of a Morton glass electrode. Filtration was extremely slow in the case of mixtures (12), (13) and (14) and the filtrates were turbid.

From Table II it appears that all the tannin is removed from solution by the dichromate treatment without destruction or adsorption of glycine or asparagine between p_{H} 3·2 and 5·0. Above this p_{H} range the low values for amino-nitrogen were probably due to some adsorption of the glycine and/or asparagine on the tannin-dichromate precipitate. Between p_{H} 3·2 and 5·0 the precipitates of tannin-dichromate complex were reddish brown and granular, changing to dark brown and gelatinous with increase of the p_{H}.

(*c*) *The tannin-dichromate precipitation in presence of apple fruit extracts.* The effect of dichromate solution on the amino-nitrogen figure of apple extracts (pulp and peel) alone and in the presence of added tannic acid, and on the amino-figure for apple extracts *plus* added glycine-asparagine solutions with and without added tannic acid was next investigated.

A brief description of the method of preparation of the apple extracts has already been given. 10 ml. of each extract were nearly neutralised with NaOH and 5 ml. of a 10 % suspension of magnesia added. The free ammonia was then distilled off under diminished pressure at 40° in a modification of the apparatus employed by Chibnall and Westall [1932]. The excess magnesia in the residue was dissolved in a minimum of warm glacial acetic acid and the liquid transferred to a 50 ml. standard flask. The requisite amount of 5 % dichromate solution was then added, followed by distilled water to the 50 ml. mark. Where glycine-asparagine solution (0·5 g. glycine and 0·5 g. asparagine per 100 ml.) and tannic acid solution (5 %) were added, this was done and the requisite buffer added before the addition of the dichromate. After bringing to the 50 ml. mark the flask was shaken vigorously for a few minutes and then placed at 1° for the times stated. The tannin precipitation is a "time reaction." The solution first gradually darkens and then the precipitate slowly forms, the whole process taking 10–30 seconds. The precipitate, under the most favourable conditions of hydrogen ion concentration, does not settle for several hours. Shaking greatly accelerates the process.

5 ml. of the filtrate from the tannin precipitation were taken for the Van Slyke estimations. The results obtained are given in Table III. As before, the figures for glycine, asparagine and ml. gas (corrected) refer to the 5 ml. of solution actually taken for the Van Slyke determination, and the volume of dichromate solution refers to that present in the 50 ml. of liquid before filtration.

Table III.

Material	p_H	ml. gas* (expected)	ml. gas (observed)
Stood for 18 hours before filtration:

,, +2 ml. dichromate	3·9	—	1·30
,, +4 ml. dichromate	3·8	—	1·29

* Assuming all the tannic acid to be removed by "dichromate-precipitation."

From the table it is clear that the dichromate treatment removes added tannic acid from apple extracts without destruction or removal of added glycine and asparagine. Presumably also the dichromate removes tannin from the apple extracts themselves. The fact that a much larger proportional decrease in the amount of gas given in the Van Slyke estimation follows the dichromate treatment in the case of peel than of pulp extracts provides corroborative evidence for such a suggestion, since, as has already been shown, the peel of apples contains much more tannin than does the pulp. The hydrion concentration of the medium does not appear to affect the precipitation of tannin at least between p_H 3·6 and 4·4. The precipitates in the case of apple extracts were very similar in colour and texture to those obtained with pure tannic acid-glycine–asparagine solutions. Even when 25 mg. of tannic acid were present in addition to that of the extracts it is seen that 4 ml. of 5 % potassium dichromate per 50 ml. of solution were sufficient to remove all tannin. It appears to be important not to use a large excess of dichromate, for 5 ml. of undiluted 5 % dichromate solution gave a "Van Slyke blank" value which was about double the water blank. In the above results the blank value obtained from results (1) and (2) in Table II was applied. This is the only satisfactory blank obtainable since the amount of free dichromate after tannin precipitation in each individual case is unknown. This blank value is only 0·02 ml. greater than the water blank and, as the maximum variation in repeated estimations is 0·04 ml., this difference is negligible.

Here may be given a typical result illustrating the relative effects on the Van Slyke figure for an apple extract of the caseinogen and the dichromate treatments. In Table IV are given the observed amounts of "amino-N" in 100 ml. of an extract of a sample of young apples (after removal of free ammonia).

Table IV.

	Direct	After caseinogen treatment	After dichromate treatment
mg. "amino-N"	39·0	35·0	26·2

This and similar results readily explain the high Van Slyke amino-nitrogen figures mentioned in the introduction.

Finally it was necessary to ascertain whether there was any adsorption of nitrogen (amino-groups) on the dichromate precipitates in the case of apple extracts. With this object in view the residues from the estimation of free ammonia in 10 ml. of extract, after neutralisation of the excess magnesia with acetic acid, were washed into a 50 ml. flask, dichromate solution was added and the liquid brought to 50 ml. After standing for 18-20 hours at 1° the precipitate formed was filtered off. 5 ml. aliquot parts of the filtrate were taken for a Van Slyke estimation. Other 5 ml. portions were evaporated nearly to dryness on a water-bath with 2 ml. of concentrated sulphuric acid. The nitrogen contents of these residues were then determined by a modification of the micro-Kjeldahl method using hydrogen peroxide as catalyst. These were compared with the total nitrogen content of an equivalent amount of original extract, after deducting the free ammonia-nitrogen. The results are given in Table V.

Table V.

		Total N	ml. gas in Van Slyke
Pulp (V).	Extract alone	1·53	2·10
	,, +4 ml. dichromate	1·49	1·40
Pulp (IVc).	Extract alone	2·17	3·20
	,, +2 ml. dichromate	2·06	1·96
	,, +3 ml. dichromate	2·13	1·93

These results show that while the amino-nitrogen figure may be reduced by the dichromate treatment by as much as 40 % the reduction is due to the removal of a non-nitrogenous substance since, under the same conditions, the total nitrogen is reduced by only about 2 %.

The final method adopted for the estimation of amino-nitrogen in apple pulp and peel extracts is as follows.

The excess magnesia present in the residue from a free ammonia estimation on 10 ml. of extract is dissolved in a minimum of glacial acetic acid and the mixture transferred to a 50 ml. standard flask. 3 ml. of 5% potassium dichromate solution are then added, and the liquid is brought to the 50 ml. mark with distilled water. After shaking well the flask is allowed to stand overnight at 1°. The dichromate-tannin precipitate is then filtered off, using a small Whatman No. 44 paper, and 5 ml. of the filtrate are taken for the usual Van Slyke determination. No p_H adjustment is necessary prior to the addition of dichromate as it was found that the p_H of the "neutralised" and diluted ammonia residues was always in the region of p_H 3·8 to 4·4.

No doubt the method is applicable to other tannin-containing plant extracts.

The fact that such small amounts of tannin give appreciable amounts of gas in the Van Slyke estimation casts serious doubts on many of the results hitherto reported for the amino-acid content of plant material. Also the data presented make it necessary to question the accuracy of Spiers's method for the estimation of tannin (depending as it does on the quantitative removal of tannin by precipitation with caseinogen), especially when applied to complex solutions such as cider and plant extracts generally.

Strange as it may appear on first consideration, it may be possible to make use of the Van Slyke amino-nitrogen technique in the estimation of the tannin content of plant material. For, since the amount of gas given by tannin in the Van Slyke estimation is a linear function of the amount of tannin present, and since dichromate appears to precipitate tannin quantitatively without affecting the true amino-nitrogen figure, the reduction in the "Van Slyke gas" volume brought about by the treatment with dichromate should be a quantitative measure of the amount of tannin present. However a method based on these facts would depend entirely on a calibration with oak gall tannin (the "purest" standard at present available commercially), and it may be argued, since the chemistry of the tannins is still somewhat obscure, that tannin from other sources may not give the same volume of gas per unit amount in the Van Slyke apparatus. Oak gall tannin is a mixture of pyrogallol tannins, whereas, for example, apple tannin appears to belong to the group of catechol tannins [Overholser and Cruess, 1923]. Nevertheless a similar objection applies to the method of Spiers and to other methods except that relative (generally to oak gall tannin) permanganate titration, relative weight of strychnine precipitate *etc.*, are used instead of the proposed Van Slyke gas volume. It is proposed to investigate such a method as outlined above for the determination of tannin in apples. Carried out in conjunction with amino-acid determination it should prove convenient, rapid and valuable, at least as a means of determining the relative tannin contents of a series of plant extracts.

One final suggestion which arises from the present results. It may be that potassium dichromate could be used with advantage to replace lead salts and other precipitants for plant extracts in certain cases.

SUMMARY.

1. Results are given which suggest that the abnormally high figures obtained for the amino-nitrogen content of apple fruits by the Van Slyke method are due to the presence of tannin.

2. It is shown that a linear relation exists between the amount of gas given in the Van Slyke estimation in the case of solutions of pure commercial preparations of tannic acid (from oak galls). As little as 10 mg. of tannic acid gives 0·20 ml. of gas in the "Van Slyke."

3. Attempts to remove tannin from pure tannin solutions and from apple extracts by precipitation with caseinogen are described. While suitable conditions can be found for thus achieving the removal of 96 % of the tannin from the

former, not more than 40 % can be removed from apple extracts by this means.

4. Experiments are described which show that complete removal of small amounts of tannic acid added to apple extracts can be achieved by precipitation with potassium dichromate. Presumably, also, tannic acid present in the extracts themselves is removed by this method which is shown not to interfere with amino- or acid amide groups.

5. A method, based on this result, is described whereby the interference of small amounts of tannin with the Van Slyke amino-nitrogen determination is entirely overcome.

6. Tentative suggestions are advanced for a new method for determining the tannin content of plant extracts.

XXXI. IODINE IN CABBAGE.

By JESSE FRANCIS McCLENDON and
CURTIS ETHAN HOLDRIDGE.

From the Laboratory of Physiological Chemistry, University of Minnesota Medical School.

(Received December 7th, 1934.)

In iodine analyses of foodstuffs the most difficult part of the technique is the destruction of organic matter without the loss of iodine, and therefore only that part of the method will be mentioned, the remainder being given by McClendon [1934, pp. 304–309].

The cabbages were sliced and dried in a current of air at slightly above room temperature, then ground in a mill, and dried in an oven at 100°. Weighed samples were packed in Visking sausage casing and burned in a modified combustion tube (see Fig. 1). The results of the analyses are shown in Table I. In order to compare them with previous data we have computed the average values of samples from two sections of the State. It will be seen that those from one section are higher in iodine than those from the other.

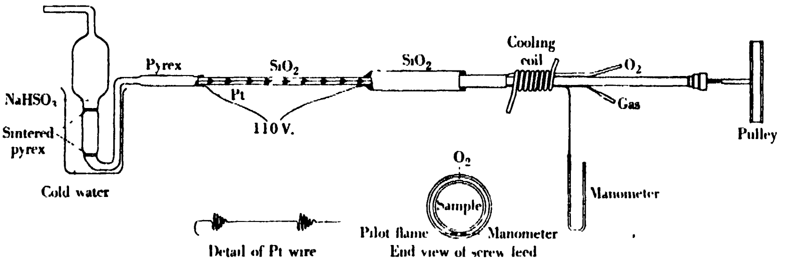

Fig. 1. Apparatus for burning dried tissue for iodine analysis. A detail of the opening of the screw-feed is shown below. The central circle is the space containing the dried tissue packed in a Visking sausage casing and round it is an annular opening from which oxygen issues to burn the tissue (one small circle below is an opening for a gas pilot flame and the other is for the manometer, used to ensure a zero or slightly negative pressure in the combustion tube). The screw is advanced by means of a belt connecting the pulley with the worm reducing gear of an electric motor.

Minnesota may be divided into two portions in relation to goitre and iodine. The most goitrous region and the one containing the least amount of iodine is the Arrowhead region (north-east), which is the region with the least soil on the top of the granite (the soil having been rubbed off by glaciers) and also the region of the greatest rainfall. The region of the most iodine and least goitre is the western part of the State. During the Permian period this region was near the shores of a gulf connected with the Pacific Ocean through Kansas, New Mexico and Arizona, but was cut off later by the rise of the Rocky Mountains. In the intermediate region one of these merges into the other and the division between them is rather indefinite so that for our purposes the line drawn between them has been made rather arbitrarily. In the table the iodine analyses of cabbage

are compared with those by McClendon *et al.* [1934] on potato, together with the goitre per thousand drafted men during the Great War. No data are available for Clearwater, Grant, Swift, Big Stone, Renville, Lyon, Nobles, Jackson, Faribault or Olmsted counties in the south-west section or for Isanti or Scott in the east-north-east section. In the east-north-east there were cabbages from 14 counties, potatoes from 9, and Draft Board data on goitre from 37. In the east-north-east section the average value of iodine in cabbage was 111 γ/kg. dry material, in potato 101, and goitre 17·2 per thousand men. In the west-south, iodine in γ/kg. cabbage (dry) averaged 174, in potato 227, and goitre per thousand drafted men 8·5 (the War Department defined goitre as a neck too large to button a military collar round).

These data indicate that goitre is associated with iodine deficiency in the foodstuffs eaten as well as in the water drunk, as shown by previous analyses. McClendon and Hathaway found 0·01 γ/kg. in the only drinking water not contaminated with sewage in the east-north-east section that was examined, whereas in the west-south section the 4 samples analysed contained 0·05, 0·05, 0·08[1] and 0·14 γ/kg. The work on water was undertaken on the assumption that the iodine content of drinking water was related in some way to the iodine content of water soaked up by plants and evaporated from the leaves and hence to the iodine content of the plants. This water is evaporated from the leaves of plants and hence iodine is concentrated in the leaves. The potato was first chosen because it was easy to obtain, but later cabbage was chosen because it consists of leaves. From the samples available the outer leaves, open to free evaporation, had been removed, and hence the iodine content was lower than it would be in such expanded leaves in which the iodide sucked up by the roots with the soil water is concentrated by evaporation. Owing to the fact that cabbage was the only leafy vegetable obtainable from these counties we have had to content ourselves with analyses of food of relatively low iodine content.

---

[1] River with sewage from 5000 population, whereas water omitted from east-north-east study contained sewage from about 100,000 population.

XXXII. OBSERVATIONS ON THE CHEMICAL METHOD FOR THE ESTIMATION OF VITAMIN C.

By BASHIR AHMAD.

From the Department of Biochemistry and Nutrition, All-India Institute of Hygiene and Public Health, Calcutta.

(*Received December 10th, 1934.*)

Since Svirbely and Szent-Györgyi [1932] showed experimentally that vitamin C was identical with hexuronic or ascorbic acid, the reducing property of the latter has been utilised for the estimation of vitamin C by a chemical method. Tillmans and his colleagues using the indicator 2 : 6-dichlorophenolindophenol estimated the reducing value of certain foods and correlated it with their vitamin C content. Following the same technique, Birch *et al.* [1933] have developed a simple method for the vitamin C assay of natural foodstuffs. The method consists in preparing a trichloroacetic acid extract of the material and rapidly titrating it with 2 : 6-dichlorophenolindophenol. These authors have put forward substantial evidence to show that under the conditions of the test naturally occurring substances other than ascorbic acid, which are likely to reduce the indicator, do not interfere with the estimation, and the values so obtained for a large number of fruits and vegetables agree with their antiscorbutic values as estimated by the biological method.

This simple method has obvious advantages over the long and tedious biological technique. More recent work, however, appears to indicate the existence of unknown reducing substances which may interfere with the test [Svirbely, 1933; Harris, 1933]. At the same time ascorbic acid is known to undergo a reversible oxidative change which does not detract from its value as an antiscorbutic, but in that state ascorbic acid will not react with the indicator dichlorophenolindophenol. Recently Guha and Ghosh [1934] have pointed out that trichloroacetic acid by itself would reduce the indicator even in a considerably dilute solution. Further, trichloroacetic acid can by no means be expected to extract quantitatively the ascorbic acid present in the material, and the proportion extracted may vary from material to material depending on the state in which it is held within the tissues.

These observations appear to show that the chemical method may be liable to errors of a rather disturbing magnitude. Opportunity was afforded to study this method during examination of the nutritional values of Indian foodstuffs which is being undertaken in this laboratory. The results of these studies are reported in this paper.

Experimental.

(1) *The reaction of trichloroacetic and ascorbic acids with the indicator*[1].

We have confirmed the observation of Guha and Ghosh [1934] that trichloroacetic acid reduces the indicator (Table I). The reaction takes place slowly, more

---

[1] The indicator solution referred to in this paper was of the strength

1 ml. indicator = 1 mg. ascorbic acid.

It was standardised against pure ascorbic acid solution which was in turn standardised with 0·01 N iodine solution.

Table I. *Reaction of trichloroacetic acid with 2 : 6-dichlorophenolindophenol.*

Concentration of trichloroacetic acid %	Volume of trichloroacetic acid added to 0·1 ml. of indicator ml.	Time of complete reduction mins.
50·0	0·5	0·75– 1·0
20·0	0·5	0·75– 1·0
10·0	0·5	1·0 – 1·25
5·0	0·5	2·0 – 2·25
1·0	0·5	13·0
1·0	1·0	8·0
1·0	5·0	6·0
0·5	0·5	20·0
0·5	1·0	15·0
0·5	5·0	10·0
0·1	1·0	40·0
0·1	5·0	30·0
0·1	10·0	25·0

so in lower concentrations when the time taken to reduce 0·1 ml. of the indicator is considerably prolonged. On the other hand the reaction of ascorbic acid solution with the indicator is quicker, being in fact almost instantaneous (Table II).

Table II. *Reaction of ascorbic acid with 2 : 6-dichlorophenolindophenol.*

Concentration of ascorbic acid mg./100 ml.	Volume of indicator solution used ml.	Volume of ascorbic acid solution required to reduce the indicator ml.	Time for completion of reaction mins.
100·0	1·00	1·05	Instantaneous
50·0	1·00	2·10	„
10·0	0·50	5·25	„
5·0	0·50	10·50	0·75–1·0
1·0	0·10	10·50	2·0 –2·5
0·5	0·10	21·00	3·0
0·1	0·02	21·00	5·0

When, however, a mixture of trichloroacetic and ascorbic acids is titrated against the indicator, the reaction depends upon three factors: (i) the concentration of trichloroacetic acid, (ii) the concentration of ascorbic acid, and (iii) the time taken to complete the titration.

When the concentration of ascorbic acid is not below a certain limit and the concentration of trichloroacetic acid is not very high, and the titration is finished reasonably quickly, the estimation of ascorbic acid is not interfered with by the presence of trichloroacetic acid. If, however, the concentration of ascorbic acid is low, the interaction of trichloroacetic acid with the indicator introduces a significant error in the estimation. These observations will be clear from a study of Table III.

These results show that when the concentration of ascorbic acid in the solution is over 2 mg./100 ml., even 10 % of trichloroacetic acid will not interfere with the titration of ascorbic acid with the indicator. Birch *et al.* [1933] have recommended a concentration of 5 % trichloroacetic acid in the vegetable extracts at the time of titration. Therefore it seems that this concentration is safe even for slightly higher dilutions than 2 mg./100 ml. of ascorbic acid.

Table III. *Reaction of a mixture of trichloroacetic and ascorbic acids with the indicator.*

Concentration of trichloroacetic acid %	Concentration of ascorbic acid mg./100 ml.	Actual volume of mixture required to reduce 0·2 ml. of indicator ml.	Volume predicted from the concentration of ascorbic acid ml.
0·0	10·80	1·90	1·85
10·0	5·40	3·70	3·70
10·0	2·16	9·25	9·25
10·0	1·08	14·00	18·50
5·0	5·40	3·70	3·70
5·0	2·16	9·25	9·25
5·0	1·08	18·30	18·50
2·5	5·40	3·70	3·70
2·5	2·16	9·25	9·25
2·5	1·08	18·50	18·50

When ascorbic acid solutions are allowed to stand in the laboratory under ordinary conditions, even after a short time their titration value with the indicator falls, apparently owing to oxidation. But when the solutions are acidified with a drop of trichloroacetic or even acetic acid at the time of titration the value is found to be higher than when titrated without the addition of the acid (Table IV).

Table IV. *Reaction of the partly oxidised solutions of ascorbic acid with the indicator.*

Time the solution was allowed to stand	Volume of solution required to reduce 0·2 ml. indicator ml.	Volume of solution required to reduce 0·2 ml. indicator after adding 1 drop of glacial acetic acid ml.
0	1·85	1·85
10 mins.	1·90	1·85
30 „	2·10	1·85
3 hrs.	2·20	1·85
24 „	2·40	2·00
72 „	3·60	3·25

It appears from these observations (Table IV) that even 10 minutes after the preparation of ascorbic acid solution the titration value is lowered, showing an appreciable oxidation of ascorbic acid. The oxidation continues and at the end of 3 hours the apparent loss is about 16 %. Up to this time one drop of glacial acetic acid added to the titration flask at the time of titration would bring the reading back to normal. As more time passes the reading does not come back to normal on acidifying though it always gives a higher value for ascorbic acid than when titrated in the unacidified form. It appears that a part of the oxidised ascorbic acid, and presumably the reversibly oxidised form, returns to the reduced state on the addition of the acid.

(2) *The titration of natural fruit juices with the indicator.*

For extracts of natural fruit juices the results of the estimation of ascorbic acid are less likely to be vitiated by the presence of trichloroacetic acid than those for pure solutions. Different dilutions of orange and lemon juices were titrated with the indicator in the presence of 5 % trichloroacetic acid. The readings were theoretically correct when the titrations were finished within 1–2 minutes. On the other hand, when the titration was delayed to 3–5 minutes, high values for ascorbic acid were obtained (Tables V and VI). Lemon juice mixed with known quantities of ascorbic acid solution also gave theoretical values.

Table V. *The titration of orange juice with the indicator.*

Concentration of juice %	Concentration of ascorbic acid in juice mg./100 ml.	Concentration of trichloroacetic acid %	For 0·5 ml. indicator	
			Predicted reading	Actual reading
100	31·25	0	—	1·60
25	7·81	5	6·4	6·4
20	6·25	5	8·0	8·0
25*	7·81	5	6·4	6·2
25†	7·81	5	6·4	6·0

* Titration delayed to 3 minutes.
† Titration delayed to 5 minutes.
In all other cases the titration was finished within 1–2 minutes.

Table VI. *The titration of lemon juice with the indicator.*

Concentration of juice %	Concentration of ascorbic acid in the juice mg./100 ml.	Concentration of trichloroacetic acid %	For 0·5 ml. indicator	
			Predicted reading	Actual reading
100	25·8	0	—	0·425
100	25·8	5	0·425	0·425
10	2·58	5	4·25	4·25
4	1·03	5	10·65	10·65
2	0·515	5	21·5	21·5

(3) *The extraction of ascorbic acid from fruits and vegetables by trichloroacetic acid.*

Birch *et al.* [1933] have recommended the use of trichloroacetic acid for the extraction of vitamin C from natural food materials. Trichloroacetic acid may precipitate protein matter and help to break up the cell-walls, thus facilitating the extraction of ascorbic acid, and may stabilise the vitamin so extracted by inhibiting the action of oxidising enzymes. But it can not be stated what proportion of the vitamin actually present in the tissues comes out in the extract. To investigate this question properly it would be necessary to test the various fractions of extracts and residues by animal feeding experiments. We, however, attempted to obtain maximum yields of ascorbic acid by modifying the method and time of extraction, varying the concentration of trichloroacetic acid used, repeating the extractions, and by the application of heat *etc.* The results of these experiments are summarised in Tables VII and VIII.

It appears from the results summarised in Table VII that 20–25 % is the optimum concentration of trichloroacetic acid to extract the maximum quantity of ascorbic acid. Boiling the vegetable with water or trichloroacetic acid did not increase the amount of vitamin C in the extract. But leaving the shredded vegetable exposed to the warm atmosphere may destroy over 67 % of the vitamin during the course of 2 hours. Storing the vegetable as such also has a very deleterious effect.

The results shown in Table VII refer to a single extraction. By repeating the extractions more reducing substance is obtained as shown in Table VIII.

Table VII.

10 g. of karela[1] were ground up with sand and trichloroacetic acid and filtered. The extract together with washings was made up to 25 ml. The final concentration of trichloroacetic acid in the diluted extracts was maintained at 5 %.

Concentration of trichloroacetic acid used for extraction	Volume required for 0·25 ml. of indicator ml.	Ascorbic acid value as calculated from the reading mg./100 g.
100	3·35	18·65
75	3·25	19·23
50	2·85	21·93
25*	1·80	34·72
20*	1·80	34·72
10†	3·0	20·83
5	3·5	17·86

* Boiling the vegetable for 5–10 minutes with water or trichloroacetic acid and then making the extracts had no effect upon the titration values.

† Cutting up or shredding the vegetable and leaving it for some time before making the extracts profoundly affected the values, *e.g.*

	Reading	Ascorbic acid value mg./100 g.
Fresh	1·20	52·08
After 10 minutes	1·35	46·30
After 20 minutes	1·45	43·10
After 2 hours	3·50	17·85
Keeping whole vegetable for 3 days at room temperature	6·50	10·00

Table VIII.

Vegetable and treatment	Reading for 0·1 ml. indicator ml.	Ascorbic acid value mg./100 g.
10 g. karela extracted in cold with 20 % trichloroacetic acid, extract made up to 25 ml. Concentration of trichloroacetic acid in the extract 5 %.		
1. First extraction of vegetable	0·50	50·0
2. Extraction of the residue	1·90	13·1
3. Further extraction of the residue	20·0	1·25
4. ,, ,, ,,	50·0	0·50
10 g. cabbage treated in the same manner as karela.		
1. First extraction of vegetable	2·5	11·0
2. Extraction of residue	25·0	1·0
3. Further extraction of the residue	40·0	0·62
4. ,, ,, ,,	—	0

This simple experiment shows that a single extraction with trichloroacetic acid does not extract anything like the full amount of vitamin C present in the vegetable tissues. Supposing the four repeated extractions to represent the full amount of vitamin C, then the first extraction represents only 77·1 % in the case of karela and 87·1 % in the case of cabbage.

(4) *The effect of boiling or cooking on cabbage.*

Cabbage behaved differently from most other vegetables in our experience. Usually boiling the vegetable with water or trichloroacetic acid did not profoundly affect the ascorbic acid value of the extract. But boiling the cabbage for 10 minutes raised the ascorbic acid value almost threefold (Table IX). Boiling for a longer time resulted in the destruction of the reducing substance in the extract.

---

[1] Karela (*Momordica charantia*, Curcurbitaceae) is a common Indian vegetable, selected on account of its richness in vitamin C.

Table IX.

10 g. cabbage extracted with 6·25 ml. of 20 % trichloroacetic acid either in the cold or with boiling. Extracts made up to 25 ml.

Treatment	Ascorbic acid value mg./100 g.
Cold extraction	13·3
Boiling 10 minutes	40·5
,, 15 ,,	29·15
,, 30 ,,	22·30
,, 1 hour	14·8
,, 1½ ,,	5·0
,, 2 ,,	1·56

It may appear from these observations that either the cell walls of cabbage are not broken up by grinding with cold trichloroacetic acid or the vitamin is more firmly bound within the tissues.

CONCLUSIONS.

The experiments described in the text of this paper show that this method can be of practical value for the estimation of ascorbic acid in its solutions and in natural materials. Under definite conditions it is capable of giving accurate and quantitative results. Trichloroacetic acid which slowly reduces the indicator by itself does not interfere in the estimation if the titrations are carried out quickly and finished within 1–2 minutes. On the other hand, in the presence of trichloroacetic acid and by titrating the solutions against the indicator instead of the reverse procedure of Tillmans, a better and sharper end-point is obtained. Solutions of pure ascorbic acid, natural fruit juices and mixtures of both in varying dilutions show theoretically correct results under the following conditions:

(i) The concentration of ascorbic acid in solutions or extracts in which estimation is desired must be higher than 2 mg./100 ml.

(ii) The concentration of trichloroacetic acid must not be higher than 5 %.

(iii) 1·0–0·1 ml. of 0·01 *M* solutions of the indicator are to be placed in the titration flask according to the potency of the extract, and the solution is to be run in from the burette steadily with constant shaking of the flask.

(iv) The titration is to be finished within 1–2 minutes.

Difficulty arises when the solutions to be titrated are weak in ascorbic acid content, containing less than 2 or even 1 mg./100 ml. Vegetables and fruits poor in vitamin C often yield extracts of this quality. In these cases the reaction is slow, the end-point indefinite, and consequently the values are only roughly approximate.

The next question which needs consideration is whether reversibly oxidised ascorbic acid, which is probably as good an antiscorbutic as the reduced form, can be estimated by the chemical method. Ordinarily the indicator will not react with this form of ascorbic acid and, when the latter constitutes an appreciable proportion of the whole, the results may be quite misleading. Some authors have utilised the action of H_2S over a prolonged period to bring the acid back to the reduced form [Eekelen *et al.*, 1933]. But it appears undesirable to treat a complex natural material with H_2S for such a long period as 6 hours, on account of the unknown changes that the treatment may induce. Further, it is not known whether this reversibly oxidised ascorbic acid exists in appreciable amounts in natural vegetable tissues.

The experiments summarised in Table IV show that a certain proportion of ascorbic acid which ordinarily does not react with the indicator does so in the presence of trichloroacetic or glacial acetic acid.

With respect to the extraction of vitamin C from fruits and vegetables, 20–25 % trichloroacetic acid appears to give the best results. Higher concentrations probably destroy the vitamin and lower concentrations do not extract it completely. Boiling the vegetable tissues with water or trichloroacetic acid solutions does not materially raise the quantity of ascorbic acid in the extracts excepting in that of cabbage. On repeated extraction of the residue, however, more of the vitamin is extracted. In the two vegetables investigated the first extract represented only 77–87 % of the total ascorbic acid. This throws considerable doubt on the value of this method of extraction, as only a proportion of the total vitamin is extracted, and this proportion may vary from material to material. It is clear that this method does not give quantitatively the vitamin present in the vegetable material. At the same time we cannot be sure that in the biological estimation of vitamin C the whole of ascorbic acid present in the food is absorbed and taken account of by the organism. Probably the efficiencies of the two processes run more or less parallel, and hence the striking agreement between the values obtained by the two methods.

Attention may also be drawn here to the ready destruction of vitamin C in vegetable tissues when left exposed to the atmosphere after being cut or shredded. In karela over 67 % of the vitamin was destroyed during 2 hours. A similar observation has been recorded by Kohman *et al.* [1931] for carrots. Storing karelas for three days at room temperature reduced their vitamin C by over 80 %. These points are of practical importance from the point of view of nutrition, for they show how considerably vegetables may vary in their vitamin C content according to their freshness.

I wish to express my deep indebtedness to Prof. H. E. C. Wilson for his constant interest, help and criticism throughout the course of this investigation, and to the Director, All-India Institute of Hygiene and Public Health, for permission to publish these results.

XXXIII. THE VARIATION IN THE METHOXYL AND CELLULOSE VALUES OF THE FIBRE OF THE FRUIT OF *COCOS NUCIFERA* DURING ITS GROWTH FROM INFANCY OF THE NUT TO ITS ULTIMATE DRYING ON THE TREE.

BY SREEKANDATH RAMAN KUTTY MENON.

From the Presidency College, Madras.

(*Received December 10th, 1934.*)

THE belief is held by coir workers on the Malabar Coast that nuts about ten months old yield the best fibre (in colour as well as in strength), and accordingly all the high quality coir from Allepey and Cochin is the product of nuts of this age.

The subject is one that has not received adequate scientific investigation [*cf.* Barker, 1933]. The present work records the determination of "Cross and Bevan cellulose" and of methoxyl in samples of fibre from nuts of different ages, the latter being regarded as an index of the extent of lignification.

EXPERIMENTAL.

Preparation of samples for analysis.

Coconuts of different ages from the youngest to the ripest on the trees were collected. It was difficult to persuade coir workers to extract the fibre from unretted husks of young nuts.

The husk was first of all peeled to pieces, soaked in water for a day and then heated to boiling in water with a little tamarind, the latter being supposed to hasten dissolution of the gummy matter and liberation of the fibre from the corky tissues. After this the husks were beaten out, and the bulk of the corky refuse was removed by repeated shuffling and combing.

The crude fibre samples obtained in this way were brought to Madras and further treated as follows. After boiling for 10 minutes with 20 % acetic acid[1], the samples were alternately beaten with a pestle on an inverted mortar and washed vigorously under the tap for an hour, followed by removal by hand of the last traces of corky matter. Finally they were washed with distilled water and air-dried.

Grinding of the samples for analysis presented difficulty and the device was adopted of cropping a bundle of fibre with a "Kodak trimmer," followed by sieving through a 40-mesh sieve. The powdered samples were preserved in stoppered weighing bottles.

Physical appearance of the samples.

The physical appearance and quality of the fibres varied considerably. That extracted from the infant nut was pale yellow in colour, shrivelled, exceedingly thin and much shorter than the fibres of the older nuts. The colour grew more intense and the thickness of the fibre increased with age until the best colour with maximum gloss was found in the fibre of the nut that was 10 months old. Thereafter the fibre reddened and became "drier" with increasing age of the nut.

---

[1] The use of dilute acetic acid is thought not to affect the chemical nature of the fibre. Thus Cross and Bevan [1903] showed that in the case of jute the action of dilute mineral acids consisted only in a physical dissolution of the fibre, and the dissolved portion isolated from the solution resembled the original fibre in all chemical properties.

Analyses.

Moisture was determined by vacuum-drying at 110°. The percentages ranged from 7 to 13, 10 % being a usual figure. Other determinations were made on air-dried samples, the results being then calculated on a dry basis. Methoxyl determinations were carried out by Zeisel's method.

Estimation of "Cross and Bevan cellulose."

Coir fibre proved unexpectedly resistant to chlorination when the original Cross and Bevan method [1889] was employed, this resistance increasing with the age of the nut to a maximum at the 10 months stage and decreasing thereafter. The following modification of the method was found to give consistent results.

A small sample (less than 0·5 g.) is boiled for half an hour (in a 100 ml. beaker with a glass rod) with 40 ml. of 1 % caustic soda solution, allowed to settle and washed thoroughly with hot water by decantation, the first liquor and washings being poured through a weighed sintered glass crucible. The moist fibre is then spread over the sides of the beaker, and the latter with the crucible exposed to a slow stream of chlorine in a glass chamber with gas inlet and outlet. The fibre is well washed by decantation as before and then heated slowly to boiling with 40 ml. of 2 % sodium sulphite solution; 0·1 % of sodium hydroxide (calculated on the weight of the solution) is then added and boiling continued for 5 minutes.

After again washing by decantation as much as possible the fibre is transferred by means of a glass rod and the aid of a jet from a wash-bottle, both from the beaker and the crucible to a small glass mortar. After trituration the fibre is again chlorinated (in the mortar). This treatment is found to lessen the number of chlorinations required. The whole series of operations is repeated until a uniformly yellowish-white cellulose is obtained, as many as five chlorinations being necessary in the case of the mature fibre, although three are enough for the infant coconut fibre.

The crude cellulose is finally purified by bleaching with dilute permanganate solution followed by sulphurous acid in the usual manner, washed on the filter, acidified with acetic acid, again washed and dried at 110° to constant weight. The crucible is weighed in a weighing bottle since the cellulose is somewhat hygroscopic.

By this procedure results concordant within 3 % could be obtained. The following table shows the results obtained:

Approximate age of the nut from which fibre was extracted	Mean value of the methoxyl percentage	Mean value of the "Cross and Bevan cellulose" percentage
3 months	3·9	66
5 ,, (tender coconut)	4·3	62
7 months	5·0	59
10 ,, (mature nut, but husk green)	5·7	53
12 months	5·3	57

The figures on the dry nut were not consistent and so are not included; the methoxyl percentage of this sample was however below and the cellulose percentage above the corresponding values for fibre from the 10 month nut.

DISCUSSION.

The results show a maximum for the methoxyl value and a minimum for the cellulose value for the fibre from nuts 10 months old, that is the nuts most favoured on the Malabar coast for the manufacture of coir.

The possibility is borne in mind that the tannin matter which increases in quantity as the nut matures, may be a disintegration product of lignin and that the apparent increase in percentage of cellulose after a minimum has been reached may be due to elimination of the lignin component. Further work on this and allied subjects is projected.

I have to express my thanks to Prof. B. B. Dey, for providing facilities for the present work.

XXXIV. HORMONES IN THE URINE FOLLOWING OOPHORECTOMY DURING PREGNANCY.

By HAMISH ALLAN and EDWARD CHARLES DODDS.

From the Courtauld Institute of Biochemistry, Middlesex Hospital.

(*Received December 18th, 1934.*)

The operation of bilateral oophorectomy during pregnancy is not commonly performed, yet there is a large number of cases on record. In the majority, the pregnancy was carried to term without interruption. Very few cases, however, have been reported in which any attempt has been made to study the hormones present in blood and urine after operation. So far as we are aware, only four such cases have been studied; these are reported by Amati [1928], Waldstein [1929], Szarka [1930] and Saidl [1932]. Table I gives a summary of their results.

Table I.

				Hormones post-operation			
				A.L.H.		Oestrone	
Authority	Age of patient	Clinical condition	Hormones pre-operation	Blood	Urine	Blood	Urine
Amati [1928]	?	Dermoid cysts	—	—	—	Present	—
Waldstein [1929]	26	Dermoid cysts	—	0·6 ml. Serum positive	1·8 ml. Positive	1–2 ml. Positive	400–500 M.U. per litre
Szarka [1930]	33	Dermoid cysts	—	—	—	5 ml. 4 units	1 ml. Positive
Saidl [1932]	23	Dermoid cysts	A.L.H. 900 M.U. per litre Ov.H. 500 M.U. per litre	—	650–1250 M.U. per litre	Positive in 1·8 ml.	450–680 M.U. per litre

* Weaker solution not tried.

Through the kindness of Mr Aleck Bourne it was made possible for us, during the autumn of 1932, to study a fifth case of this type. In this instance bilateral oophorectomy was performed about three months after conception.

Unfortunately, after the patient's discharge from hospital she returned to her home, some fifty miles from London, and a further move about three months later brought the experiment to an end. The period during which specimens have been obtainable is about 108 days, beginning 112 days after the last menstruation and ending about 50 days before delivery.

Owing to the available stocks of experimental animals the estimations of hypophyseal hormone were carried out first, and it is these only on which a report is now made. A small number of oestrone estimations were carried out as described below.

Clinical details.

Mrs K. M. Age 36, Nullipara. Admitted to hospital on account of abdominal pain and swelling.

Operation 27. ix. 32 by Mr Aleck Bourne—Bilateral oophorectomy. Pathologically these were found to consist of multiple lutein cysts. Convalescence was uneventful and patient returned home on 17th day Delivery at ten months of a normal, healthy child. The child was not breast-fed.

Examination of urine and blood.

A. *Pre-operative.*

(1) *Urine.* Since information of the approaching operation was only received a few hours before it actually occurred only a small quantity of urine was available for test. There was sufficient for a rough oestrone test (7 rats only), giving a value of 2000 M.U. per litre. Tested for hypophyseal hormone, a positive result was obtained with 0·18 ml. urine.

(2) *Blood.* No blood was obtained for test before operation.

B. *Post-operative.*

The tests for hypophyseal hormone were carried out using batches of five infantile mice, 21 days old on first day of test. Each animal received 6 doses of 0·3 ml. of urine (or diluted urine) during 48 hours. They were killed after 96 hours and the ovaries examined with a hand lens. The total number of corpora lutea or haemorrhagica in the group of five mice has been recorded in the table, together with total weight in mg. of 8 ovaries and 8 uterine horns.

A few further tests, not included in Table II, were carried out, in the hope of obtaining a better qualitative result by the use of larger numbers of mice. The last such test, 112 days after operation gave, out of 48 mice, 12 showing positive results, *i.e.* presence of corpora lutea or haemorrhagica.

Table II. *Response to injections.*

* Indicates approximate time of menstrual period in absence of pregnancy.

Examination of Table II brings to light that there is no significant change in the excretion of hypophyseal hormone brought about by the operation, apart from a very brief rise on the first and second days after operation.

Comparison of present results with earlier workers.

The experiments of Amati were not quantitative and his results have since been confirmed and amplified. Waldstein's figure for oestrone, while agreeing with that of Saidl, is lower than that obtained in the present case. In this connection it must be pointed out that no details of oestrone assay are given by Saidl, and that Waldstein appears to have used the method of diminishing doses—*i.e.* in a batch of animals each one receives a different dose, and the smallest dose to give a positive reaction is taken as containing 1 unit. This method is now known to give unreliable results. In regard to our own figure, *i.e.* 1400 M.U. per litre, it must be admitted that a relatively small number of animals (30) was employed, but it is probably more accurate than an estimation by the method of diminishing doses. The figures for anterior lobe hormone (A.L.H.) given by Saidl show that he obtained a steady increase from 150 to 1250 M.U. per litre in the course of 10 days after operation.

In the present case a similar, but smaller and shorter rise was noted. Owing to lack of detail regarding the "unit" adopted it is impossible to compare directly our figures with those of Saidl. It may be added that a response similar to those of Table II has been obtained by us with urine from normal pregnant women.

SUMMARY.

1. The operation of bilateral oophorectomy in pregnancy does not bring about any change in the anterior hypophyseal hormone content of the urine.

2. The oestrone content of the urine is definitely decreased.

It is a pleasure to express our gratitude to Mr Aleck Bourne for his courtesy in drawing our attention to this case and permitting us to publish our results, and to Mr E. R. E. Spence for his careful work in the animal experiments.

XXXV. STUDIES IN THE METABOLISM OF THE STRICT ANAEROBES (GENUS *CLOSTRIDIUM*).

II. THE REDUCTION OF PROLINE BY *CL. SPOROGENES*.

By LEONARD HUBERT STICKLAND.[1]

From the Biochemical Laboratory, Cambridge.

(*Received December 19th, 1934.*)

The first paper of this series [Stickland, 1934] showed that washed suspensions of *Cl. sporogenes* are able to oxidise certain amino-acids (*e.g.*, *d*-alanine, *d*-valine, *l*-leucine, *l*-histidine) and reduce certain others (glycine, *l*-proline, *l*-hydroxyproline) and are able also to catalyse direct oxidation-reduction reactions between pairs of these amino-acids. The study of the chemistry of these reactions obviously involves the use of two substrates simultaneously, so that there is difficulty in deciding from which of these substrates the products have arisen. If, however, the products of reaction of any one amino-acid can be determined, the rest of the information required will follow from the analysis of the products of reaction of the various pairs. The oxidation of alanine by cresyl blue, described in the previous paper, would serve as a starting point, but it is impossible by this method to oxidise sufficient alanine to permit of the identification and estimation of the products. Eventually for various reasons the reduction of *l*-proline was chosen as a starting point, and the present paper deals with this subject.

EXPERIMENTAL.

Preparation of bacterial suspensions.

Suspensions of *Cl. sporogenes* were prepared as before [Stickland, 1934] by growing the bacteria for 40 hours anaerobically on tryptic digest of caseinogen, centrifuging and washing twice with Ringer's solution.

Preliminary experiments.

It was first shown that *l*-proline is not deaminated during reduction. A series of Thunberg tubes (usually five tubes) was prepared containing 0·5 ml. *M*/10 *d*-alanine, 0·5 ml. *M*/5 *l*-proline, 0·5 ml. *M*/2 phosphate buffer p_H 7·5 and 1·0 ml. suspension of *Cl. sporogenes*, and another series of controls with neither amino-acid. These were all evacuated thoroughly and incubated at 40°. After various intervals of time pairs of tubes, one from each series, were taken and the ammonia was estimated in 2 ml. of their contents. It was found that ammonia production ceased when an amount equivalent to the alanine present had been liberated. (See Fig. 1 and Table I.)

In the previous paper it was shown that alanine is deaminated during oxidation, so these results show that proline is not deaminated during reduction.

The reduction of proline must therefore take place by a simple opening of the ring, giving an amino-*n*-valeric acid. The amino-group might equally well occupy the α- or δ-position, according to the point at which the ring was opened (see

[1] Beit Memorial Fellow.

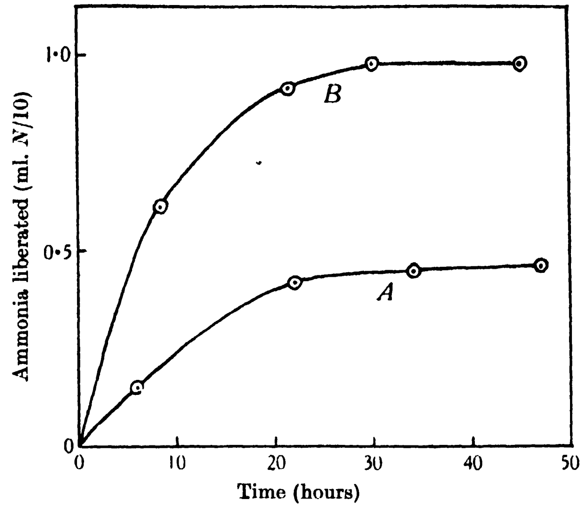

Fig. 1. The course of liberation of ammonia from
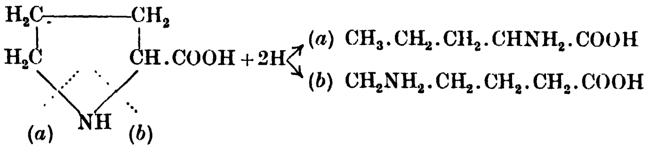
A. 0·5 ml. *M*/10 *d*-alanine + 0·5 ml. *M*/5 *l*-proline.
B. 0·5 ml. *M*/5 *d*-alanine + 0·5 ml. *M*/2·5 *l*-proline.

Table I. *Ammonia production from 1 mol. alanine + 2 mols. proline.*

Alanine	Proline	Ammonia found (ml. *M*/10) (corrected for blank)	Ammonia as % of theoretical from alanine
0·5 ml. *M*/10	0·5 ml. *M*/5	0·46	92
,,	,,	0·45	90
0·5 ml. *M*/5	0·5 ml. *M*/2·5	0·98	98
,,	,,	0·99	99

equations). Results reported by Neuberg [1911] and Ackermann [1911] on the action of mixed putrefactive bacteria on proline to give δ-amino-*n*-valeric acid make it likely that in the present case also the ring is opened to give the δ-amino compound.



$$\text{CH.COOH} + 2\text{H} \to \begin{cases} (a)\ CH_3.CH_2.CH_2.CHNH_2.COOH \\ (b)\ CH_2NH_2.CH_2.CH_2.CH_2.COOH \end{cases}$$

*Synthesis of δ-amino-*n*-valeric acid.*

Piperidine was benzoylated by the method of Marvel and Lazier [1929]. Oxidation of benzoylpiperidine to benzoyl-δ-amino-*n*-valeric acid and hydrolysis of this to δ-amino-*n*-valeric acid hydrochloride were carried out by the method of Schotten [1884]. The nitrogen content of the product dried *in vacuo* was 9·20 % ($C_5H_{12}O_2NCl$ requires N 9·14 %).

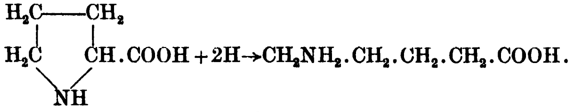
Preparation of α-naphthyl isocyanate *derivative of δ-amino-*n*-valeric acid.* The reaction with α-naphthyl *iso*cyanate was carried out exactly as described by Neuberg and Rosenberg [1905]. The product decomposed at 195–196° and melted at 231° [*cf.* Keil, 1932]. (Found: N 9·9 %; $C_{16}H_{18}O_3N_2$ requires N 9·8 %.)

*Isolation of the α-naphthyl isocyanate derivative of δ-amino-*n*-valeric acid from the products of the reaction between alanine and proline.*

A large (75 ml.) Thunberg tube was prepared containing 8 ml. *M*/5 *d*-alanine, 8 ml. *M*/2·5 *l*-proline (368 mg.), 8 ml. *M*/2 phosphate buffer p_H 7·5 and 16 ml. of a suspension of *Cl. sporogenes*. To enable the course of the reaction to be followed, two sets of small Thunberg tubes were set up containing (*a*) 0·5 ml. *M*/5 alanine, 0·5 ml. *M*/2·5 proline, 0·5 ml. buffer and 1·0 ml. suspension of bacteria, and (*b*) 1·0 ml. water, 0·5 ml. buffer and 1·0 ml. suspension. All the tubes were evacuated and incubated at 40°. Pairs of the small tubes (one of (*a*) and one of (*b*)) were taken from the incubator from time to time, and the ammonia was estimated in them in the usual way. It was found that in 22½ hours 99 % of the nitrogen of the alanine had been liberated as ammonia.

The contents of the large tube, after the greater part of the bacteria had been removed by centrifuging, were strongly acidified with hydrochloric acid and evaporated to dryness *in vacuo*. From the dry residue the hydrochloride of δ-amino-*n*-valeric acid was extracted with hot 97 % alcohol (once with 30 ml. and twice with 10 ml.), and the combined filtered extracts were evaporated to dryness *in vacuo*, taken up in 15 ml. of water and filtered. The solution was neutralised with *N* NaOH, made alkaline by the addition of a further 5 ml. of NaOH, and freed from a trace of ammonia by a current of air. The solution was now treated with 0·5 g. of α-naphthyl *iso*cyanate and shaken for one hour. The precipitate of di-α-naphthylurea was filtered off and the filtrate acidified with hydrochloric acid and kept at 2° for several hours. The precipitated derivative was now filtered off and washed, redissolved in hot dilute ammonia and reprecipitated with dilute acetic acid. After two such reprecipitations the product was dried and weighed. At this stage the yield was 0·52 g., which is equivalent to 58 % of the proline originally taken.

After three recrystallisations from dilute alcohol, the substance alone and in admixture with synthetic α-naphthylcarbamido-*n*-valeric acid decomposed at 190–191° and melted at 231°. (Found: N 9·7 %; $C_{16}H_{18}O_3N_2$ requires N 9·8 %.) The decomposition temperature of this product is rather low, but the melting-point, mixed melting-point with the synthetic substance and nitrogen content afford satisfactory proof that *Cl. sporogenes* reduces *l*-proline to δ-amino-*n*-valeric acid according to the equation



SUMMARY.

Washed suspensions of *Cl. sporogenes* reduce *l*-proline, at the expense of the oxidation of alanine, to δ-amino-*n*-valeric acid.

XXXVI. DILATOMETRIC DETERMINATION OF THE RELATIVE DIGESTIBILITY OF PROTEINS.

By HEMMIGE BILIGIRIRANGACHAR SREERANGACHAR
AND MOTNAHALLI SREENIVASAYA.

From the Department of Biochemistry, Indian Institute of Science, Bangalore.

(*Received November 7th, 1934.*)

Digestibility of proteins is usually determined by feeding tests employing either the method of Mitchell [1924] or the alternative method of Osborne *et al.* [1919]. Experiments with animals are time consuming and cumbersome as compared with the *in vitro* studies carried out by Waterman and his colleagues [Waterman and Johns, 1921; Waterman and Jones, 1921; Jones and Waterman, 1923]. According to them the relative digestibilities of the proteins of a food material can be directly and satisfactorily determined by enzymic digestions *in vitro.*

In vitro studies offer a convenient method of investigating the digestion of proteins and starches as influenced by cooking, addition of salts and other activating or inhibiting agencies. The increased digestibility of phaseolin on cooking [Waterman and Jones, 1921], the relative indigestibility of arachin [Jones and Waterman, 1922], the inhibiting effect of gossypol on the digestibility of cotton seed proteins [Jones and Waterman, 1923], the influence of fats on protein digestion in general [Maughan, 1926] have all been studied by *in vitro* methods. These methods are particularly suitable for investigating the influence of active principles like glucosides and alkaloids on the digestion of proteins.

All *in vitro* experiments involve the enzymic digestion of the material under certain standardised conditions of reaction and temperature, so chosen that they approximate as closely as possible to the condition obtaining in the animal. The course of digestion is followed mostly by chemical methods involving a determination of either the amino-nitrogen released by van Slyke's method or the total nitrogen in the filtrate after removing the undigested protein by precipitants like trichloroacetic and phosphotungstic acids. In a few investigations the rate at which a particular amino-acid is liberated during digestion has been adopted as a measure of digestibility. Jones and Gersdorff [1933] have thus followed the peptic and acid digestions of caseinogen by estimation of the liberated cystine.

The relative digestibility of proteins can also be studied by any of the physical methods whose experimental values are proportional to the extent of digestion. Thus, the dilatometric estimation offers a convenient method of studying the relative digestibility of proteins, since it has been shown that the release of amino-nitrogen is proportional to the volume change accompanying the enzymic digestion [Sreenivasaya *et al.*, 1934]. The quantity of material required for an investigation of this type is comparatively small, the results are quickly and easily reproducible and the digestibility of a number of proteins with reference to that of a standard protein like caseinogen can be simultaneously determined.

EXPERIMENTAL.

The present communication relates to a study of the digestibility of three proteins, gelatin (Gold-label), and the globulins of *Phaseolus mungo* and *Dolichos lablab*, as compared with the digestibility of "Hammersten's casein." Since the principal object of the investigation was to demonstrate the adaptability of the dilatometric method for *in vitro* digestion studies, all the digestions were carried out with Pfanstiehl's trypsin at 30° and at p_H 7·7 employing Sørensen's phosphate buffer.

The globulins were extracted from the respective pulses with 5 % sodium chloride solution, the clear extract was dialysed against distilled water in cellophane bags, and the precipitated globulins were recovered by centrifuging. The wet precipitate was dissolved directly in the phosphate buffer and after a preliminary determination of the protein content (N × 6·25) it was adjusted to yield a 1 % protein solution. 50 ml. of this solution and 10 ml. of a 1 % trypsin solution were employed for the dilatometric determination. The reaction was conducted simultaneously in another flask and the digestion followed independently by a determination of the amino-nitrogen by van Slyke's method at definite intervals. The experimental procedure employed in this study is the differential method fully described in one of our earlier communications (1932).

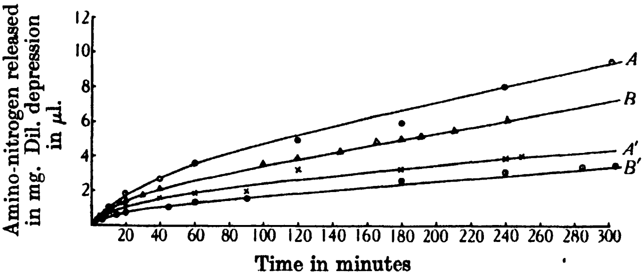

Fig. 1. *A*, *Phaseolus mungo* protein amino-nitrogen; *B*, *Phaseolus mungo* protein dil. depression; *A'*, *Dolichos lablab* protein amino-nitrogen; *B'*, *Dolichos lablab* protein dil. depression.

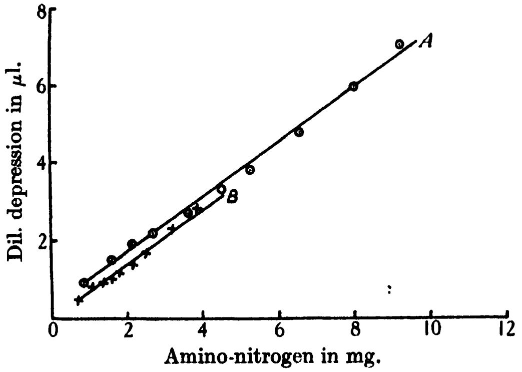

Fig. 2. *A*, *Phaseolus mungo* protein; *B*, *Dolichos lablab* protein.

The course of digestions of the globulins from *Phaseolus mungo* and *Dolichos lablab* has been followed both by the dilatometric and van Slyke's methods and the results are graphically represented in Fig. 1. Fig. 2 gives the correlation between the dilatometric depression and amino-nitrogen indicating thereby that the dilatometric depressions are proportional to the release of amino-nitrogen during the digestion. That a similar proportionality also exists in the case of caseinogen and gelatin digestions has been established in one of our earlier communications.

DISCUSSION.

If X is the amount of amino-nitrogen that is released during the digestion of a protein (expressed as A g. of total nitrogen) under certain standardised experimental conditions, then the digestibility K of the protein is given by $K = X \times 100$. The digestibilities of caseinogen, gelatin and the *Phaseolus mungo* and *Dolichos lablab* globulins for different intervals of time, are given in Table I.

Table I.

Time in hours ...	1	2	3	4	5
Caseinogen	11·1	14·8	16·9	18·0	18·6
Gelatin	6·7	9·1	10·4	10·9	11·3
P. mungo	5·7	8·3	10·3	12·6	14·5
D. lablab	2·9	4·0	5·1	6·1	6·7

The digestibility appears to increase with time (Table I) reaching a fairly steady value in about 4–5 hours. For comparative studies of digestibility a 4–5 hour period can therefore be fixed as a standard.

Since the dilatometric depressions V have been shown to be proportional to the amino-nitrogen release X during the digestion, the ratio between the digestibility of a protein and that of the caseinogen standard will be equal to the ratio of either the amounts of amino-nitrogen released or the depressions that accompany the digestion. The relative digestibility is therefore given by either

$$K_1 = \frac{\text{NH}_2\text{ (protein) } X_1}{\text{NH}_2\text{ (caseinogen) } X_2} \times 100$$

or

$$K_2 = \frac{\text{Dil. depression } V_1 \text{ (protein)}}{\text{Dil. depression } V_2 \text{ (caseinogen)}} \times 100.$$

The values of K_1 and K_2 for two periods of digestion are given in Table II and there is a fair agreement between the two values indicating the usefulness and reliability of the dilatometric method in assaying the relative digestibility of proteins.

Table II.

	Gelatin		*P. mungo*		*D. lablab*	
	K_1	K_2	K_1	K_2	K_1	K_2
4 hours	60	58	70	65	34	32
5 hours	60	59	78	74	36	35

The results indicate that *Phaseolus* protein is digested much more easily (about twice) than that of *Dolichos*, and are in agreement with the observations of Desai *et al.* [1931–32] made by feeding tests of these proteins.

SUMMARY.

1. The globulins from *Phaseolus mungo* and *Dolichos lablab* have been subjected to tryptic digestion and the course of reaction followed both by the dilatometric and van Slyke's methods; it is found that the dilatometric depression obtained in each case is proportional to the release of amino-nitrogen.

2. It is shown that dilatometric depressions can be directly taken as a measure of digestibility and that the ratio of the depressions observed with the experimental protein and with the standard caseinogen represents the relative digestibility.

Our best thanks are due to Mr B. N. Sastri for his kind help in the preparation of the globulins and for his many helpful suggestions.

XXXVII. AN ISOTHERMAL CALORIMETER[1].

BY HEMMIGE BILIGIRIRANGACHAR SREERANGACHAR
AND MOTNAHALLI SREENIVASAYA.

From the Department of Biochemistry, Indian Institute of Science, Bangalore.

(*Received November 26th, 1934.*)

AMONG the existing isothermal calorimeters for the measurement of the heat liberated during reaction, dilution or solution are the compensation device of Wasserman [1930], where the heat liberated is balanced by the cooling caused by diluting a concentrated solution of ammonium nitrate, and the isothermal calorimeter of Hirobe [1926] in which the temperature change is prevented by adding simultaneously with the progress of the reaction, the necessary quantity of an indifferent substance at a different temperature. Coon and Daniels [1933] recommend a calorimeter particularly suitable for measuring the heat changes accompanying prolonged reactions like the hydrolysis of ethyl acetate and the fermentation of yeast.

While the above instruments are cumbersome and require skilled and elaborate manipulation, the original ice calorimeter of Bunsen [1870] remains one of the most simple and successful devices in the field. For biochemical reactions Bunsen's calorimeter cannot be employed since the reactions proceed extremely slowly at 0°, but if ice could be replaced by a substance melting at 25–30° the instrument might find extended application in biochemistry. The substance chosen should satisfy the following requirements: (1) a reproducible and sharp melting-point, (2) stability at the temperature of melting without any decomposition on repeated meltings and coolings, (3) indifference towards the mercury used in the capillary, (4) appreciable volume change during the melting of the solid and (5) low latent heat of fusion contributing towards a greater sensitivity of the instrument.

Diphenylmethane, which has been tried in our present study, meets most of these requirements, in that it is a stable hydrocarbon melting at 24·5° and has a latent heat of fusion of 26 cal./g. *p*-Bromotoluene (M.P. 28·5°), *tert*butyl alcohol (M.P. 25°), *iso*quinoline (M.P. 24·5°) and diphenylether (M.P. 28°) are suggested as possible alternatives.

The instrument and its manipulation.

The instrument (Fig. 1*a*) (kindly made to our design by Messrs Greiner and Freidrichs) consists of a reaction tube *A* surrounded by a bulb *B* which, in turn, is thermally insulated by a vacuum jacket *C*. The tube *D* leading to the bottom of the bulb *B*, communicates with the capillary *L* through the standard ground glass joint *J*. The capillary tube leading out of the apparatus is bent at right angles towards its extreme end and can be made whenever necessary to dip into mercury contained in a crucible.

---

[1] A preliminary report of this paper was presented before the Joint Session of the Society of Biological Chemists, India, and the Association of Economic Biologists held at Coimbatore in October 1932 (*Proc. Soc. Biol. Chemists, India*, 1932, **18**). It formed part of a thesis submitted by one of the authors (H. B. S.) for the Associateship of the Indian Institute of Science, Bangalore. While this paper was being prepared for publication, there appeared a note on this subject by Schukarew *et al.* [1934].

The bulb *B* is evacuated and filled with diphenylmethane. The tube *D* is then filled with mercury and the capillary inserted at the ground joint when the column of mercury fills the capillary. When the instrument is not in use the capillary end is kept dipping into mercury so that changes in surrounding temperature will not effect a break in the mercury column and necessitate refilling of the apparatus.

The instrument after filling is placed in a Dewar flask containing melting diphenylmethane. Initially part of the liquid inside the calorimeter is frozen by evaporating dry ether in the reaction tube *A*, by means of a current of dry air. The calorimeter is then allowed to remain in the Dewar flask containing melting diphenylmethane for 48–72 hours so as to attain thermal equilibrium with the surroundings.

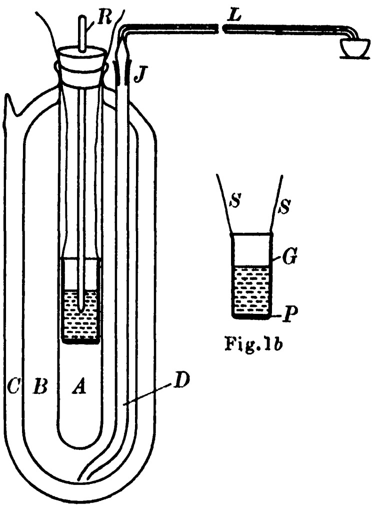

Fig. 1*b*

Fig. 1*a*

Experimental procedure.

Before the commencement of an experiment, 1 ml. of pure dry ether is introduced into the reaction tube and evaporated by a current of dry filtered air. By this means, a uniform incrustation of solid diphenylmethane is formed on the outer walls of the reaction tube. The mercury meniscus in the capillary can be adjusted to any desired position by withdrawing the mercury cup at the end of the capillary and continuing the operation of cooling. The interior of the reaction tube is then dried by means of a swab of clean cotton wool.

The "housing" of the reagents. The "housing" of the two reacting liquids separately in the calorimeter offered considerable difficulty. Before mixing they should be kept separate inside the calorimeter and allowed to attain the temperature of the melting diphenylmethane. The mixing operation itself should not involve any disturbance in the thermal equilibrium of the whole system. After several trials, the arrangement illustrated in Fig. 1*b* was found to be satisfactory. One of the solutions is introduced directly into the reaction tube while the other is contained in a separate small glass tube *G* closed at one end with a thin layer of paraffin wax *P* and suspended in the reaction tube by means of a non-conducting string *S* of cotton. A glass rod *R* which passes through the cork closing the reaction tube dips into the liquid contained in *G*. The projection of the glass rod over the cork is covered with felt to minimise transference of heat from outside to inside. After the calorimeter has attained thermal equilibrium as shown by the steadiness of the creep of the mercury column, the glass rod is gently pushed in, breaking the paraffin bottom of the glass tube *G* and effecting a mixture of the two liquids. That the operation of mixing itself does not lead to any detectable disturbance in the thermal equilibrium of the calorimeter can be shown by mixing distilled water in the reaction tube with water in the suspended glass tube; the position of the mercury column remains undisturbed.

The heat of reaction produced is measured by the shift in the mercury meniscus along the capillary. Before an experiment is begun, the rate of flow of mercury is determined. When this is minimum and fairly steady, the liquids are mixed and measurements continued. The shift of mercury column due to the heat of reaction is obtained by allowing for the already determined creep.

Fig. 2 gives a graphical representation of the course of heat evolution during a few typical experiments. Curve *A* is characteristic of all reactions like the neutralisation of HCl with NaOH wherein the heat liberation is instantaneous.

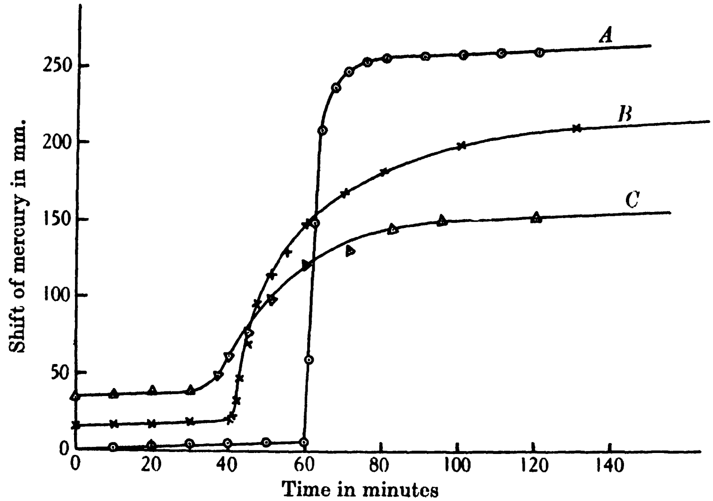

Fig. 2. *A*, neutralisation of HCl with NaOH. *B*, *C*, quinol-peroxidase system (two concentrations of substrate.)

B and *C* represent the curves characteristic of reactions, particularly enzymic reactions, where heat generation is gradual. In all three cases there is first a flat portion of the curve corresponding to a uniform change in the initial conditions of the calorimeter, then either a steep or a gradual rise corresponding to either a rapid or slow liberation of heat due to reaction and finally again, a flat portion showing the completion of the reaction and the attainment of a state of thermal equilibrium. By the use of a thermostat maintained at the melting temperature of diphenylmethane, more steady conditions could be obtained in these various stages.

Calibration of the instrument.

The calorimeter is calibrated by conducting standard reactions which evolve known amounts of heat. Dilution of sulphuric acid, neutralisation of hydrochloric acid with sodium hydroxide and double decomposition of barium chloride and sodium sulphate were all carried out in the calorimeter and the results obtained are given in Table I. The heats liberated in each case have been calculated from the values given in Standard Physical Tables.

It will be observed from the results in Table I that the calorimeter gives reliable and concordant results as tested by three independent reactions. The average quantity of heat corresponding to 1 mm. shift of mercury column is 0·063 cals.

Table I.

Reaction	Mercury shift mm.	Heat liberated cals.	Heat liberated per mm. shift of mercury cals.
1. Dilution of 49 % sulphuric acid	153		0·063
2 ml. of acid + 1 ml. water	155	9·58	0·062
	154		0·062
Mean	154		0·062
2. Neutralisation of HCl with NaOH	254		0·066
2 ml. 0·62N acid +	252	16·76	0·067
2 ml. 0·65N alkali	253		0·066
Mean	253		0·066
3. Double decomposition of $BaCl_2$ and Na_2SO_4	25		0·059
2 ml. 2 % Na_2SO_4 +	25	1·48	0·060
2 ml. 3 % $BaCl_2$	24		0·061
Mean	25		0·060

Application to biochemical reactions.

The heat changes accompanying the enzymic hydrolysis of a few substrates, urea, sucrose, amygdalin and quinol, have been investigated in the calorimeter. While the amounts of heat in the cases of urease-urea, invertase-sucrose and emulsin-amygdalin systems, as determined by our present calorimeter are too small to be accurately estimated, the instrument has shown itself suitable for a study of the peroxidase-quinol system (Table II).

Table II. *Peroxidase-quinol.*

Quinol mg.	Quantity of enzyme	Shift of mercury column mm.	Heat liberated per g. of substrate cals.
91·0	2 ml. potato extract + 1 ml. 1 % H_2O_2	93·0	64·4
81·6	,,	90·5	70·4
80·2	,,	89·0	69·8

The mean value obtained for the liberation of heat by the peroxidase-quinol system is 68·2 cals. per g. of quinol. In the case of the other three systems, urease-urea, emulsin-amygdalin and invertase-sucrose, the heat changes involved have been found to be too small to be measured with adequate accuracy. If, for example, the value for sucrose hydrolysis be accepted as 11·21 cals. per g. of sucrose, as determined by Brown and Pickering [1897] and Dixon and Ball [1920], then the expected value under the conditions of our experiment should correspond to a shift of 9 mm. in the mercury column which can be detected by the present calorimeter but not measured with sufficient accuracy. Obviously, those reactions which are accompanied by heat changes corresponding to shifts of less than 15–20 mm. of mercury cannot be investigated by the instrument in its present form. By employing a capillary with a smaller bore, the sensitivity of the calorimeter can be increased and reactions involving smaller heat changes studied. An attempt in this direction is being made. The calorimeter is now being employed for measuring the heat liberated during the respiration of small insects, germination of seeds and a few typical fermentations.

SUMMARY.

1. An isothermal calorimeter using diphenylmethane, which is very simple in operation, is described.

2. The calorimeter has been calibrated with the help of the following standard reactions: (*a*) dilution of sulphuric acid, (*b*) neutralisation of HCl with NaOH, and (*c*) double decomposition of Na_2SO_4 and $BaCl_2$.

3. The heat changes accompanying a few enzymic reactions have been investigated; the peroxidase-quinol system yields an average value of 68·2 cals. per g. of substrate.

4. The possibility of employing the calorimeter for the investigation of other biological reactions, *e.g.* respiration, germination and fermentation, is indicated.

In conclusion, we wish to express our grateful thanks to Mr G. Gundu Rao, Chemist, Mysore Sugar Factory, for many helpful suggestions in the course of the work and to Dr M. A. Govinda Rau, Department of Physics, Indian Institute of Science, for his constructive criticisms in the preparation of the paper.

XXXVIII. STUDIES IN THE BIOCHEMISTRY OF MICRO-ORGANISMS.

XLI. THE METABOLIC PRODUCTS OF *PENICILLIUM CHARLESII* G. SMITH. II. THE MOLECULAR CONSTITUTION OF CAROLIC AND CAROLINIC ACIDS.

BY PERCIVAL WALTER CLUTTERBUCK, HAROLD RAISTRICK AND FRITZ REUTER.

From the Division of Biochemistry, London School of Hygiene and Tropical Medicine, University of London.

(*Received December 21st, 1934.*)

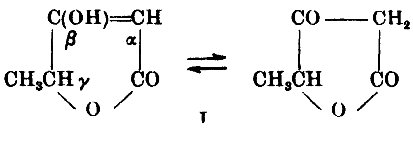
IN a recent communication [Clutterbuck *et al.*, 1934] it was shown that *Penicillium Charlesii* G. Smith, a new species of *Penicillium* isolated by our late colleague Mr J. H. V. Charles from mouldy Italian maize, produced from glucose a polygalactose and a polymannose together with a number of hitherto undescribed organic acids. Of these acids carolic and carolinic acids were obtained in the largest yields. It is the purpose of this paper to describe the investigation of the molecular constitutions of these two acids.

Carolic acid gives an orange $FeCl_3$ colour but does not give an immediate violet colour with $NaNO_2$. In aqueous solution it is acid to Congo red and titrates in the cold as a monobasic acid, the titration not being materially altered by gently warming with excess $N/10$ NaOH. The acid does not however contain any active hydrogen as determined in dry anisole by the Zerewitinoff method, whilst it contains one active hydrogen when determined in pyridine (Roth). It appears therefore that carolic acid contains a non-lactonic ring which opens up almost completely during titration in the cold in aqueous solution, whilst in pyridine one ketonic group becomes enolised.

Carolinic acid gives with $FeCl_3$ an immediate precipitate, soluble in excess to a bright orange coloured solution, but does not give an immediate $NaNO_2$ colour. The acid turns Congo red blue, titrates sharply in the cold as a dibasic acid and contains 2 atoms of active hydrogen as determined in dry anisole or pyridine by the Zerewitinoff method (Roth).

Both carolic and carolinic acids on boiling with $2N$ H_2SO_4 undergo immediate hydrolysis, carolic acid giving quantitatively 1 molecule each of acetoin, CO_2 and butyrolactone, whilst carolinic acid gives 1 molecule each of acetoin, CO_2 and succinic acid.

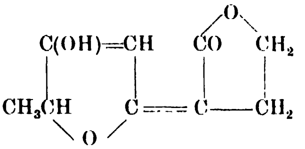
Both carolic and carolinic acids on brominating in dilute acetic acid solution give *d*-α-bromo-γ-methyltetronic acid ($C_5H_5O_3Br$) which on catalytic reduction with palladium and hydrogen very readily loses its bromine to give *l*-γ-methyltetronic acid (I).



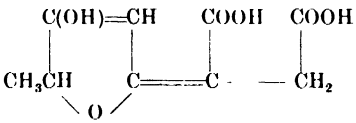
I

On hydrolysis with $2N$ H_2SO_4 (I) quantitatively gives 1 molecule each of acetoin and CO_2 and it is therefore reasonable to suppose that the acetoin and CO_2 obtained on hydrolysis of carolic and carolinic acids arise from the γ-methyltetronic acid nucleus present in these acids and separated from them on bromination. Carolic and carolinic acids may therefore be represented as arising from the condensation of 1 molecule of *l*-γ-methyltetronic acid with 1 molecule butyrolactone and 1 molecule succinic acid respectively, in each case with the elimination of 1 molecule of water.

Various methods of postulating these condensations might be suggested. It is improbable that an esterification occurs at the enolised β-carbonyl group of the γ-methyltetronic acid ring since both carolic and carolinic acids on reduction with Pd and hydrogen give products which on hydrolysis still decarboxylate (though much more slowly than the parent acids) but no longer break down into two C_4 compounds. Since both the acids themselves and the reduced acids give hydroxyketones on hydrolysis it seems unlikely that the β- and γ-carbons of the γ-methyltetronic acid ring are involved in the condensation. On the other hand condensation might take place at the lactonic carbonyl group of the γ-methyltetronic acid ring, when carolic and carolinic acids would have structures II and III respectively.



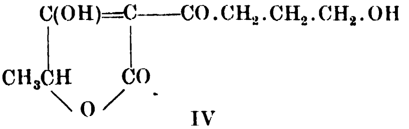
II



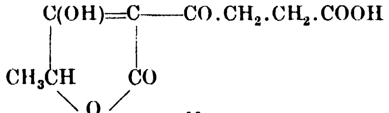
III

An example of this type of structure is given by Fittig and Ström's [1892] dibutyrolactone. It will be shown however that formulae of this type cannot explain a number of properties of these acids.

Alternatively linkage may occur at the α-CH_2 group, when carolic acid ($+H_2O$) and carolinic acid would have the structures IV and V respectively.

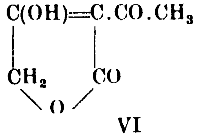


IV

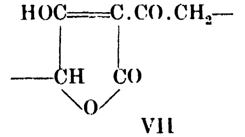


V

An example of this type of structure is given in Benary's [1910] α-acetyltetronic acid (VI) which has the grouping VII, in common with carolic and carolinic acids.



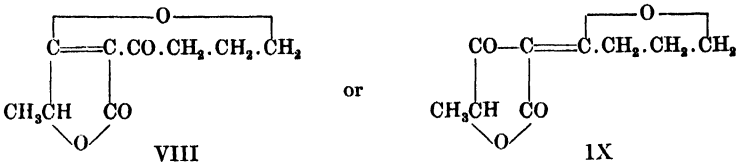
VI



VII

As a result of the absolute analogy in properties and absorption spectra between α-acetyltetronic and carolic and carolinic acids and their derivatives, the ketonic formulae IV and V have now been adopted for the hydrated form of carolic acid ($C_9H_{10}O_4+H_2O$) and for carolinic acid respectively.

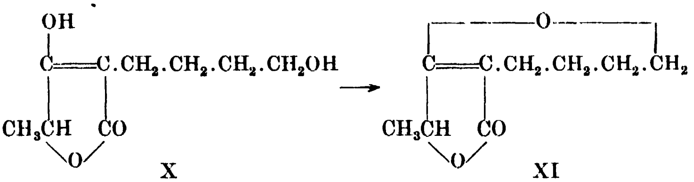
The structural formula of carolic acid ($C_9H_{10}O_4$) then requires the removal of the elements of water from IV. This may be done in two ways giving formulae VIII and IX.



VIII IX

No decisive chemical evidence can be advanced for these formulae, but VIII is to be preferred. Thus it seems probable that the 7-membered ring of VIII would be more labile than the 5-membered ring of IX and would therefore more readily explain the addition of H_2O by mere solution in water. Moreover some heterocyclic structures containing more than six members are known, and on solution in water do form equilibrated systems [*cf. e.g.*, Helferich and Schäfer, 1924].

Further, it should be noted that reduced carolic acid ($C_9H_{14}O_4$), which is a liquid titrating as a monobasic acid, and which is shown later to have the structure X, readily loses one molecule of H_2O on distillation *in vacuo* to give a crystalline neutral compound $C_9H_{12}O_3$ (XI).



X XI

This reaction cannot lead to the formation of a 5-membered ring but must give the same 7-membered ring as is postulated above in the formula VIII for carolic acid with the exception that the CO group immediately outside the tetronic acid ring in carolic acid is reduced to a CH_2 group. In order to account for the single active hydrogen in carolic acid when dissolved in pyridine it is postulated that the $COCH_2$ group of the 7-membered ring undergoes enolisation to $C(OH)=CH$. A number of similar enolisations in pyridine have recently been reported [Ishikawa and Kojima, 1934].

It remains now to be shown that these constitutional formulae are in full agreement with all the known properties of carolic, carolinic and α-acetyltetronic acids.

(*a*) *General properties of carolic, carolinic and α-acetyltetronic acids.*

The above formulae for carolic and carolinic acids would obviously permit optical activity. Carolic and carolinic acids give with excess of $FeCl_3$ characteristic orange colours indistinguishable from that obtained with α-acetyltetronic acid. In view of the substitution of the α-carbon of the tetronic acid ring we should not expect any of them to give an immediate $NaNO_2$ colour, as is indeed the case. The fact that all three acids can be recovered unchanged after boiling with acetyl chloride is explained by the fact that the only hydroxyl group is of the keto-enol type and is reconverted into the ketonic form in presence of this reagent. The acids also do not give benzoyl, *p*-nitro- or *p*-bromo-benzoyl derivatives, the material being recovered unchanged. Assuming the above configuration, carolic acid would not contain any active hydrogen in dry anisole whereas carolinic acid would contain two active hydrogens. Assuming also that carolic acid adds 1 molecule of water in aqueous solution, it would then become a monobasic acid, the three carbonyl groups surrounding the hydrogen atom of the α-carbon of the tetronic acid ring imparting to it strongly acidic properties.

(*b*) *Bromination of carolic, carolinic and α-acetyltetronic acids.*

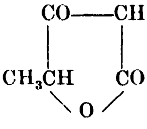
Considerable advance in our knowledge of the structure of these acids has been made by a detailed study of the products of bromination under varying conditions. Thus carolic acid in glacial acetic acid solution absorbs 1 molecule of bromine and gives 1 molecule of HBr and 1 molecule of monobromocarolic acid, $C_9H_9O_4Br$, containing its bromine atom in the butyrolactone half of the molecule since on hydrolysis it gives acetoin, CO_2 and bromobutyrolactone. In dilute acetic acid solution, on the other hand, carolic acid reacts in two ways:

$$\text{I.}\quad C_9H_{10}O_4 + 2Br_2 + H_2O = C_5H_4O_3Br_2 + C_4H_6O_2 + 2HBr$$

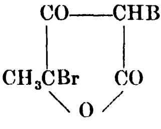
$$\text{II.}\quad C_9H_{10}O_4 + 2Br_2 + H_2O = C_5H_5O_3Br + C_4H_5O_2Br + 2HBr$$

In reaction I the products are a C_5 dibromide and butyrolactone, and in reaction II a C_5 monobromide and a bromobutyrolactone. In aqueous solution reaction I occurs, and in 50 % acetic acid solution both reactions occur but reaction II predominates. If carolic acid is, on the other hand, allowed first to react with 1 molecule of bromine in glacial acetic acid solution, then diluted to about 50 % acetic acid and a further molecule of bromine added, the products are exclusively the C_5 monobromide, bromobutyrolactone and HBr.

The C_5 monobromide has been shown to be *d*-α-bromo-γ-methyltetronic acid (XII) whilst the dibromide is very probably *d*-αγ-dibromo-γ-methyltetronic acid (XIII). Both of these bromides on catalytic reduction readily give the same *l*-γ-methyltetronic acid (I).



XII



XIII

With bromine in aqueous or 50 % acetic acid solution, carolinic acid reacts, like carolic acid, in two ways, the same *d*-α-bromo-γ-methyltetronic acid being obtained, whilst succinic and probably bromosuccinic acid replace butyrolactone and bromobutyrolactone. The identity of the two samples of *d*-α-bromo-γ-methyltetronic acid from carolic and carolinic acids respectively was proved by M.P., mixed M.P., titration and conversion into *l*-γ-methyltetronic acid and its dinitrophenylhydrazone.

It appears therefore that during bromination in dilute acetic acid solution the α-side chains are replaced by bromine. An exactly analogous behaviour was observed with synthetic α-acetyltetronic acid, which on bromination in dilute acetic acid gave α-bromotetronic acid.

(*c*) *Hydrolysis of carolic, carolinic and α-acetyltetronic acids.*

All three acids undergo hydrolysis with $2N$ H_2SO_4 at comparable rates, each giving 1 molecule of CO_2, carolic acid giving in addition 1 molecule acetoin and 1 molecule γ-hydroxybutyric acid (butyrolactone), carolinic acid giving 1 molecule acetoin and 1 molecule succinic acid, and α-acetyltetronic acid giving 1 molecule acetol and 1 molecule acetic acid. This rather striking property is undoubtedly due to the structure VII which they all have in common and which on opening the tetronic acid ring represents them as derivatives of diacetylacetic acid.

It will be noted, on the other hand, that formula II for carolic acid, obtained by analogy with dibutyrolactone, does not fit the ready hydrolysis of these compounds, since dibutyrolactone has been shown by Fittig and Ström [1892] on boiling with dilute mineral acid not to break down into its two C_4 compounds but to yield the extremely stable compound, oxetone:

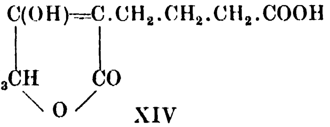
$$C_8H_{10}O_3+H_2O=C_7H_{12}O_2+CO_2.$$

(*d*) *Reduction of carolic, carolinic and α-acetyltetronic acids.*

Carolic acid, $C_9H_{10}O_4$, on reduction with palladium-charcoal-hydrogen, absorbs $2H_2$ and gives the reduced monobasic acid $C_9H_{14}O_4$ which on distillation loses H_2O and gives the neutral substance $C_9H_{12}O_3$. Carolinic acid, $C_9H_{10}O_6$, absorbs $2H_2$, giving the reduced acid $C_9H_{12}O_5$ whilst α-acetyltetronic acid $C_6H_6O_4$ also absorbs $2H_2$ at a comparable rate with carolic and carolinic acids, giving α-ethyltetronic acid. With α-acetyltetronic acid therefore the ketonic group of the side-chain is reduced to CH_2, and by analogy we might expect carolic and carolinic acids to behave similarly. Carolinic acid also gives the same general reaction, and the fact that reduced carolic acid appears to contain 1 molecule H_2O more than would be expected by analogy with reduced carolinic and α-acetyltetronic acids is explained by assuming that in reduced carolic acid the second ring becomes stabilised in the open form, and 1 molecule H_2O is lost only on distillation. All three acids before reduction give orange and after reduction red $FeCl_3$ colours, which are indistinguishable. The red colours given by the reduced acids are identical with those given by γ-methyltetronic and acetoacetic acids and are due to the keto-enol grouping in the tetronic acid ring.

Reduced carolic, carolinic and α-acetyltetronic acids (α-ethyltetronic acid) all give on hydrolysis substances which reduce Fehling's solution in the cold and slowly give bis-dinitrophenylhydrazones, and probably therefore contain the CHOH.CO grouping. This confirms the view that the tetronic acid ring itself is not affected by reduction under our conditions, and moreover γ-methyltetronic acid itself is not reduced with our catalyst.

Reduced carolic acid may therefore be represented by structure X and reduced carolinic acid by structure XIV.



XIV

It would be difficult to fit the results obtained on reduction with formula II for carolic acid and impossible with formula III for carolinic acid.

(*e*) *Absorption spectra of carolic, carolinic, α-acetyltetronic, γ-methyltetronic acids and of their reduction products.*

As will be shown in a subsequent publication, the structures assigned to the above compounds fit the requirements of their absorption spectra. These have been investigated by Dr E. L. Hirst of Birmingham University. Thus whilst carolic, carolinic and α-acetyltetronic acids all give a double-banded spectrum, one band characterising the tetronic acid ring and the second the ketone group immediately outside this ring, all the three corresponding reduced acids show only a single band corresponding to that of either γ-methyl- or α-ethyl-tetronic acid. Thus reduction results in all three cases in the loss of the ketonic absorption band.

(*f*) *Reactions of carolic, carolinic and α-acetyltetronic acids with 2:4-dinitrophenylhydrazine.*

The ketonic nature of all these compounds can be readily confirmed by means of 2:4-dinitrophenylhydrazine. Benary [1910], working with α-acetyltetronic acid and phenylhydrazine, found that a monophenylhydrazone was readily formed, and he showed that it was the carbonyl group of the side chain and not that of the tetronic acid ring which reacted. We have found that on treating α-acetyltetronic acid or carolinic acid with Brady's reagent (2:4-dinitrophenylhydrazine in 2*N* HCl) the yellow monodinitrophenylhydrazone is immediately precipitated. Carolic acid does not give any immediate precipitate. After standing 24–48 hours, a precipitate begins slowly to separate and continues to separate for 6–8 weeks. The precipitate initially contains a monodinitrophenylhydrazone which is fairly soluble in water, together with a bis-dinitrophenylhydrazone and after 8 weeks consists entirely of the pure bis-compound. Both compounds are dinitrophenylhydrazones of carolic acid + H_2O ($C_9H_{12}O_5$). The bis-dinitrophenylhydrazone tends to revert to the monoderivative on storing. It appears therefore that during this reaction, which is carried out in 2*N* HCl solution, H_2O is slowly added to open the second ring and that the monodinitrophenylhydrazone is then slowly precipitated and transformed into the bis-derivative.

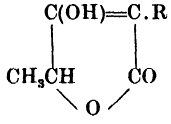
All three monodinitrophenylhydrazones are soluble and the bis-derivative of carolic acid is insoluble in bicarbonate. It would be impossible to obtain a bis-derivative with formula II for carolic acid. Attempts to obtain the bis-derivatives with α-acetyltetronic and carolinic acids, on standing 6–8 weeks with Brady's reagent, were unsuccessful. Carolinic acid still gave only the monoderivative, while α-acetyltetronic acid suffered slow hydrolytic degradation under these conditions giving the bis-dinitrophenylhydrazone of methylglyoxal. The difference in behaviour of the monodinitrophenylhydrazones of carolic and carolinic acids towards an excess of Brady's reagent is probably due to the fact that the former dinitrophenylhydrazone is very soluble whilst the latter is insoluble in the reagent.

(*g*) *Reactions of carolic, carolinic, α-acetyltetronic and γ-methyltetronic acids with diazomethane.*

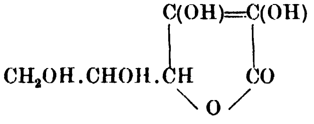
Carolic acid on treatment with diazomethane in incompletely dry ether, reacted very slowly, and after keeping overnight, removing the solvent and drying, a yellow oil was obtained which had a methoxyl content slightly greater (15·9 %) than that of a monomethyl derivative (14·5 %). This compound however slowly hydrolysed, even on shaking with water and readily on keeping overnight at room temperature with *N* NaOH, the methoxyl content of the material recovered from the alkaline solution being only 2·8 %. This behaviour was at first regarded as favouring the lactonic acid formula II for carolic acid, assuming that the lactonic ring opened to give the methyl ester. It has now been found however that the arrangement of ketonic groups in these acids renders the methoxyl group much more labile than in a normal methyl ether. Thus the methoxyl content of the monomethyl ether of γ-methyltetronic acid (I), which contains only one CO group in the β-position to the methoxyl group, fell on keeping with *N* NaOH for 24 hours from 24·5 to 14·7 %, and of the monomethyl ether of α-acetyltetronic acid (VI), which contains two CO groups in β-positions to the methoxyl group, fell from 20·7 to 3·6 %, the behaviour exactly resembling that of carolic acid itself. Carolinic acid gives a dimethyl derivative with diazomethane—a methyl ether methyl ester—which with N NaOH very readily loses one, and more slowly loses the second (presumably the ester), methyl group.

This close similarity in behaviour between α-acetyltetronic, carolic and carolinic acids, supported by the absorption spectra data, makes it very probable that in carolic and carolinic acids γ-hydroxybutyric and succinic acids are condensed respectively with γ-methyltetronic acid to give ketonic structures (IV and V) similar to α-acetyltetronic acid. These formulae have therefore been allotted to carolic ($+H_2O$) and carolinic acids respectively, which may therefore be formulated as α-[γ-hydroxybutyryl]-γ-methyltetronic and α-[β-carboxypropionyl]-γ-methyltetronic acids.

Finally the close analogy between the tetronic acid half of the molecule of carolic and carolinic acids (XV) and the structure of ascorbic acid (XVI) (vitamin C) should be noted.



XV



XVI

This analogy in structure is strongly borne out by the absorption spectra. As will be shown in a later publication, γ-methyltetronic acid gives a similar spectrum to that of ascorbic acid, and the band moves in acid and alkaline solution in the same way as does the band of ascorbic acid.

EXPERIMENTAL.

A. *General properties of carolic, carolinic and α-acetyltetronic acids.*

(i) *Carolic acid.*

Carolic acid, $C_9H_{10}O_4$, M.P. 132°, $[\alpha]_{5461}+84°$, gives a bright orange $FeCl_3$ colour and a negative nitro-chromic acid reaction for the primary alcohol grouping, but the latter test becomes positive on standing, due probably to ring opening. The immediate violet colour with $NaNO_2$, which is given by tetronic acids having the α-CH_2 group either unsubstituted or substituted by an easily removable substituent, *e.g.* bromine [Wolff, 1896], is not given immediately by carolic acid. On warming with concentrated H_2SO_4, carolic acid dissolves, giving a colourless solution which on heating to 140° becomes a deep bluish red.

An aqueous solution of the acid blues Congo red. The acid in dry anisole solution has however no active hydrogen as indicated by negative Zerewitinoff determinations by Roth's method. In pyridine, on the other hand, the acid possesses one active hydrogen. Thus 7·52 mg. carolic acid at 28° in dry anisole gave 0·02 ml. CH_4, and 9·75 mg. in pyridine gave 1·18 ml. CH_4, the latter corresponding to 0·98 active hydrogen atom. Carolic acid titrates in cold aqueous solution as a monobasic acid; thus 0·2322 g. required 12·80 ml. $N/10$ NaOH for titration to a permanent pink colour with phenolphthalein (the first pink flush was obtained with 12·6 ml. $N/10$ NaOH), corresponding to an equivalent of 181·4 ($C_9H_{10}O_4$, assumed monobasic, requires 182·1). This titration was not materially altered on heating with excess NaOH. Thus heating for ½ hour at 55°, and subsequently for a further ¾ hour at 80–85° only increased the titre from 12·8 to 13·3 and 13·7 ml. respectively.

The acid also shows a somewhat anomalous behaviour in respect to melting-point. A sample of the acid crystallised from absolute alcohol melted at 132°. Not only did the melting-point tend to fall on storage, but on melting and resetting it fell and became constant at 112°. Moreover there was no loss of water or CO_2 on heating in dry nitrogen at the melting-point although the melting-point again fell from 132 to 112°. The material melting at 112° on recrystallisation from alcohol again melted at 132°. This change may be related to the keto-enolic type of structure.

The acid gives a very soluble silver salt. Thus 0·3073 g. of carolic acid was neutralised with 17·1 ml. $N/10$ NaOH and $AgNO_3$ added. The silver salt on concentration *in vacuo* at room temperature to 5 ml. showed no signs of crystallising.

Attempted acetylation of carolic acid. Acetylation of carolic acid both by the acetic anhydride-pyridine and by the acetic anhydride-sodium acetate methods failed owing to complete decomposition and blackening. Darkening did not occur however when carolic acid was heated either with acetic anhydride or with acetyl chloride, and acetylation was therefore attempted as follows. 1 g. carolic acid was heated with 15 ml. acetyl chloride for 1 hour in a boiling water-bath, the acetyl chloride mostly distilled off and light petroleum added. The product (0·95 g.) separated as a colourless crystalline solid, was rubbed up with successive amounts of light petroleum and melted at 112°. After recrystallisation from ethyl alcohol, it melted at 132° (*cf.* previous section). The melting-point was not depressed on mixing with carolic acid. Also 0·0264 g. required 1·48 ml. $N/10$ NaOH corresponding to an equivalent of 178·3. ($C_9H_{10}O_4$, assumed monobasic, requires 182). It appears that carolic acid does not form an acetyl derivative and that it is unlikely therefore that it contains a free OH grouping.

Action of alkaline iodine on carolic acid. Although carolic acid with strong reagents (10 % NaOH and $N/10$ I) readily gives CHI_3, no CHI_3 is formed nor is iodine absorbed when the acid is titrated with alkaline iodine in very dilute solution by the method used for determination of kojic acid [Birkinshaw and Raistrick, 1931]. Thus 5 ml. of an aqueous solution containing 10·86 mg. carolic acid, on standing at room temperature for 90 minutes with 40 ml. $N/10$ iodine and 50 ml. $N/10$ NaOH showed an absorption of only 0·3 ml. $N/10$ iodine.

Action of Wijs's reagent on carolic acid. 0·3947 g. carolic acid in 10 ml. CCl_4 was treated with 25 ml. Wijs's solution. The difference in titration of the blank and the reaction fluid was only 0·8 ml. $N/10$ thiosulphate. (Theoretical for absorption of 1 molecule $I_2 = 43·4$ ml.). The absorption may therefore be regarded as negligible.

(ii) *Carolinic acid.*

Carolinic acid, $C_9H_{10}O_6$, M.P. 129° (monohydrate, M.P. 123°), $[\alpha]_{5461} + 60°$ (in water) gives with $FeCl_3$ an immediate orange precipitate soluble in excess to a bright orange coloured solution. It does not give a colour with $NaNO_2$. An aqueous solution blues Congo red. The acid titrates sharply in the cold as a dibasic acid, and determinations in dry anisole by the Zerewitinoff method for active hydrogen give values which are slightly high for two active hydrogen atoms (Roth). Thus 11·015 mg. carolinic acid gave 2·39 ml. CH_4 (at 18°) and 2·46 ml. CH_4 (at 95°). ($C_9H_{10}O_6$ requires for one active hydrogen the production of 1·05 ml. CH_4 at N.T.P.) Similar values were obtained in pyridine.

Carolinic acid like carolic acid does not react with Wijs's reagent nor does it acetylate on boiling with acetyl chloride. It does not give a bluish red colour with hot concentrated H_2SO_4 as does carolic acid.

(iii) *α-Acetyltetronic acid,* $C_6H_6O_4$.

This was synthesised by Benary's [1909] method, by condensation of ethyl β-aminocrotonate and chloroacetylchloride with subsequent hydrolysis of the condensation product. After recrystallisation from benzene it melted at 83·5°. (Found: C, 50·65; H, 4·25 %. $C_6H_6O_4$ requires C, 50·69; H, 4·26 %.) It gives an orange $FeCl_3$ colour identical with that of carolic acid but no colour with $NaNO_2$. On titration to phenolphthalein 53·1 mg. required 3·695 ml. $N/10$ NaOH corresponding to an equivalent of 143·7 ($C_6H_6O_4$ titrating as a monobasic acid requires 142).

B. *Bromination of carolic, carolinic and α-acetyltetronic acids.*

Considerable advance in our knowledge of the structure of these acids has been made by a detailed study of the products obtained by bromination under varying conditions.

(I) *Bromination of carolic acid in glacial acetic acid solution: preparation of* d-*monobromocarolic acid.* 2 g. carolic acid were dissolved in 20 ml. glacial acetic acid and a solution containing 2·5 ml. Br in 100 ml. glacial acetic acid was added 1 ml. at a time at room temperature. The reaction was slow at first but became very much more rapid, and an amount of bromine was decolorised corresponding to 2 atoms Br. Hydrobromic acid was given off. The solution was placed in a desiccator over solid KOH and the hydrobromic and acetic acids were quickly removed at room temperature at very low pressure. A thick yellow oil remained which crystallised only after standing for several weeks. The dried material from a second experiment was therefore immediately rubbed up with a little methyl alcohol and allowed to stand in the cold room, when 1·37 g. of crystals separated. The mother-liquor was boiled with a little charcoal, filtered and again placed to crystallise in the cold room, giving a second crop of crystals, weight 0·65 g. The total crude yield represents 70 % of the theory for the production of monobromocarolic acid. The crystals melted at 149–151°. Bromocarolic acid is best purified by recrystallisation (1·2 g.) from boiling methyl alcohol (14 ml.) from which solvent it separates in hard, very large homogeneous plates (0·8 g.), M.P. 158°. (Found (Schoeller): C, 41·57, 41·59; H, 3·47, 3·42; Br, 31·15, 31·29 %. $C_9H_9O_4Br$ requires C, 41·38; H, 3·48; Br, 30·61 %.)

0·1435 g. in 20 ml. absolute alcohol required 5·53 ml. $N/10$ NaOH for neutralisation to phenolphthalein, corresponding to an equivalent of 260 ($C_9H_9O_4Br$ titrating as a monobasic acid requires 261).

Monobromocarolic acid in water ($c = 1·06$) has $[\alpha]_{5461} = +39°$.

In a control experiment it was shown that 50 % of the bromine absorbed had been eliminated as HBr and was precipitated and estimated as AgBr.

Hydrolysis of d-*monobromocarolic acid.* This hydrolysis was carried out in order to determine whether the bromine atom had entered the butyrolactone or the methyltetronic acid half of the molecule. Thus if it had entered the methyltetronic acid ring we should expect on hydrolysis to obtain diacetyl, butyrolactone and CO_2, whereas if it had entered the butyrolactone half of the molecule we should expect acetoin, CO_2 and either bromo- or hydroxy-butyrolactone.

0·818 g. bromocarolic acid was hydrolysed by boiling for 3 hours with 20 ml. $2N$ H_2SO_4 in a stream of CO_2-free nitrogen, the gases evolved being passed up a reflux condenser and then first through a bubbler containing Brady's reagent (2 : 4-dinitrophenylhydrazine in $2N$ HCl) and finally through bubblers containing $N/10$ baryta. The baryta bubblers showed an evolution of 58·9 ml. $N/10$ CO_2 corresponding to 94 % of the theoretical for 1 molecule CO_2. The bubbler containing Brady's reagent, on standing, contained only a very slight precipitate as is usual when acetoin is formed. Diacetyl could not have been formed since this substance is so very volatile that a heavy precipitate would have been obtained under our conditions.

The hydrolysate was next cooled and titrated. On subtracting from the total titration figure the titre of the H_2SO_4 used for hydrolysis, it was found that 3·4 ml. *N* acid still remained. This corresponds closely to one equivalent of acid (theoretical 3·13 ml.) and it appears therefore that the bromo- (or hydroxy-)butyrolactone is almost entirely present as the opened-up acid. This was later confirmed by titration of the isolated acid. The neutralised solution was made up to a standard volume and aliquot portions used in the following experiments.

(*a*) A portion of the neutralised hydrolysate was distilled *in vacuo* and the distillate shown to contain acetoin by its reduction of Fehling's solution in the cold, by its positive Voges-Proskauer reaction and by the slow production, in the way characteristic of acetoin, of the bis-dinitrophenylhydrazone of diacetyl, M.P. 318° decomp., unaltered by admixture with an authentic specimen.

(*b*) The acetoin content was determined in an aliquot by the Wood-Ost method, the reducing power of the whole hydrolysate corresponding to 0·2656 g. acetoin, representing 96 % of the theoretical from 0·818 g. of bromocarolic acid.

(*c*) The ionised Br of a portion of the hydrolysate was determined by precipitation as AgBr and corresponded to 31 % of the bromine actually present. It appears therefore that only one-third of the bromine has been separated by hydrolysis and that two-thirds still remain attached to one of the hydrolysis products, *viz.* to the butyrolactone.

(*d*) The residual neutral hydrolysate was extracted continuously with ether until acetoin was completely removed, the solution then acidified and again extracted continuously with ether. On removing the ether, a brown oil remained which was dried overnight over H_2SO_4 *in vacuo*. 0·0972 g. of this oil required, on neutralisation in the cold to phenolphthalein, 5·4 ml. *N*/10 NaOH corresponding to an equivalent of 180 ($C_4H_7O_3Br$ titrating as a monobasic acid requires 183), and contained 40·3 % Br (theoretical for $C_4H_7O_3Br = 43{\cdot}7$ %). The material did not give a crystalline phenylhydrazide as does butyrolactone under the same conditions, and on heating with NaOH lost its bromine, giving presumably a dihydroxybutyric acid which was not, however, further identified.

From these experiments it appears certain that bromination of carolic acid in glacial acetic acid leads to the absorption of 1 molecule Br and to the formation of monobromocarolic and hydrobromic acids, the former of which has its Br atom in the butyrolactone half of the molecule.

(II) *Bromination of carolic acid in aqueous solution and in 50 % acetic acid solution.* Carolic acid reacts with bromine in aqueous and in 50 % acetic acid solution in two ways:

$$\text{(i)} \qquad C_9H_{10}O_4 + 2Br_2 + H_2O = C_5H_4O_3Br_2 + C_4H_6O_2 + 2HBr$$

thus giving rise to $\alpha\gamma$-dibromo-γ-methyltetronic acid and butyrolactone;

$$\text{(ii)} \qquad C_9H_{10}O_4 + 2Br_2 + H_2O = C_5H_5O_3Br + C_4H_5O_2Br + 2HBr$$

thus forming α-bromo-γ-methyltetronic acid and bromobutyrolactone. In aqueous solution reaction (i), and in 50 % acetic acid solution reaction (ii) predominates.

Thus when 1 g. carolic acid is dissolved in 40 ml. water or 50 % acetic acid and a standardised solution of bromine in water or 50 % acetic acid respectively is added, immediate decoloration of bromine occurs and a sharp end-point is obtained after the equivalent of 2 molecules of bromine has been added. If the ionised bromine of an aliquot portion of these two solutions be then determined by precipitation as AgBr, it is found that 2 molecules of HBr have been formed in both reactions.

(*a*) *Isolation of* d-*α-bromo-γ-methyltetronic acid, $C_5H_5O_3Br$.* 1 g. of carolic acid was dissolved in 20 ml. 50 % acetic acid and the theoretical amount ($2Br_2$) of a solution containing 2·5 ml. bromine in 100 ml. 50 % acetic acid slowly added. The solution was then rapidly evaporated to dryness by standing over sticks of KOH in a high vacuum at room temperature. Under these conditions, acetic and hydrobromic acids, butyrolactone and bromobutyrolactone pass over to the KOH, together with any dibromomethyltetronic acid which may have been formed, since this is decomposed under these conditions. 0·85 g. of crude material remained (the theoretical amount for the production of 1 molecule of $C_5H_5O_3Br$ is 1·06 g.). The residual crude α-bromo-γ-methyltetronic acid was well washed with cold benzene and light petroleum and then weighed 0·60 g. M.P. 165°. After several recrystallisations from benzene it separated in beautiful long needles and the M.P. became constant at 172°. It gave a red $FeCl_3$ and a violet $NaNO_2$ colour. (Found (Schoeller): C, 31·17; H, 2·83; Br, 41·49 %. $C_5H_5O_3Br$ requires C, 31·10; H, 2·61; Br, 41·40 %.)

0·0604 g. required 6·30 ml. $N/20$ NaOH for neutralisation to phenolphthalein corresponding to an equivalent of 192 ($C_5H_5O_3Br$ titrating as a monobasic acid requires 193).

It had in water ($c=2·7$ g.) $[\alpha]_{5461}=+9·47°$.

(*b*) *Reduction of* d-*α-bromo-γ-methyltetronic acid $C_5H_5O_3Br$ to an acid $C_5H_6O_3$, shown to be* l-*γ-methyltetronic acid.* *d*-α-Bromo-γ-methyltetronic acid (2 g.) was next reduced catalytically by palladium-charcoal-hydrogen. The sodium salt of the acid hydrogenated with great ease and was therefore used in order to minimise loss by adsorption on the charcoal.

The reduction, which was carried out as described later, was complete in about 5 minutes and corresponded to an uptake of 1 molecule H_2. The catalyst was filtered off and washed with $2N$ NaOH and then with water. The filtrate and washings were combined, acidified and extracted three times with an equal volume of ether. The ethereal extracts were dried over $MgSO_4$ and the ether removed *in vacuo*. In this way was obtained 0·71 g. of almost pure crystalline acid corresponding to 60 % of the theoretical yield, M.P. 112°. The acid recrystallised from benzene-light petroleum in curved feathery needles, M.P. 115°. It also readily sublimed *in vacuo* and the sublimate melted at 115°. (Found (Schoeller): C, 52·72, 52·75; H, 5·33, 5·30 %. $C_5H_6O_3$ requires C, 52·61; H, 5·30 %.)

0·1329 g. required 11·63 ml. $N/10$ NaOH for neutralisation to phenolphthalein, corresponding to an equivalent of 114 ($C_5H_6O_3$ titrating as a monobasic acid requires 114).

The free acid in water ($c=1·426$) had $[\alpha]_{5461}=-21°$.

The acid gave strong red $FeCl_3$ and violet $NaNO_2$ colours, and with Brady's reagent readily gave a crystalline monodinitrophenylhydrazone, M.P. 235°, unchanged by recrystallisation from nitrobenzene-toluene. (Found (Schoeller): C, 44·95; H, 3·31; N, 18·71 %. $C_{11}H_{10}O_6N_4$ requires C, 44·90; H, 3·43; N, 19·05 %.)

The products of hydrolysis of the acid were next investigated.

The titrated solution referred to above (0·1329 g.) was washed into a hydrolysis flask, the total volume with washings being 50 ml. 50 ml. $2N$ H_2SO_4 were added and the solution heated to boiling in a stream of CO_2-free nitrogen, the resultant gases being passed through baryta bubblers. After 3 hours' hydrolysis, 23·4 ml. $N/10$ CO_2 had been evolved (theory for 1 molecule $CO_2=23·3$ ml.). The hydrolysate was cooled, the H_2SO_4 neutralised with concentrated KOH, made up to 150 ml. and aliquot portions used for the following tests. The solution gave a positive Voges-Proskauer reaction, reduced Fehling's solution in the cold, slowly in the manner characteristic of acetoin gave the bis-dinitrophenylhydrazone of diacetyl, M.P. 318° (not depressed by mixing with an authentic specimen), and on determination of the acetoin content by the Wood-Ost method was shown to contain 0·1004 g. of carbinol (theory for 1 molecule acetoin 0·1026 g. carbinol).

The acid melted at 115°, was laevorotatory, titrated as a monobasic acid, contained one CO group and gave on hydrolysis 1 molecule each of CO_2 and acetoin. It seemed certain therefore that it was *l*-γ-methyltetronic acid the *dl*-form of which had previously been synthesised by Benary [1911], who gives the M.P. as 117°. The *dl*-variety of γ-methyltetronic acid was accordingly synthesised by Benary's method by condensation of ethyl sodiomalonate with chloroacetyl chloride and subsequent hydrolytic decarboxylation. It melted at 115°. The synthetic acid gave the same red $FeCl_3$ and violet $NaNO_2$ colours, and on hydrolysis under the conditions quoted above gave quantitatively 1 molecule each of CO_2 and acetoin. Although the melting-points of the two samples of methyltetronic acid were the same, they showed a slight depression on mixing due, undoubtedly, to the fact that the synthetic acid was the *dl*-variety, whereas the acid from the monobromide was the *l*-variety. Both samples of acid, however, gave the same dinitrophenylhydrazone, M.P. 235°, and the two hydrazones on admixture showed no depression of melting-point.

The acid was brominated in dry chloroform under conditions used by Wolff [1896] for bromination of tetronic acid, *i.e.* conditions leading with certainty to the formation of *d*-α-bromo-γ-methyltetronic acid. An acid was thus readily obtained which after recrystallisation from benzene had M.P. 172°. The acid gave a red $FeCl_3$ and violet $NaNO_2$ colour and showed no depression of M.P. on mixing with the *d*-α-bromo-γ-methyltetronic acid, $C_5H_5O_3Br$, obtained by bromination of carolic acid in 50 % acetic acid solution. It is certain therefore that the acid split off from carolic acid on bromination in 50 % acetic acid solution is *d*-α-bromo-γ-methyltetronic acid.

(*c*) *Isolation of the dibromide* $C_5H_4O_3Br_2$ *and its identification as* d-$\alpha\gamma$-*dibromo*-γ-*methyltetronic acid.* 1 g. of carolic acid was dissolved in 40 ml. water and the theoretical amount of bromine water added. Using the silver method it was shown that 50 % of the bromine absorbed was eliminated as HBr. The solution was then extracted three times with an equal volume of ether, the ethereal extracts dried with anhydrous $MgSO_4$, filtered and the ether removed *in vacuo*. In this way 1·55 g. of a product were obtained consisting chiefly of beautifully crystalline material together with a little oil, presumably butyrolactone. The product was dissolved in dry ether and two volumes of light petroleum were added. On standing 0·38 g. of large crystals, consisting of a mixture of long colourless prisms and flat hard plates was obtained, M.P. 114–5°. It was found impracticable to separate this mixture by fractional crystallisation but a satisfactory separation was effected by fractional sublimation into the anhydrous dibromide $C_5H_4O_3Br_2$, prisms, M.P. 88°, and its monohydrate $C_5H_4O_3Br_2, H_2O$, plates, M.P. 135°. The hydrate loses water at the melting-point and, after resetting, melts constantly at 88°. (Found for anhydrous substance (Schoeller): C, 21·82; H, 1·48 %. $C_5H_4O_3Br_2$ requires C, 22·08; H, 1·49 %: Found for hydrate: C, 20·90; H, 2·05 %. $C_5H_4O_3Br_2$, H_2O requires C, 20·70; H, 2·09 %.)

Bromine determinations on these two compounds were unsatisfactory, probably owing to the large amount of bromine in the molecule. Thus a duplicate specimen of each of the anhydrous and hydrated materials was submitted to two independent analysts (*a*) and (*b*) with the following results: *Anhydrous dibromide*, Found: (*a*) 57·4 %; (*b*) 55·9 %. ($C_5H_4O_3Br_2$ requires 58·8 %.) *Monohydrate*, Found: (*a*) 53·4 %; (*b*) 52·7 %. ($C_5H_4O_3Br_2$, H_2O requires 55·1 %.)

Specific rotation of monohydrate in water ($c = 2{\cdot}04$) $[\alpha]_{5461} = +36{\cdot}2°$.

Both dibromides on titration to an initial end-point, followed by keeping overnight at room temperature with excess $N/10$ NaOH, showed the presence of one acidic and one lactonic grouping, from which it follows that the bromide M.P. 135°, $C_5H_4O_3Br, H_2O$ is a true hydrate and not the opened-up acid. Accurate titration values could not be obtained owing to the partial hydrolysis (about 8 %) of the bromine atoms on standing with $N/10$ NaOH at room temperature overnight.

Both the hydrated and anhydrous forms of the dibromide on hydrogenation with Pd-charcoal and hydrogen readily give a monobasic acid, $C_5H_6O_3$, M.P. 115°, giving a red $FeCl_3$ colour and a violet $NaNO_2$ colour, which shows no depression of melting-point when mixed with the corresponding acid obtained by hydrogenation of *d*-α-bromo-γ-methyltetronic acid. This acid $C_5H_6O_3$ has been shown to be *l*-γ-methyltetronic acid. The dibromide is therefore almost certainly αγ-dibromo-γ-methyltetronic acid, since with this formulation the substance would behave as a mono-acid monolactone, and moreover, as we have shown, αα′-dibromo-γ-methyltetronic acid, like αα′-dibromotetronic acid [Wolff, 1896] is a very unstable neutral substance and in presence of water readily decomposes.

(III) *Bromination of carolic acid first in glacial acetic acid, followed by dilution to 50 °/₀ acetic acid and further bromination.* The best yields of *d*-α-bromo-γ-methyltetronic acid were obtained by adding bromine (1 molecule) in glacial acetic acid solution to a solution of carolic acid (1 molecule) in the same solvent, diluting to 50 % acetic acid solution and then adding a second molecule of bromine in 50 % acetic acid. The bromide was then isolated as in the previous experiments and the yield proved to be almost theoretical. The bromide did not depress the M.P. of the specimen prepared as previously described.

(IV) *Bromination of carolinic acid in 50 °/₀ acetic acid solution.* Carolinic acid (1 g.) was brominated in 50 % acetic acid solution exactly as in the experiment with carolic acid; 2 molecules bromine were absorbed giving rise as was shown by precipitation as AgBr to 2 molecules HBr. The solution was evaporated in high vacuum over KOH to dryness. A crystalline residue remained which was extracted with boiling benzene. The insoluble portion was filtered off and the filtrate, on cooling, deposited crystals of *d*-α-bromo-γ-methyltetronic acid which were shown to be identical with the bromide from carolic acid. On bromination, carolinic acid gives, therefore, the same *d*-α-bromo-γ-methyltetronic acid as does carolic acid.

The benzene-insoluble residue was carefully sublimed and the sublimate resublimed. A white powder was obtained which melted at 188° and did not depress the M.P. of an authentic specimen of succinic acid. On titration to phenolphthalein, 0·0641 g. required 10·80 ml. $N/10$ NaOH corresponding to an equivalent of 59·4 ($C_4H_6O_4$ titrating as a dibasic acid requires 59).

(V) *Bromination of carolinic acid in aqueous solution.* 1 g. of carolinic acid was brominated in aqueous solution exactly as with carolic acid, in order to discover whether the same αγ-dibromo-γ-methyltetronic acid was also produced. Here on evaporation to dryness a crystalline residue remained which was shown to consist of this dibromide and succinic acid. With carolic acid the products were the dibromide and the volatile oily butyrolactone and these were readily separated. Greater difficulty was experienced with the products from carolinic acid. The readiest separation was obtained by fractional sublimation. On subliming, succinic acid first formed the usual compact sublimate whilst below this the dibromide formed very characteristic large well-shaped prisms. These were easily detached and after resublimation had M.P. 88°, not depressed by mixing with a sample of the dibromide $C_5H_4O_3Br_2$ from carolic acid. The succinic acid was also resublimed and characterised by M.P., mixed M.P. with an authentic specimen, and by titration.

It appears, therefore, that carolinic acid on bromination gives the same *d*-α-bromo- and *d*-αγ-dibromo-γ-methyltetronic acids as does carolic acid, and this was confirmed by reduction of the two bromides, when the same *l*-γ-methyltetronic acid resulted, which gave the same monodinitrophenylhydrazone as was obtained in the experiments with carolic acid.

(VI) *Bromination of α-acetyltetronic acid.* 1·19 g. of α-acetyltetronic acid were dissolved in 15 ml. 50 % acetic acid and a standard solution of bromine in 50 % acetic acid was added from a burette. The solution, which absorbed 2 molecules bromine, was evaporated as before over KOH in a high vacuum and gave a colourless crystalline solid. After recrystallisation from benzene it melted at 183°. (Found: C, 26·95; H, 1·94; Br, 44·30 %. $C_4H_3O_3Br$ requires C, 26·83; H, 1·69; Br, 44·66 %.) It did not depress the M.P. of a synthetic sample of α-bromotetronic acid [Wolff, 1896]. Like the latter, it gave a violet colour with $NaNO_2$, bromine being displaced from the α-position. These facts show conclusively that during the bromination of α-acetyltetronic acid, the acetyl group is removed and replaced by a bromine atom in the same way as are the side chains of carolic and carolinic acids.

C. *Hydrolysis of carolic, carolinic and α-acetyltetronic acids.*

One of the most characteristic properties of these acids is their very ready hydrolysis by boiling dilute acids and alkalis.

(I) *Hydrolysis of carolic acid.* Carolic acid (5 g.) was hydrolysed by boiling under a reflux condenser for 3 hours with 250 ml. $2N H_2SO_4$ in a current of CO_2-free nitrogen, the gases evolved being passed through bubblers containing standard baryta. CO_2 equivalent to 524 ml. $N/10$ baryta was produced. The evolution of 1 molecule CO_2 by 1 molecule of carolic acid requires 549 ml. baryta.

The hot hydrolysis solution was neutralised with N NaOH to a permanent end-point, the solution titrating in the manner of a lactone. The neutral solution was then distilled *in vacuo* to dryness several times and the distillate and residue were examined separately.

(*a*) *Distillate.* This was made up to 1250 ml. and aliquot portions were examined.

(1) A portion readily reduced Fehling's solution in the cold and gave a strong Voges-Proskauer reaction usually regarded as characteristic of acetoin and diacetyl.

(2) On adding excess 2 : 4-dinitrophenylhydrazine in $2N$ HCl, an orange turbidity was produced and a crystalline bis-dinitrophenylhydrazone slowly separated on standing 6 weeks, which after recrystallisation from nitrobenzene-toluene melted at 318°. Samples of diacetyl and acetoin were similarly treated with Brady's reagent. Diacetyl immediately gave a heavy precipitate of the yellow monodinitrophenylhydrazone which on standing overnight with excess of reagent was gradually converted into the orange bis-dinitrophenylhydrazone. This, on crystallisation from nitrobenzene-toluene, melted at 318°. With acetoin, however, an orange turbidity was first obtained and an orange bis-dinitrophenylhydrazone, M.P. 318°, gradually separated over a period of 6 weeks. It did not depress the melting-point of the bis-dinitrophenylhydrazone of diacetyl.

Acetoin, therefore, which according to Kling [1905, 1, 2; 1906] is not a hydroxyketone but has the structure

$$CH_3.CH\overset{O}{—}C(OH).CH_3,$$

does not give an immediate precipitate with 2:4-dinitrophenylhydrazine, but is slowly oxidised to diacetyl.

The bis-dinitrophenylhydrazone obtained from the distillate gave the following figures on micro-analysis (Schoeller): C, 43·44, 43·35; H, 3·25, 3·28; N, 24·99, 24·87 %. $C_{16}H_{14}O_8N_8$ requires C, 43·04; H, 3·16; N, 25·11 %.

It did not depress the melting-point of the bis-dinitrophenylhydrazone of diacetyl, but the manner of its separation showed conclusively that acetoin and not diacetyl was the actual product of hydrolysis.

(3) The amount of acetoin present was estimated by the reducing power as determined by the Wood-Ost method. 10 ml. contained 0·016 g. acetoin. Hence the total reducing power corresponded to that of 2 g. of the carbinol (theory 2·42 g. assuming that 1 molecule carolic acid gives 1 molecule acetoin). As a trace of acetoin is lost in the stream of nitrogen during hydrolysis this result may be regarded as sufficiently accurate.

(4) The amount of acetoin present was also estimated by weighing the bis-dinitrophenylhydrazone. 250 ml. with excess of Brady's reagent gave, after standing 6 weeks, 2·39 g. dinitrophenylhydrazone. The theoretical amount of hydrazone assuming $C_9H_{10}O_4 \rightarrow C_{16}H_{14}O_8N_8$ is 2·45 g.

(*b*) *Residue.* The residue was dissolved in a little water, acidified with 2*N* H_2SO_4 and the solution exhaustively extracted with ether. After removal of the ether, a very mobile sweet-smelling light brown oil remained and was dried for a short time *in vacuo* over H_2SO_4. This was shown to be butyrolactone as follows.

On distillation at the ordinary pressure, it almost completely passed over at 203°. It was redistilled and a sample on micro-analysis gave the following figures (Schoeller): C, 55·48, 55·58; H, 7·03, 7·06 %. $C_4H_6O_2$ requires C, 55·77; H, 7·03 %. 0·0930 g. required on titration in the cold less than 0·1 ml. *N*/10 NaOH, and after heating for ½ hour with excess NaOH and back-titrating, 10·75 ml. corresponding to an equivalent of 86·5 ($C_4H_6O_2$ titrating as a monobasic acid requires 86).

The oil on oxidation with HNO_3 (1:1) readily gave succinic acid. On heating with a slight excess of phenylhydrazine in a few ml. alcohol for 2 hours on a boiling water-bath, it gave a phenylhydrazide which crystallised in large shining plates from ethyl acetate, M.P. 94°. (Found: C, 61·88, 61·87; H, 7·09, 7·26; N, 14·68, 14·45 %. $C_{10}H_{14}O_2N_2$ requires C, 61·83; H, 7·27; N, 14·43 %.)

The phenylhydrazide did not depress the melting-point of a specimen prepared from butyrolactone which had been synthesised by the method of Fittig and Chanlaroff [1884]. Similar production of a hydrazide by valerolactone was early recorded by Wislicenus [1887].

The amount of butyrolactone produced on hydrolysis was estimated in a separate experiment as follows. 2·1521 g. carolic acid were hydrolysed as above, washed into a 700 ml. Erlenmeyer flask and titrated with *N* NaOH, first in the cold to neutralise the mineral acid present, and then after heating to estimate the butyrolactone. The total amount of *N* NaOH used by the butyrolactone was 11·90 ml. Assuming that 1 molecule carolic acid gives 1 molecule butyrolactone and no other acid products, 11·82 ml. *N* alkali would be required.

It is thus evident that hydrolysis of carolic acid gives rise to CO_2, acetoin and butyrolactone according to the equation

$$C_9H_{10}O_4+2H_2O=CO_2+CH_3.CO.CHOH.CH_3+\underbrace{CH_2.CH_2.CH_2.CO}_{O}$$

(II) *Hydrolysis of carolinic acid.* 1·004 g. carolinic acid (the hydrated form $C_9H_{10}O_6$, H_2O, M.P. 122° was used) were hydrolysed by boiling with 40 ml. dilute H_2SO_4 (equivalent to 95·2 ml. *N* acid) in a stream of CO_2-free nitrogen, the gases evolved being passed through standard baryta as with carolic acid. After 3 hours the equivalent of 84·0, after 4 hours of 85·9 ml. *N*/10 alkali had been used. The reaction $C_9H_{10}O_6, H_2O \rightarrow CO_2$ requires the production of 86·5 ml. *N*/10 CO_2. 1 molecule of CO_2 had therefore been produced.

The residual fluid and washings after cooling required 103·8 ml. *N* alkali for neutralisation in the cold, corresponding to a residual acidity of 103·8 − 95·2 = 8·6 ml. *N* acid. This figure was not increased on heating with excess NaOH. Assuming that a dibasic acid remained after hydrolysis, the residual acidity should be equivalent to 8·65 ml. *N* acid. The neutralised fluid was then evaporated *in vacuo* to dryness, water added and the process repeated five times. The combined distillates were made up to a known volume. This solution reduced Fehling's solution readily in the cold, gave a positive Voges-Proskauer reaction, and a portion of it with dinitrophenylhydrazine in 2*N* HCl slowly, after the manner of acetoin, gave the bis-dinitrophenylhydrazone of diacetyl, M.P. 318°, the M.P. not being depressed by admixture with an authentic specimen. The amount of acetoin in an aliquot portion of the distillate was determined as with carolic acid by the Wood-Ost method. The solution contained 0·3639 g. carbinol. The reaction $C_9H_{12}O_7 \rightarrow C_4H_8O_2$ requires from 1·004 g. carolinic acid, the production of 0·3808 g. carbinol. The amount recovered represents therefore 96 % of the theoretical for 1 molecule acetoin.

The residue remaining after distillation was dissolved in a little water, acidified and extracted continuously with ether. After removal of ether and drying, 0·528 g. of very pale brown crystalline material remained, which was shown to be succinic acid. The theoretical amount of succinic acid assuming that 1 molecule carolinic acid gave 1 molecule succinic acid is 0·51 g.

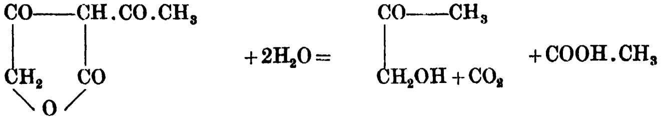
Carolinic acid therefore is hydrolysed with the same ease as carolic acid, giving 1 molecule each of CO_2, acetoin and succinic acid, according to the equation:

$$C_9H_{10}O_6+2H_2O=CO_2+CH_3.CO.CHOH.CH_3+COOH.CH_2.CH_2.COOH.$$

(III) *Hydrolysis of α-acetyltetronic acid.* 1·0551 g. of the acid were dissolved in 40 ml. dilute H_2SO_4 (≡ 82·6 ml. *N* H_2SO_4) and hydrolysed as with carolic acid. Immediately the fluid began to boil, CO_2 was evolved rapidly, as with carolic, carolinic and γ-methyltetronic acids. The total amount of CO_2 evolved corresponded to 146 ml. *N*/10 baryta. (The theoretical amount, assuming that 1 molecule $C_6H_6O_4$ gives 1 molecule CO_2 is 148·6 ml.) The hydrolysis fluid required 90·0 ml. *N* NaOH for neutralisation and there was, therefore, in addition to mineral acid 7·4 ml. *N* acid remaining after hydrolysis. Assuming that 1 molecule of a monobasic acid had been formed, the residual acidity would correspond to 7·43 ml. *N* acid. The neutralised fluid was distilled to dryness several times *in vacuo* and the combined distillates made up to a known volume. This liquid immediately reduced Fehling's solution in the cold, and with 2:4-dinitrophenylhydrazine gave slowly, over a period of 6 weeks, after the manner of acetoin, an orange-red precipitate which after recrystallisation from nitrobenzene-toluene melted at 304°. It did not depress the M.P. of an authentic specimen of the bis-dinitrophenylhydrazone of methylglyoxal. From the slow formation, oxidation appeared to occur and the actual hydrolysis product was very probably acetol. (Found: C, 41·78; H, 2·97; N, 25·97 %. $C_{15}H_{12}O_8N_8$ requires C, 41·66; H, 2·80; N, 25·92 %.)

The residual salts, on treatment with *p*-phenylphenacyl bromide [Drake and Bronitsky, 1930], gave an ester of M.P. 111°, which was not depressed by mixing with an authentic specimen of the phenylphenacyl ester of acetic acid. (Found: C, 75·67; H, 5·53 %. $C_{16}H_{14}O_3$ requires C, 75·56; H, 5·55 %.)

α-Acetyltetronic acid therefore breaks down on acid hydrolysis in the same way and with the same ease as do carolic and carolinic acids, giving 1 molecule each of acetol, CO_2 and acetic acid.



D. *Reduction of carolic, carolinic and α-acetyltetronic acids.*

In these and all subsequent reductions a palladium-charcoal catalyst was used. This was prepared as follows: 0·2 g. palladium chloride was dissolved in 25 ml. 2*N* HCl, shaken with 1 g. norite and saturated with hydrogen. The catalyst was filtered off and washed thoroughly with water. The activity of the catalyst appeared to be even greater after such short exposure to air, agreeing with the results of Willstätter and Waldschmidt-Leitz [1921]. The catalyst was now returned to the shaking apparatus and resaturated with hydrogen. The substance to be reduced was dissolved in the appropriate solvent, added to the catalyst and shaken, the rate of absorption of hydrogen being measured.

(I) *Reduction of carolic and carolinic acids.* With carolic acid (1 g. in 50 ml. water) and carolinic acid (1 g. in 50 ml. alcohol) the reduction was complete in 3 hours and hydrogen corresponding to $2H_2$ was absorbed in each case.

With carolic acid the reduction product, after filtering off the catalyst, was isolated by continuous extraction with ether, the ethereal extract being dried with $MgSO_4$ and the solvent removed. A colourless oil remained which did not crystallise even on long standing. It only became constant in weight when dried in high vacuum at 60–70° for 10 hours. (Found: C, 58·11, 58·31; H, 7·85, 7·81 %. $C_9H_{14}O_4$ requires C, 58·03; H, 7·58 %.)

0·1736 g. dissolved in water required 9·50 ml. *N*/10 NaOH for neutralisation in the cold to phenolphthalein corresponding to an equivalent of 183 ($C_9H_{14}O_4$ titrating as a monobasic acid requires 186). It appears therefore that in the reduction of carolic acid, $C_9H_{10}O_4$, $2H_2$ are absorbed and the reduced acid $C_9H_{14}O_4$ contains $2H_2$ more than carolic acid.

The reduced acid, on distillation in a high vacuum, loses 1 molecule H_2O, giving a neutral product which after recrystallisation from ether-light petroleum melted at 45°. (Found (Schoeller): C, 64·19, 64·10; H, 7·11, 7·19 %. $C_9H_{12}O_3$ requires C, 64·24; H, 7·19 %.) This compound does not titrate in the cold with dilute NaOH.

These results are explained with our formula for carolic acid (VIII) by assuming that on dissolving carolic acid in water before reduction, 1 molecule H_2O is added, thus opening the 7-membered ring (IV), that the CO group of the side chain so formed is reduced to CH_2 and the molecule becomes stabilised in the open form (X), but that on distillation 1 molecule H_2O is again split off with reformation of the 7-membered ring (XI).

With carolinic acid, the reduction product was isolated, after filtering off the catalyst, by evaporating the alcoholic fluid *in vacuo* to a small volume, when the reduced acid crystallised. After recrystallising from water it melted at 143°. (Found: C, 53·95, 54·15; H, 6·05, 6·05 %. $C_9H_{12}O_5$ requires C, 53·98; H, 6·05 %.)

0·0703 g. required 6·95 ml. *N*/10 NaOH for neutralisation to phenolphthalein corresponding to an equivalent of 101 ($C_9H_{12}O_5$ titrating as a dibasic acid requires 100). It appears therefore that in the reduction of carolinic acid, $C_9H_{10}O_6$, $2H_2$ are absorbed and that the product has the empirical formula $C_9H_{12}O_5$. This is readily explained by assuming that the CO group immediately outside the tetronic acid ring in (V) is reduced to CH_2.

(II) *Reduction of α-acetyltetronic acid.* 0·7 g. of acetyltetronic acid was dissolved in 25 ml. of water and reduced with palladium-charcoal-hydrogen as with carolic acid. 2 molecules of hydrogen were absorbed. The reduction was complete in about 3 hours, the rate being identical with those for carolic and carolinic acids. The reduced acid, after filtering off the catalyst, was recovered by continuous ethereal extraction. On removing the ether a colourless crystalline residue was obtained which after recrystallisation from benzene melted at 127–28°. (Found: C, 56·14; H, 6·28 %. $C_6H_8O_3$ requires C, 56·22; H, 6·30 %.) The acid did not depress the M.P. of a sample of α-ethyltetronic acid which was synthesised by bromination of ethyl α-ethylacetoacetate in ether with subsequent ring closure by removal of ethyl bromide on heating [Wedel, 1883]. The reduction reaction is therefore $C_6H_6O_4+2H_2=C_6H_8O_3+H_2O$, and the product is undoubtedly α-ethyltetronic acid having the CO group immediately outside the tetronic acid ring in (VI) reduced to CH_2.

The close similarity in structure between the three acids is further seen from the fact that whereas carolic, carolinic and α-acetyltetronic acids give orange $FeCl_3$ colours, the corresponding reduced acids all give red $FeCl_3$ colours indistinguishable from those of γ-methyltetronic or acetoacetic acids. None of them gives a colour with $NaNO_2$.

(E) *Hydrolysis of reduced carolic and carolinic acids.*

(*a*) *Reduced carolic acid.* 1·079 g. of dried reduced carolic acid were hydrolysed by boiling with 50 ml. dilute H_2SO_4 in a stream of CO_2-free nitrogen, the CO_2 evolved being absorbed in the usual way in baryta bubblers. The hydrolysis was effected very much more slowly than with carolic acid itself, hydrolysis of which was complete in less than 3 hours. Thus the amounts of CO_2 evolved in 7, 15, 26, 34 and 41 hours' boiling respectively corresponded to 42·1, 72·6, 90·8, 98·3 and 101·3 ml. *N*/10 baryta. The theoretical amount of CO_2, assuming that 1 molecule $C_9H_{14}O_4$ gives 1 molecule CO_2, corresponds to 116 ml. *N*/10 baryta. The hydrolysis was stopped after 42 hours, the flask cooled and the solution titrated. Whereas the H_2SO_4 originally used required 102·2 ml. *N* NaOH for neutralisation, the hydrolysis fluid required 102·8 ml. *N* NaOH. It appears therefore, since hydrolysis was not absolutely complete, that no acid other than CO_2 had been formed during hydrolysis.

The neutralised solution was made up to 250 ml. It no longer gave any $FeCl_3$ colour. It reduced Fehling's solution readily in the cold, and on distillation of an aliquot portion to dryness *in vacuo* at 45° the substance causing reduction of Fehling's solution did not pass over into the distillate but could be extracted by means of ether from the salts remaining. The reducing substance was not therefore acetoin but a neutral non-volatile substance. The solution gave with 2:4-dinitrophenylhydrazine in 2 *N* HCl an immediate orange turbidity, and a crystalline product slowly separated during 2 weeks which after recrystallisation from nitrobenzene-toluene melted at 225° and gave the following figures on micro-analysis: C, 46·72, 46·69; H, 4·31, 4·47; N, 21·39, 21·58 %. $C_{20}H_{22}O_9N_8$ requires C, 46·31; H, 4·28; N, 21·61 %. This is obviously the bis-dinitrophenylhydrazone of a diketone $C_8H_{14}O_3$ and, since from the slow formation of the dinitrophenylhydrazone oxidation has occurred, as previously noted with acetoin, the product of hydrolysis is most probably the corresponding ketone-alcohol $C_8H_{16}O_3$. Such a compound would arise from reduced carolic acid by hydrolytic decarboxylation. $C_9H_{14}O_4 + H_2O = C_8H_{16}O_3 + CO_2$.

Ethereal extraction of the residual salts gave a colourless oil which did not crystallise even on long standing. No method was found of isolating this ketone-alcohol in a state of complete purity. On distillation in a high vacuum condensation occurred, a change which we have frequently encountered with other ketone-alcohols.

(*b*) *Reduced carolinic acid.* The hydrolysis was carried out as before. 1·1896 g. reduced carolinic acid gave amounts of CO_2 corresponding to 73·0, 105·3, 109·9, 113·9 ml. *N*/10 baryta in 6, 20, 27 and 34 hours respectively. The theoretical amount of CO_2, assuming that 1 molecule $C_9H_{12}O_5$ gives 1 molecule CO_2 is 119 ml. *N*/10 baryta. In this experiment, unlike that with reduced carolic acid, an amount of residual acid resulted which corresponded to 6·5 ml. *N* acid. Assuming that 1 molecule of a monobasic acid had been formed, the residual acid should correspond to 5·95 ml. *N* acid. The neutral solution was then evaporated to a small volume, acidified with H_2SO_4 and extracted continuously with ether. After removal of ether and drying, a pale yellow oil remained which did not crystallise and could not be obtained in a state of purity. On neutralisation in the cold to phenolphthalein, 92·2 mg. of this oil required 5·12 ml. *N*/10 NaOH corresponding to an equivalent of 180 ($C_8H_{14}O_4$ requires 174). The oil reduced Fehling's solution readily in the cold and was characterised by the fact that with dinitrophenylhydrazine in 2*N* HCl it slowly gave, in the manner of acetoin, a bis-dinitrophenylhydrazone, which after recrystallisation from nitrobenzene-toluene melted at 248° and was soluble in sodium bicarbonate. (Found: C, 45·34; H, 3·93; N, 20·23 %. $C_{20}H_{20}O_{10}N_8$ requires C, 45·09; H, 3·79; N, 21·04 %.) This would correspond to a bis-dinitrophenylhydrazone of a diketone $C_8H_{12}O_4$ and since its formation was slow and oxidation probably occurred as with acetoin the hydrolysis product was probably $C_8H_{14}O_4$ as required by the equation $C_9H_{12}O_5 + H_2O = C_8H_{14}O_4 + CO_2$.

It has been shown that acid hydrolysis of reduced carolic and carolinic acids proceeds much more slowly than that of the parent acids. Further, while the parent acids each give rise to two C_4 compounds on hydrolysis—acetoin and butyrolactone in the case of carolic acid and acetoin and succinic acid from carolinic acid—each of the two reduced acids gives rise to a C_8 hydroxyketone. The results also indicate that the tetronic acid ring in carolic and carolinic acids has not been attacked during reduction, a conclusion which is supported by the fact that γ-methyl- and α-ethyl-tetronic acids are not reduced under the conditions of our reduction experiment.

These facts are readily explained from the formulae proposed for carolic acid (IV) and carolinic acid (V). Writing these structural formulae with the tetronic acid ring opened, as occurs during hydrolysis, we find

(1) 
$$\mathrm{CH_3.CHOH.CO.\underset{COO\,H}{\overset{H\,OH}{CH}}.\,CO.CH_2.CH_2.CH_2.OH}$$

Carolic acid and its hydrolysis products; acetoin, CO_2 and γ-hydroxybutyric acid (butyrolactone).

(2) 
$$\mathrm{CH_3.CHOH.CO.\underset{\overset{|}{COO.H}}{CH}.CH_2.CH_2.CH_2OH}$$

Reduced carolic acid and its hydrolysis product $C_8H_{16}O_3$, *i.e.* octan-6-one-1:7-diol.

(3) 
$$\mathrm{CH_3.CHOH.CO.\underset{\overset{|}{COO.H}}{CH}.\overset{H:OH}{\vdots}CO.CH_2.CH_2.COOH}$$

Carolinic acid and its hydrolysis products, acetoin, CO_2 and succinic acid.

(4) 
$$\mathrm{CH_3.CHOH.CO.\underset{\overset{|}{COO.H}}{CH}.CH_2.CH_2.CH_2.COOH}$$

Reduced carolinic acid and its hydrolysis product $C_8H_{14}O_4$, *i.e.* ζ-hydroxy-ϵ-keto-*n*-octanoic acid.

F. *Reactions of carolic, carolinic and α-acetyltetronic acids with 2:4-dinitrophenylhydrazine.*

(I) *Carolic acid.* Carolic acid does not give an immediate precipitate with Brady's reagent (2:4-dinitrophenylhydrazine in 2*N* HCl) but, on standing with excess of reagent, a voluminous crystalline precipitate begins to separate after 48 hours and continues to increase over a period of several weeks. Thus, using 1·0024 g. carolic acid and a large excess of reagent, the dry weight of hydrazone was after 1 week 1·70 g.; after 2 weeks 2·06 g.; after 3 weeks 2·45 g.; and after 8 weeks 3·12 g. (Theory, assuming total conversion into $C_{21}H_{20}O_{11}N_8$, 3·08 g.) This material appeared homogeneous and melted at 219°. After repeated crystallisation from nitrobenzene-toluene it separated in orange needles melting at 225° (decomp.). A sample was dried and analysed. (Found (Schoeller): C, 45·02, 45·15; H, 3·61, 3·66; N, 20·03, 20·10 %. $C_{21}H_{20}O_{11}N_8$ requires C, 44·98; H, 3·60; N, 19·99 %.) The substance is insoluble in bicarbonate and is probably the bis-dinitrophenylhydrazone of the opened-up form of carolic acid $C_9H_{12}O_5$ (IV).

When the above reaction was stopped after 8–10 days, the product contained in addition to the above bis-dinitrophenylhydrazone, the monodinitrophenylhydrazone of carolic acid. This was separated from the bis-dinitrophenylhydrazone by fractional recrystallisation from absolute alcohol in yellow needles melting at 176° (decomp.). (Found (Schoeller): C, 47·23; H, 4·19; N, 14·82 %. $C_{15}H_{16}O_8N_4$ requires C, 47·36; H, 4·24; N, 14·73 %.)

The substance is readily soluble in bicarbonate and is therefore the monodinitrophenylhydrazone of the opened-up form of carolic acid $C_9H_{12}O_5$.

It is fairly soluble in water and this probably explains the fact that the hydrazone does not appear immediately on treating carolic acid with Brady's reagent. The slow formation of these precipitates may also be due to the slow opening in 2*N* HCl solution of the 7-membered ring of carolic acid, with the slow unmasking of the second carbonyl group.

The same products can be obtained more quickly by allowing carolic acid and dinitrophenylhydrazine to react in alcoholic solution, as in Brady's more recent method [1931].

(II) *Carolinic acid.* Carolinic acid gives an immediate yellow precipitate with dinitrophenylhydrazine in 2*N* HCl. This material after recrystallisation from nitrobenzene-toluene separated in orange needles melting at 228°. A sample was dried and analysed. (Found (Schoeller): C, 46·06, 46·06; H, 3·81, 3·78; N, 14·14, 14·19 %. $C_{15}H_{14}O_9N_4$ requires C, 45·67; H, 3·58; N, 14·21 %.) The substance is soluble in bicarbonate and is therefore the monodinitrophenylhydrazone of carolinic acid.

When this derivative was allowed to stand for 8 weeks in contact with a large excess of Brady's reagent there was no further reaction.

(III) *α-Acetyltetronic acid.* According to Benary [1910] this acid with phenylhydrazine gives a monophenylhydrazone, the CO group of the side chain, and not of the tetronic acid ring, reacting. With 2:4-dinitrophenylhydrazine, also, it gives an immediate yellow precipitate, which after recrystallisation from nitrobenzene-toluene was obtained as yellow needles, melting at 226°, and was soluble in $NaHCO_3$. (Found (Schoeller): C, 44·92, 44·81; H, 3·19, 3·25; N, 17·17, 17·15 %. $C_{12}H_{10}O_7N_4$ requires C, 44·71; H, 3·13; N, 17·39 %.)

It was found however that if this monodinitrophenylhydrazone were kept with excess of the reagent for 6–8 weeks, it was slowly degraded by acid hydrolysis, giving the bis-dinitrophenylhydrazone of methylglyoxal.

G. *Reactions of carolic, carolinic, γ-methyltetronic and α-acetyltetronic acids with diazomethane.*

The acids were suspended in commercial dry (incompletely dry) ether and a solution of diazomethane in ether was added. With carolinic, γ-methyltetronic and α-acetyltetronic acids the reaction was vigorous, but with carolic acid it proceeded slowly for several hours. After standing overnight with excess of reagent, the ethereal solutions were evaporated and dried over H_2SO_4 *in vacuo* for several days. In all cases yellow oils resulted. With γ-methyltetronic acid, the oil contained 24·5 % OMe ($C_5H_5O_2OMe$ requires 24·2 % OMe), with carolic acid 15·9 % OMe ($C_9H_9O_3OMe+H_2O$ requires 14·5 % OMe), with carolinic acid 28·4 % OMe ($C_9H_8O_4(OMe)_2$ requires 25·6 % OMe), and with α-acetyltetronic acid 20·7 % OMe ($C_6H_5O_3OMe$ requires 19·9 % OMe).

Valuable information as to the nature of these methyl derivatives, particularly in relation to the molecular constitutions of carolic and carolinic acids, was obtained by examining their behaviour towards cold dilute NaOH.

The four methylation products (1 g. in each case) were kept at room temperature for 24 hours with 20 ml. *N*/NaOH.

The monomethyl derivative of γ-methyltetronic acid almost completely dissolved, and extraction of the alkaline solution with ether led to the recovery of only a trace of material. After acidification and ethereal extraction, removal of solvent and drying, a yellow oil was obtained, the methoxyl content of which had fallen from 24·5 % to 14·7 %.

The monomethyl derivative of carolic acid did not go completely into solution. The oil recovered by extraction of the alkaline solution still contained 14·6 % OMe (originally 15·9 %), but the oil recovered after acidification and constituting the larger portion contained only 2·8 % OMe. The portion reacting had therefore been almost completely demethylated. It was found also that shaking the neutral methyl compound with water quickly rendered it acidic, some demethylation occurring.

The dimethyl derivative of carolinic acid almost completely dissolved and the oil recovered from the Na salts after acidification contained 10·0 % OMe (originally 28·4 %). After a further period of hydrolysis the methoxyl content fell to 8·1 %. One methyl group appears therefore to be lost readily and the second group much more slowly.

The monomethyl derivative of α-acetyltetronic acid, which, like the methyl derivatives of carolic and carolinic acids, contains two CO groups in β-positions to the methoxyl group, was hydrolysed with great ease and the product recovered from the Na salts after acidification contained only 3·6 % OMe.

It appears therefore that the methyl derivative of γ-methyltetronic acid, which contains only one CO group in the β-position to the methyl group, behaves much more like a true methyl ether in that it is not readily attacked by NaOH, whereas the methyl groups of the derivatives of α-acetyltetronic and carolic acids and one of the methyl groups of carolinic acid all react like readily hydrolysable methyl ester groupings. The methyl group of α-acetyltetronic acid is however a true methyl ether grouping, is in the β-position of the tetronic acid ring and has two CO groups in β-positions to it, this juxtaposition of potentially acidic groups accounting for the ease with which it is hydrolysed. It seems likely therefore that the readily hydrolysable methyl groups of carolic and carolinic acids are true methyl ether groupings and have the same relative positions. The second methyl group of carolinic acid, which hydrolyses more slowly, must therefore be the true methyl ester grouping.

SUMMARY.

Penicillium Charlesii G. Smith produces from glucose carolic acid ($C_9H_{10}O_4$) and carolinic acid ($C_9H_{10}O_6$). The molecular constitutions of these two acids have been investigated and it has been shown that they are closely related derivatives of γ-methyltetronic acid.

Carolic acid hydrate has been shown to be α-[γ-hydroxybutyryl]-γ-methyltetronic acid and carolinic acid to be α-[β-carboxypropionyl]-γ-methyltetronic acid. Both acids are therefore closely related structurally to ascorbic acid (vitamin C).

A number of derivatives and breakdown products are described.

We gratefully acknowledge much assistance in the preparation of large quantities of carolic and carolinic acids given by Messrs G. Smith and W. K. Anslow.

XXXIX. EGG-WHITE AS SOLE SOURCE OF PROTEIN AND VITAMIN B_2 FOR YOUNG RATS.

By FREDERIK JAN GORTER.

Laan van Altena 47, Delft, Holland.

(*Received December 1st, 1934.*)

When we consider the literature concerning egg-white in nutrition we are struck by the fact that some authors have found toxic properties in dried or fresh egg-white [*e.g.* Boas-Fixsen, 1931; Parsons and Kelly, 1933] and that others have used cooked egg-white as source of protein and vitamin B_2 [*e.g.* Chick, Copping and Roscoe, 1930; György, 1934]. The toxic effect, according to Boas [1927] may be counteracted by a "factor X", occurring in many foodstuffs including dried yeast, and according to Parsons [1930], by liver and yeast. Moreover the damaging property of the egg-white is counteracted by certain treatments, as, for example, thorough coagulation or denaturation by heat [Parsons and Kelly, 1933]. A very slowly acting poison which is counteracted by a normally non-stimulating foodstuff (liver, yeast) may not be considered toxic in the strict sense of the word. Many foodstuffs may become toxic, if fed in too great quantities and if certain counteracting foodstuffs are omitted or reduced. On the other hand, specific deficiency diseases are accompanied, if not caused, by an intoxication with metabolic products. The question whether egg-white, in the dried, fresh, raw or cooked state, is deleterious in the presence of all known food-substances and vitamins, and to what extent the damage may be counteracted by other foodstuffs, containing perhaps a hitherto unrecognised dietary principle, appeared to deserve further investigation. With this aim I undertook the experiments, the results of which are summarised briefly in this paper.

EXPERIMENTAL.

Section I.

Experiments were first made with egg-white subjected to various preparatory treatments, analogous to those already employed by other workers. Albino rats were used and kept in iron cages with mesh floors. The breeding diet contained raw meat, raw vegetables, wheaten bread, wheat, raw milk and a commercial chicken-food, composed of cereal, milk, peanut, meat and fish products and calcium phosphate. This food was administered until the litters were 3 weeks old. The young rats then received, with their mother's milk, an artificial diet containing: 20 % previously coagulated egg-white; 60 % potato-starch; 16 % hardened arachis fat; 4 % salt-mixture [see Stammers, 1909] with traces of $CuSO_4, 5H_2O$. The ration was thoroughly mixed and cooked with 4 parts of tap-water and administered in paste form, supplemented by 2 % cod-liver oil ("jeco-vitol"), to provide vitamins A and D, and by 0·5 % activated acid clay, made from rice-bran according to the method of Jansen and Donath [1927], as source of vitamin B_1. The young rats were weaned when 4 weeks old and the above diet was continued for a further week. When 5 weeks of age, the litters were distributed evenly over three groups, in which the 20 % protein was varied thus: A, 20 % egg-white; B, 20 % purified caseinogen; C, 10 % egg-white + 10 % caseinogen.

In the A diets the treatment of the egg-white was varied as follows:

Diet A1: 20 % raw, dried, powdered Chinese egg-white mixed in the raw state through the cooled food paste.

Diet A2: 20 % (by dry weight) raw, fresh, undried egg-white mixed in the ration.

Diet A3: as A1, but the Chinese egg-white cooked 5 minutes with the ration.

Diet A4: as A2, but the fresh egg-white cooked 5 minutes with the ration.

Diet A5: as A1, but the Chinese egg-white dissolved in water (1½ hours at 30°), then thoroughly coagulated by heating the solution for 3 hours at 80°.

Diet A6: as A5, but the solution denatured by treatment with HCl at p_H 2·4 for 3 days at 37° [Parsons and Kelly, 1933], the reaction being adjusted to p_H 5 by addition of $NaHCO_3$ before mixing with the ration.

In Diets C1 and C2 the 10 % egg-white was respectively dried Chinese and fresh, treated as in Diets A1 and A2.

Diets D3–D6 and E3–E6, contained 20 % egg-white, treated exactly as in Diets A3–A6, but in the D diets 2 % dried brewer's yeast was added and in the E diets 2 % raw, dried horse-liver.

The results of these trials are summarised in Table I. 23 out of 24 young rats on Diets A1 and A2, containing 20 % untreated raw egg-white, dried or fresh, as sole source of protein and vitamin B_2, survived for 42–96 days; cooking the egg-white for a short time (A3 and A4) did not improve matters, as Parsons had

Table I.

All diets contained 60 % potato-starch.

Protein in diet	20 % egg-white						20 % purified caseinogen	10 % egg-white + 10 % purified caseinogen	
	A1	A2	A3	A4	A5	A6	B	C1	C2

Protein in diet	20 % egg-white + 2 % dried brewer's yeast				20 % egg-white + 2 % dried horse-liver		
	D3	D4	D5	D6	E3	E5	E6
No. of rats	8	54	8	8	4	3	2
Duration of exp. (days)	62	22	42	20	33	13	20
Average weekly increase in wt. (g.)	11·5	10·5	9	7·5	7·5	14	15
Affections and symptoms	Eyes Ears Mouth	Eyes Ears	Baldness (1 rat)	None	Baldness	None	None
No. of rats dying	2	12	0	0	0	1	0

already found. Diet A5, in which the egg-white was heated for 3 hours, showed an unexpectedly high rate of mortality (4 out of 8 rats). This I believe to be due to the fact that the egg-white used was not milled as finely as that of the other rations, at least during the first 3 weeks of the experiment; at the end of those 3 weeks half of the rats died. It would seem that the coagulation of a certain part of the egg-white had not been complete. Diet A6, in which the Chinese egg-white was denaturated with HCl, gave the best results.

Diet B (20 % caseinogen) was unsatisfactory in consequence of the deficiency in vitamin B_2.

Diets C1 and C2 (10 % caseinogen with 10 % Chinese dried, or 10 % fresh, egg-white) gave unexpectedly good results during the short time of the trial (12–20 days).

Diets D1–D5, in which the 20 % egg-white was supplemented with 2 % dried brewer's yeast, were not wholly harmless; diets E1–E5, with 2 % dried liver, were rather better during the relatively short time of observation.

The dried egg-white did not generally prove more injurious than the fresh material, but while the latter caused no paresis or baldness, affections of eyes, ears and mouth were often present and the fur was always dirty.

Refection was never seen in these experiments and coprophagy was hindered by the use of wire cage floors of 1 cm. mesh. But, in order to exclude further the chance of refection, most of the above experiments were repeated, using rice-starch and sucrose instead of potato-starch, which according to Boas [1927] has a counteracting effect on the damage caused by egg-white. These results are collected in Table II.

Diets a, b, c, *etc.* correspond to diets A, B, C, described above, with 60 % rice-starch in place of 60 % potato-starch: diets a′, b′, c′, *etc.* contained 20 % of rice starch and 40 % sucrose.

Diets f contained 3 % (by dry weight) of egg-yolk and diets g 20 % of egg-yolk.

Of the diets marked with Greek letters, α contained 40 % egg-white and 40 % rice-starch; α′ 40 % egg-white, no rice-starch and 40 % sucrose; β 40 % purified caseinogen and 40 % rice-starch; γ 20 % egg-white, 20 % purified caseinogen and 40 % rice-starch. Diet γ′ contained 20 % egg-white, 20 % purified caseinogen, no rice-starch and 40 % sucrose; diet δ′ contained 40 % egg-white, 40 % sucrose and 2 % dried brewer's yeast.

In the different experiments summarised in Table II the results regarding growth are not altogether comparable with one another, for the trials of longer duration naturally show lower average growth-rates, owing to the fact that the rats are becoming more nearly adult (see *e.g.* diets α3 and γ3). From these experiments it may, however, be concluded that egg-white in the raw, dried state, is not so very detrimental as source of protein in a diet if all known vitamins are present, including the factors supposed to occur in yeast, egg-yolk and liver, *e.g.* the "factor Y", of Chick and Copping [1930] or "factor X" of Boas [1927; Fixsen, 1930]. If these factors are omitted, damage occurs in some animals, but not in all, unless the egg-white is treated with HCl according to Parsons and Kelly [1933]. The process of drying in itself did not prove to result in damage to the rats, as was thought by Boas [1927].

When the diets contained 60 % cooked potato-starch (Table I) growth was promoted and symptoms prevented rather more effectively than when rice-starch and sucrose (Table II) were used as source of carbohydrates; compare *e.g.* diets A3, A5 with a3, a5 and diet C1 with c1. When, in addition, yeast or liver was given, there was no difference; compare *e.g.* diets D3, D5, E3, E5 with diets

d3, d5, e3, e5. These results confirm the conclusion of Boas [1927] that a "factor X", occurring in potato-starch, as well as in yeast, commercial caseinogen and several other foodstuffs, was able to counteract the toxic properties of egg-white in the diet.

During the above experiments (section I) my attention was attracted to the extraordinarily good growth on diets C, c and γ, which contained both purified caseinogen and egg-white as sources of protein. Boas-Fixsen found that factor X occurred to a relatively small extent in commercial caseinogen, but although a special growth-promoting property has been ascribed to commercial "light white casein" (Coward) no such property has been shown to exist in "purified" caseinogen. Further evidence on this subject is described in the following section.

Section II.

In order to accustom 124 young rats 3 weeks old to egg-white, 5 % (dry weight) of fresh rapidly coagulated egg-white was added to a b-ration, which already contained 20 % purified caseinogen, which had been purified by washing the caseinogen in a mixture of 10 l. "Monster" tap-water, 5 l. 96 % alcohol and 28 ml. *N* HCl (p_H 4·1 measured by glass-electrode) during 1 week, subsequently washing in acid 85–90 % alcohol (p_H 5·1) during 1 week and finally extracting with ether in a Soxhlet-apparatus for 2 weeks. After 2 weeks, when 5 weeks old, the rats were distributed over 2 groups, one of which received 20 % purified caseinogen as sole source of protein (39 rats), the other 20 % (dry weight) of fresh, rapidly coagulated egg-white. For both groups the increase in weight during the following 6 weeks (18–20 g.) was about equal to that of the comparable groups in section I above (a4, b see Fig. 1 and Table II) and in both the greater part of this increase (*ca.* 12 g.) occurred in the first 2 weeks, that is in the 6th and 7th weeks of life (Fig. 1). The young rats described above in section I had never shown this peculiarity; those fed on diet a4 increased by 2 g. during the first 10 days and those on diet b by 3·5 g. during the first 2 weeks, *i.e.* by rather less than the average weekly rate of growth shown over the longer period, which was 2 and 2·5 g. respectively. It was evident that in the present instance the previous presence in the rations of egg-white and purified caseinogen exerted a beneficial effect on the growth even for 2 weeks after one of them had been omitted. If this is true, the growth should also be enhanced for a period of about 2 weeks when a change is made from 20 % egg-white to 20 % purified caseinogen or *vice versa*. Special experiments were made to test this. 47 rats 3 weeks old received diet a4 (egg-white), 65 others diet b (caseinogen). When 4 weeks old they were weaned and, when 5 weeks old, distributed over 4 groups; some which had been fed on diet a4 (egg-white) now received diet b (caseinogen) and some which had been fed on diet b, now received diet a4. The remainder in each

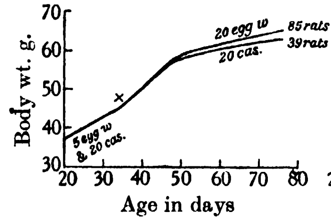

Fig. 1.

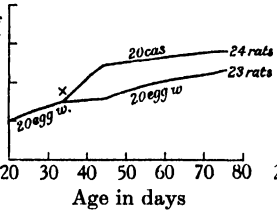

Fig. 2.

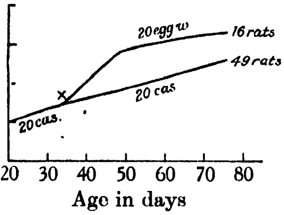

Fig. 3.

× Denotes division of the rats into 2 groups, each group receiving a different kind of protein.

group were continued on the previous diet. The result was a clear-cut corroboration of my expectation (Figs. 2 and 3).

When the diet during the 4th and 5th weeks of life had contained 20 % egg-white, the average growth on the changed diet (caseinogen, 24 rats) was 9·5 g. during the first 10 days, while that on the unchanged diet (23 rats) was 0·5 g. When the diet during the 4th and 5th weeks had contained 20 % purified caseinogen, the average growth on the unchanged diet (49 rats) was 3·5 g. during the 6th and 7th weeks and on the changed diet (egg-white) 12·5 g. (16 rats). Thus, in either case when the protein of the diet was altered, the growth was at first stimulated, presumably because the changed protein provided some factor absent from the previous one. After 10–14 days, the rate diminished (1–3 g. weekly), presumably because the reserve of some factor present in the first protein, but absent from the second, was becoming exhausted. When, on the contrary, the protein was not altered, there was no improvement in either growth or condition. Change in appetite could not have played any part, for the food intake was kept the same in all groups by giving a relatively small supply every day, so that each rat could eat it all.

We may conclude, therefore, that purified caseinogen, preferably in combination with potato-starch, can partially replace the growth-promoting action of yeast, liver or egg-yolk when added to diets containing egg-white as source both of protein and vitamin B_2. Vitamins A, B_1 and D were always given in sufficient doses. In such diets both purified caseinogen and egg-white are required to maintain an appreciable though subnormal growth; the first supplies an unrecognised food principle, the second vitamin B_2.

Section III.

In the following experiments additional evidence is given that growth may be almost completely restored by incorporation of 40 % purified caseinogen (see group 3) into the ration containing egg-white as source of protein, and that the essential dietary factor, which is thus added, is not extractable by washing the caseinogen with dilute acid alcohol (27 %), acid, 85–90 % alcohol or ether.

Two litters of young rats during the 4th and 5th weeks of life received a diet containing as much as 50 % (dry weight) egg-white, this high proportion being at the expense of the potato-starch, which was reduced to 30 %. In other respects the diet resembled diet A3 of section I. No symptoms of "proteintoxicose" [Glanzmann, 1934] caused by the large amount of rapidly coagulated, previously dried egg-white were to be seen during these 2 weeks. (Glanzmann often observed paresis and death within 2 days with dried buttermilk.) The litters were then distributed over three groups, 6 rats in each, maintained on diets containing different proteins, with results as follows:

Group 1: 50 % egg-white; weekly growth 10·5 g. during 3 weeks.

Group 2: 50 % purified caseinogen; weekly growth 12 g. during 3 weeks.

Group 3: 10 % egg-white and 40 % purified caseinogen; weekly growth 19·5 g. during 4 weeks.

In group 3 growth was almost maximum, because the two factors contained in egg-white and in purified caseinogen, respectively, supplemented each other in their growth-promoting actions. Maximum growth (25 g. weekly, as was obtained with the breeding diet) was only secured by the addition of 3 % dried yeast (suggesting the further action of the factor Y of Chick and Copping [1930]).

In groups 1 and 2 the weight increase stopped after 1 month; in group 3 it diminished, but remained almost maximum during 2 months, even when no yeast was added, showing that not only "factor Y" but also another factor may be growth-promoting when added to the egg-white rations. The rats of group 1 (50 % egg-white) when 6 weeks old, developed bald patches on head, neck and back, giving them a rather moth-eaten appearance. The rats of group 2 (50 % purified caseinogen), after recovering from a slight degree of baldness evidently due to the preceding feeding with egg-white during the 4th and 5th weeks, developed rather shaggy coats when 8 weeks old. The rats of group 3 remained in good condition, but after 2 months incipient depigmentation sometimes appeared when pied rats were used [Gorter, 1934]. One may conclude that the baldness is associated with egg-white feeding and that this can probably be prevented by a dietary factor which occurs to a relatively small extent in purified caseinogen.

DISCUSSION.

The question arises, whether 20 % egg-white is to be regarded as an incomplete, or as a toxic, source of protein and whether it contains enough vitamin B_2 for growth. Mitchell [1925] found 18 % coagulated egg-white to be a satisfactory source of protein; in this work dried whole yeast was the source of B-vitamins, but this contains protein also. Boas [1927; Boas-Fixsen, 1931] and Parsons [1930] described, however, specific ill-effects caused by 20–66 % egg-white (dry weight) in the diet; as source of B-vitamins they used marmite (Boas) and wheat embryo or an extract of wheat embryo.

According to Parsons and Kelly [1933] the toxic effect of egg-white cannot be due to an amino-acid deficiency; for when thoroughly denatured (with HCl), 20–66 % egg-white in a diet always proved harmless. The possible influence of the protein provided by the 10 % whole wheat embryo used in their most successful growth experiments should, however, be remembered, as a hint that an amino-acid deficiency of the egg-white is still possible.

In respect of the vitamin B_2 quality of egg-white, Chick, Copping and Roscoe [1930] concluded that 20 % egg-white (dry weight), as sole source of protein and of vitamin B_2, provided an ample supply of vitamin for a few weeks only.

If egg-white be regarded as adequate for provision of vitamin B_2 there must be some other nutritive fault of diets containing 20 % coagulated egg-white as sole source of protein and vitamin B_2, a defect which, however, does not influence the growth for the first 2 weeks. If purified caseinogen is also present in sufficient quantity in the diet (preferably in combination with potato-starch), the damage associated with egg-white does not appear for a period of 3 months. The hypothetical dietary factor, occurring in purified caseinogen, possibly an amino-acid, is distinguished from all known B-vitamins except B_3 [see O'Brien, 1934] by its relative insolubility in acid dilute alcohol. It may be connected with the equally insoluble factor X [Boas, 1927; Boas-Fixsen, 1931; Glanzmann, 1934; Lease and Parsons, 1934, 1] which counteracts the deleterious effect of egg-white in the dried raw state, or perhaps with the dietary factor described by Coward *et al.* [1929] in "light white casein" (see also Mapson [1933]). The latter, however, was not present in (purified) "Glaxo casein" and was soluble in 96 % alcohol.

Lease and Parsons [1934, 2] recently extracted a factor curative of the egg-white dermatitis in rats from kidney or liver, after previous digestion with papain. I have not yet tried this method with caseinogen.

SUMMARY.

1. The toxic effects of egg-white, when present as sole source of protein and vitamin B_2 in a diet, which cause the well-known skin disorder in young rats, can be counteracted by substitution of purified caseinogen for part of the egg-white.

2. The dietary factor contained in caseinogen and lacking in egg-white is present also in liver, yeast and egg-yolk; it is insoluble in dilute or strong acid alcohol or in ether.

3. While differing in solubility from the known B-vitamins and from the dietary factor in commercial caseinogen described by Coward *et al.*, it would appear to be similar in distribution and function to the "factor X" described by Boas, and partly also to the "factor Y" described by Chick *et al.* The possibility that it may be an amino-acid is not excluded.

XL. THE IRON AND COPPER CONTENTS AND THE HAEMOPOIETIC ACTIVITIES OF STOMACH AND LIVER PREPARATIONS.

By HAROLD JACKSON, LOUIS KLEIN
and JOHN FREDERICK WILKINSON.

From the Department of Clinical Investigations and Research, University and Royal Infirmary, Manchester.

(*Received December 12th, 1934.*)

The modern treatment of pernicious anaemia with preparations of liver or hog's stomach has led to much speculation as to the precise cause of the success of the treatment, and many laborious fractionation experiments have been carried out with the object of isolating and studying the properties of the active anti-anaemic substances presumed to be present in these organs. These active principles have not yet been isolated in pure form; only concentrated preparations or fractions are known whose haemopoietic activity can be determined solely by the clinical method of observing their effects in cases of pernicious anaemia.

The investigations of Cohn *et al.* [1928; 1930] suggest that the active principle in liver is a nitrogenous base, possibly an ω-amino- or imino-acid. Further, the work of two of us [Wilkinson and Klein, 1932; 1933; 1934; Klein and Wilkinson, 1933; 1934] has shown that the anti-anaemic factor in hog's stomach, haemopoietin, is not identical with the liver principle but is probably an enzyme, which, reacting with a substrate present in the normal diet, produces a substance which from its chemical and therapeutic properties appears to be identical with the so-called active liver principle; this liver principle is utilised for the formation of red blood cells by some mechanism at present unknown.

The liver therapy had its origin in the classical experiments of Whipple *et al.* [1920], who, selecting liver owing to its relatively high iron content, showed that it was the most potent foodstuff in causing blood regeneration in dogs which had been kept at a constant low haemoglobin level by bleeding. This work on post-haemorrhagic anaemia induced Minot and Murphy [1926] to try the effect of liver feeding on cases of pernicious anaemia. The success they had with this diet was later paralleled by the even more striking results that followed the treatment of pernicious anaemia with preparations of hog's stomach [Wilkinson, 1930; 1931].

The preparations of liver and stomach used in the treatment of pernicious anaemia contain small amounts of iron and copper and it has been suggested in many quarters [*cf.* for example Schultze, 1932] that they owe their value to the presence of these mineral constituents. Iron, of course, is known to be essential for haemoglobin formation and has been used with great success in the treatment of the hypochromic microcytic anaemias.

The possibility that copper may also be an active blood-regenerating agent or may stimulate haemoglobin formation has been suggested by many workers [*cf.* McHargue *et al.*, 1928; Flinn and Inouye, 1929; Hart *et al.*, 1928; Waddell *et al.*, 1929, 1, 2; Elvehjem, 1932]. According to Warburg and Krebs [1927], Schönheimer and Oshima [1929], Guillemet [1931], McFarlane [1932], Locke *et al.* [1932] and Tompsett [1934, 1], human blood contains small amounts of copper, the amount being of the order of 0·1–0·2 mg. Cu per 100 ml. McHargue [1925] suggests that it may also perform important functions in the absorption and transfer of oxygen in the respiration of mammals. Indeed, copper is an essential constituent of haemocyanin, the respiratory pigment of certain molluscs and crustacea. Beard and Myers [1928], working on nutritional anaemia of rats, found that traces of copper added to iron brought about regeneration of haemoglobin in less time than the same dose of iron alone. Mills [1930], among others, reports the successful use of copper and iron in idiopathic anaemia of adults.

The experimental evidence so far accumulated appears to suggest that iron and copper may play an important part in certain forms of anaemia, though whether they do so in pernicious anaemia is open to question. The object of the present work was to determine whether the quantities of iron and copper present in various liver and stomach preparations and fractions used in the treatment of pernicious anaemia could be correlated with the haemopoietic activities of the fractions as judged by clinical trial on cases of this disease.

EXPERIMENTAL.

In view of the relatively small quantities of iron and copper present in the preparations used, it was decided to employ colorimetric methods of estimation using a Klett colorimeter, and throughout the work, distilled water and analytical reagents shown to be free from iron and copper were used. In view of the fact that there appears to be some vagueness in the literature as to the exact procedure in these methods, it has been thought advisable to describe our experimental technique at some length.

Ashing of preparations. The following dry ashing method was found to be the most satisfactory. Porcelain crucibles (2 in. in diameter) of the best Berlin make were soaked in alcoholic sodium acetate and then evaporated to dryness several times with concentrated hydrochloric acid in order to remove any iron and copper from the glaze [*cf.* Elvehjem and Lindow, 1929]. In the case of stomach preparations, 5 g. samples were generally used, but, owing to scarcity of material, 1 g. or even less of some of the liver fractions was used. The crucible was heated over a very low flame until visible charring commenced, when concentrated sulphuric acid (about 10–15 drops per 5 g. sample) was carefully added. Heat was then gently applied until a carbonaceous mass was obtained. A further similar quantity of acid was then added and heating continued for approximately an hour, when ashing was usually complete. If this were not so, the crucible was allowed partially to cool, one drop of acid added to any portion where carbonaceous material remained and the crucible reheated for a short period.

Extraction of ash. This was carried out by heating for a short time almost to boiling point with concentrated hydrochloric acid (5–10 ml.) over a microburner. The acid solution was then measured into a volumetric flask (50 ml. for a 5 g. sample, 20 ml. for smaller samples) and further extractions were made with similar quantities of water. The solution was made up to volume after cooling, filtered through a sintered glass filter and was then ready for the iron and copper estimations.

Preparation of standard iron and copper solutions. Iron standards were prepared as follows:

(*a*) Ferric alum A.R. (0·8630 g.) was dissolved in 50 ml. water, 20 ml. of 10 % hydrochloric acid were added to prevent hydrolysis and the solution was then diluted to 1 litre (1 ml. = 0·1 mg. iron). The purity of the salt was confirmed by gravimetric analysis.

(*b*) Pure iron wire (0·0639 g.) was dissolved in 50 ml. of 10 % hydrochloric acid, oxidised with 5 ml. hydrogen peroxide (20 vols.) and the solution boiled and made up to 500 ml. This solution should contain 0·128 mg. iron per ml., and colorimetric estimation by the thiocyanate method (following the details given below), taking the ferric alum solution as standard, gave a value of 1 ml. = 0·129 mg. iron.

The standard copper solution contained 0·3928 g. copper sulphate A.R. ($CuSO_4$, $5H_2O$) per litre (1 ml. = 0·1 mg. copper).

Determination of iron by the thiocyanate method. The intense wine-red coloration produced by the action of thiocyanates on ferric salts (sensitivity 1 in 1,000,000) has been the basis of the common methods in use for the determination of iron in biological material. Many workers recommend extraction of the colouring matter with amyl alcohol before colorimetric comparison [*cf.* Kennedy, 1927; Elvehjem, Kemmerer *et al.*, 1929; McFarlane, 1932], whilst others consider this procedure to be unnecessary [*cf.* Brown, 1922; Wong, 1923; Rees, 1933]. We find, however, that very poor colour matches are obtained if readings are made directly without extraction. On the other hand, with the extraction method, it is sometimes necessary to dry the amyl alcoholic extracts with sodium sulphate owing to their turbidity.

An accurately measured aliquot portion (usually 5 or 10 ml.) of the unknown solution was measured into a 100 ml. cylindrical separating funnel, the iron oxidised to the ferric condition by addition of 2 drops of concentrated nitric acid and water added from a burette to a volume of 20 ml. This was followed by an exact volume of amyl alcohol (usually 20 ml. but varying according to the colour developed) and 5 ml. of 20 % potassium thiocyanate solution. Extraction was then carried out immediately, the amyl alcoholic extract dried if necessary, by filtration through a thin layer of anhydrous sodium sulphate (about 1 g.) on a sintered glass filter, and the depth of colour compared with that of a standard iron solution freshly made up in an identical manner.

The minimum concentration of iron which gave a sufficiently intense colour for convenient reading (standard at 20 mm. depth) on the colorimeter was $2{\cdot}5 \times 10^{-6}$ mg. iron per ml. amyl alcohol solution (*i.e.* ≡ 0·5 ml. of standard extracted with 20 ml. amyl alcohol).

Determination of iron by the thiolacetic acid method. Lyons [1927] has shown that ferric or ferrous salts give a purple coloration with thiolacetic acid (sensitivity 1 in 5,000,000) which can be utilised for the quantitative estimation of iron, and Hanzal [1933], Burmester [1934] and Tompsett [1934, 2] have applied the test to the determination of iron in biological material. The main objections to the use of this reaction as a basis for a colorimetric method of analysis are (*a*) the instability of the coloration which fades in the course of a few hours, owing apparently to the presence of copper, and (*b*) the formation of a fine precipitate of alkaline earth hydroxides and phosphates in the ammoniacal solution which makes readings difficult. We find, however, that when the solutions are allowed to stand for 15 minutes and then filtered through a sintered glass filter, the results are in good agreement with those obtained by the thiocyanate method.

An aliquot portion of the unknown solution was diluted with water to 20 ml., 1 drop of thiolacetic acid added, followed by 1 ml. of ammonia (sp. gr. 0·88). It was occasionally necessary to add 2–3 ml. of ammonia when the aliquot portion of the unknown solution was large. The depth of colour was then compared with that of 1 ml. of the standard iron solution treated similarly.

The minimum concentration of iron which gave a sufficiently intense colour for convenient reading (standard at 30 mm.) on the colorimeter was $4{\cdot}0 \times 10^{-6}$ mg. iron per ml. solution (*i.e.* ≡ 1 ml. of standard solution made up to a total volume of 25 ml.).

Estimation of copper in the presence of iron. The most delicate colour test for copper is the reaction with sodium diethyldithioçarbamate [Callan and Henderson, 1929], which gives a golden-yellow coloration with dilute solutions of copper salts (sensitivity 1 in 100,000,000). Since iron also gives a coloration with this reagent, a modification of the original method first suggested by Haddock and Evers [1932] has been used. It was found, however, that carbon tetrachloride as used by the latter authors was unsatisfactory as an extractant since several extractions were necessary for the complete removal of the colour developed and, moreover, the solutions in this solvent were not very stable. The use of amyl alcohol, introduced by McFarlane [1932] in place of carbon tetrachloride, had none of these objections and has recently been recommended by Tompsett [1934, 1].

The unknown solution (25 ml. or an aliquot portion made up to 25 ml. with water) was introduced into a 100 ml. cylindrical separating funnel and 2 drops of concentrated nitric acid were added. This was followed by 1 g. of citric acid and, after solution had taken place, 4 ml. of ammonia (sp. gr. 0·88) were added, giving a p_H greater than 9·0. The total volume was then made up to 40 ml. with water from a burette. A known volume of amyl alcohol (usually 20 ml.) followed by 5 ml. of a 0·1 % solution of sodium diethyldithiocarbamate was now added and the whole vigorously shaken for a short time. After separation had taken place, the aqueous layer was removed. It was very occasionally found necessary to dry the amyl alcohol layer as in the iron estimation described above. Comparison was then made with a standard copper solution (0·5 ml. or 1 ml.) treated in the same way as the unknown.

In many cases where the quantity of available material was small (0·35–0·5 g.), the hydrochloric acid solution of the ash was made up to 25 ml., and 20 ml. were subsequently extracted with 10 ml. of amyl alcohol.

The minimum concentration of copper giving a sufficiently intense colour for convenient reading (standard at 30 mm.) was $2{\cdot}5 \times 10^{-6}$ mg. copper per ml. of amyl alcohol solution (*i.e.* ≡0·5 ml. of standard extracted with 20 ml. amyl alcohol).

DISCUSSION OF RESULTS.

The results of our determinations of iron and copper in various products derived from hog's stomach and from various livers are shown in Tables I–III. Estimations were carried out in duplicate except in the cases of one or two human liver fractions where the amount available did not permit of duplicate ashing.

All the preparations have been tested for haemopoietic activity on specially controlled cases of pernicious anaemia, the stomach and ox liver preparations being administered orally and the human liver fractions by intramuscular injection. Haemopoietically active products produced a "peak" in the number of reticulocytes in the circulating blood in the course of a few days, followed by a fall to normal values, and this was accompanied by an increase in the number of red blood cells and in the percentage of haemoglobin [*cf.* Wilkinson, 1932; 1933]. The clinical material used for this purpose conformed to certain rigid criteria already laid down by one of us, and the clinical details have already been published elsewhere [Wilkinson, 1932; Klein and Wilkinson, 1933; 1934; Wilkinson and Klein, 1934].

In considering the determinations on the desiccated stomach preparations (Table I) it will be noted that the copper content was very small compared with the amount of iron present and showed quite a reasonable constancy, varying only between 1·3 and 2·0 mg. per 100 g. The iron content of these products was very much higher and, moreover, showed variations between wider limits. One of the preparations (A) gave a much higher figure for iron than the others. The data presented appear to show conclusively that there is but little difference in the metallic contents of the haemopoietically active and inactive preparations, the inactive preparation F, for example, containing practically the same amount of iron and copper as the active preparation H. The haemopoietic inactivity of certain desiccated stomach preparations is due then not to any deficiency or excess of iron or copper but to the methods of treatment during their manufacture, which causes inactivation of the sensitive gastric enzyme, haemopoietin [Wilkinson, 1932]; this is further manifest from the fact that gentle heating destroys haemopoietin but has no influence on the iron and copper contents of the preparations.

Table I.

Preparation	Haemopoietic activity	Mean values mg. per 100 g. preparation: Iron	Mean values mg. per 100 g. preparation: Copper
	Commercial desiccated hog's stomach		
A	Active	33·2	1·7
B	Inactive	17·5	1·7
C	Active	10·5	1·8
D	Active	12·4	1·9
E	Active	16·4	1·3
F	Inactive	11·5	1·2
G	Inactive	8·5	2·0
H	Active	11·5	1·5
	Fractions from hog's stomach press juice		
Fraction P5	Active	95·8	3·3
Fraction P5 (i)	Inactive	97·3	5·9
Fraction P5 (ii)	Active	33·2	7·0

Table I also shows the iron and copper contents of three stomach fractions prepared by two of us from the expressed juice of hog's stomach [Wilkinson and Klein, 1932; Klein and Wilkinson, 1933].

Fraction P5 was obtained by precipitating the press juice directly with alcohol. Fraction P5 (i) represented the precipitate rich in pepsin obtained by dissolving fraction P5 in $N/10$ hydrochloric acid and bringing to p_H 4·2 by addition of alkali. Fraction P5 (ii) was the pepsin-free precipitate obtained by adding alcohol to the filtrate from the preparation of fraction P5 (i).

Two of these fractions (P5 and P5 (i)) had very high iron contents, though one was active and the other was not. Moreover, the active fraction P5 (ii) had only one-third of the amount of iron present in the inactive fraction P5 (i), which provides further evidence of lack of any relationship between haemopoietic activity and metallic content. In point of fact, most of the iron present in these fractions was probably derived from the metal press used in the preparation of the press juice.

Table II gives the results obtained with an ox liver extract and an extract prepared by digesting ox liver with hog's stomach—both preparations were for oral use and were clinically very active, the latter preparation being more active than the former. In one of these fractions, the quantity of copper was in

Table II. *Preparations from ox liver and hog's stomach.*

Preparation	Haemopoietic activity	Mean values mg. per 100 g. preparation: Iron	Mean values mg. per 100 g. preparation: Copper
Liver extract S.P.I. (7·8 g. ≡ ½ lb. liver)	Active	23·6	43·9
Liver—hog's stomach L.S.I. (6·4 g. ≡ ½ lb. liver)	Active	12·3	9·6

excess of the iron content whereas in the other the converse held. Here again there appears to be no evidence of any parallelism between the haemopoietic activities and the contents of iron and copper.

The results obtained with liver fractions prepared for intramuscular injection from various normal and abnormal human livers as described elsewhere [Wilkinson and Klein, 1934] are shown in Table III.

Table III. *Fractions from human livers.*

Clinical source of liver	Fraction	Haemopoietic activity	Mean values mg. per 100 g. fraction: Iron	Mean values mg. per 100 g. fraction: Copper
Untreated pernicious anaemia	L.I. 3	Inactive	<1·0	8·6
	L.I. 19	Inactive	4·3	9·1
Partially treated pernicious anaemia	L.I. 1	Slight	<1·0	15·7
Remitting pernicious anaemia	L.I. 4	Active	—	4·3
	L.I. 13	Active	4·9	15·7
Normal	L.I. 7	Active	4·0	2·9
	L.I. 12	Active	18·9	5·1
Haemolytic anaemia	L.I. 22	Active	5·8	11·3
Polycythaemia rubra	L.I. 14	Very active	<1·0	7·9

It will be seen that there is a very wide variation in the copper and iron contents of the different liver fractions and that no correlation exists between their clinical potencies and contents of these metals.

Thus, in the haemopoietically active fractions iron varied from <1·0 to 18·9 mg. while the copper was between 2·9 and 15·7 mg.; the inactive or slightly active ones had ranges of <1·0 to 4·3 mg. for iron and 8·6 to 15·7 mg. for copper.

It is clear, therefore, that the haemopoietic activities of these liver fractions are quite independent of the iron and copper they contain, but it should be appreciated that these values do not represent the metallic contents of the original fresh tissues, which values do not concern the main objects of this paper.

In passing it may be noted, however, that Meyer and Eggert [1932] found that only part of the iron and copper in livers from various mammals could be extracted with water. These metals tended to accumulate in the fraction which was precipitated by 67 % alcohol, a fraction which Whipple *et al.* [1930] found effective in microcytic hypochromic anaemias. On the other hand, the fraction subsequently obtained by precipitation in 95 % alcoholic solution (corresponding with the fraction G shown by Cohn *et al.* [1928] to be effective in pernicious anaemia) contained less copper and very little iron. These authors concluded that the substance in liver effective in pernicious anaemia has no relation to the iron and copper content of the liver. Moreover, Cohn *et al.* [1930] state that they have succeeded in preparing from liver a fraction containing no iron which is very effective in the treatment of pernicious anaemia.

The evidence, then, provided by our own data and those of these other workers goes to show that the iron and copper contents of the preparations of liver and stomach used in the treatment of pernicious anaemia bear no relationship to their haemopoietic potencies, and there is no support for the view that the anti-(pernicious) anaemic factors owe their activities to the presence or absence of these metals. Further, the total amounts of iron and copper in these preparations are infinitesimal in comparison with the quantities ingested in the ordinary diet and, indeed, in comparison with the normal therapeutic dose used in the treatment of other anaemias.

SUMMARY.

1. Determinations have been made of the quantities of iron and copper in various clinically tested preparations of stomach and liver used in the treatment of pernicious anaemia.

2. Iron was determined colorimetrically by slight modifications of existing methods involving the use of potassium thiocyanate and thiolacetic acid respectively.

3. Copper was estimated colorimetrically by a modification of the sodium diethyldithiocarbamate method.

4. The results do not indicate any obvious relationship between the iron and copper contents and the haemopoietic potencies as judged by clinical trial on cases of pernicious anaemia.

Acknowledgment is due to the Medical Research Council for grants to two of us (L. K. and J. F. W.) in the furtherance of this work.

XLI. THE FORMATION OF CARBOHYDRATE FROM FAT IN THE LIVER OF THE RAT.

BY CHALMERS LAUGHLIN GEMMILL[1] AND
ERIC GORDON HOLMES.

From the Biochemical Laboratory, Cambridge.

(*Received December 17th, 1934.*)

THERE have been many attempts to test whether or not fat can be transformed into carbohydrate in the animal body. The majority of the experiments have been negative, and the few which have given positive results have met with criticism. Burn and Marks [1926] reported an increase in glycogen in a perfused liver taken from a cat or dog after a high fat diet. At the same time they observed an increase in the sugar of the perfusion fluid. Gregg [1933] repeated these experiments and found, in the majority of his experiments, a decrease of liver glycogen. He explained the results of Burn and Marks and similar results obtained by earlier investigators on the grounds that feeding fat to dogs and cats does not completely rid the liver of glycogen. Also, he found that the distribution of the glycogen in the liver was so variable that a sample from one lobe did not give any information concerning the carbohydrate content of the whole liver.

Apart from perfusion experiments, evidence of this transformation is provided by the increase of glycogen found to occur in the livers of intact animals fed on fat diets. Takao [1926], Burn and Ling [1929] and Magnüsson [1929] have reported high glycogen values under this condition. For example, Burn and Ling found values as high as 5·0 % after 96 hours of fat feeding. In contrast to these results are those of Bodey *et al.* [1927], Gregg [1931] and Greisheimer [1931]. These observers failed to find such high percentages of glycogen as the workers quoted above, although in the majority of their experiments they did find a small but definite increase. Gregg [1931] claimed that this rise was due to the glycerol content of the fat. In support of this view, he found that when a rat was given the soaps of butter fat, there was no increase in the glycogen content over that shown by his series of fasting rats. As Gregg reported only one experiment of this nature, his conclusion is only suggestive.

Another type of evidence has been obtained from a study of the D/N ratio in depancreatised dogs. Soskin [1929] fed fat and lecithin to diabetic dogs. He found in 3 out of 15 experiments an increase in sugar in the urine. He concluded from this evidence that gluconeogenesis from fatty acids was proven. Page and Young [1932] were unable to obtain any increase in urinary sugar following an intravenous injection of lecithin into phlorhidzinised dogs. These experiments do not contradict those of Soskin, as it is now well recognised that the metabolism of a diabetic animal and a phlorhidzinised one are not the same; it is very difficult to transfer the results from one type of experiment to the other. The three positive experiments of Soskin are the most direct evidence that we have had, up to the present time, for transformation of fat into carbohydrate in the animal body.

---

[1] Associate in Physiology, Johns Hopkins University, School of Medicine.

The respiratory quotient of man and animals on fat diets has given suggestive evidence for this transformation. This subject has been studied recently by Hawley *et al.* [1933]. They found many respiratory quotients of less than 0·70 for men on a diet of cream. They concluded that these low quotients could be explained by the supposition that the process of desaturation of fats occurred more rapidly than that of oxidation, although they did not offer any experimental proof in support of this suggestion. Gregg [1931] in the same laboratory, found that rats on a diet of fat had an average R.Q. of 0·72.

The difficulty of interpreting the results from respiratory exchange, in man and animal, is that the process of conversion may take place in one organ, but the metabolism of the rest of the body may obscure the lowered respiratory quotient of that single organ. Therefore, it would be more significant to determine the respiratory quotient of individual tissues. Meyerhof and Lohmann [1926] obtained the respiratory quotient in serum of liver slices taken from fasting rats. They obtained quotients of 0·48, 0·76 and 0·67 for this preparation. Dickens and Šimer [1931] reported quotients of less than 0·70 for liver slices from fasting rats whether the experiments were made with phosphate or bicarbonate-buffered Ringer's solution. However, when serum was used for the determinations, an average value of 0·71 was obtained. Neither of these observers claimed a transformation of fat into carbohydrate from these low quotients. Needham observed figures as low as 0·35 for the respiratory quotient of the developing yolk sac. He was unable to detect sufficient transformation of fat into carbohydrate to explain these low quotients and concluded that they were due to some unknown retention of carbon and oxygen for synthetic purposes.

A fourth type of experimentation has been a study of the output of sugar in the urine following the injection of adrenaline into a depancreatised dog. Chaikoff and Weber [1928] obtained a definite increase of sugar by this method. They claimed that the excess sugar came from fatty acids. However, it is now well known, from the work of Cori and Cori [1928], that adrenaline mobilises muscle glycogen. Chambers *et al.* [1932] and others have demonstrated that depancreatised dogs have considerable amounts of carbohydrate in their muscles and other tissues. Therefore, the results of Chaikoff and Weber can be explained by the liberation of carbohydrate from the tissues under the action of adrenaline.

Since the majority of workers have observed a small but definite increase in the glycogen content of the liver of rats fed on fat, we thought that this problem might be solved for this particular tissue by two types of experimentation: a determination of the respiratory quotient of the fatty livers and an estimation of any change in the carbohydrate content of slices shaken in bicarbonate-Ringer for several hours.

METHODS.

Feeding of rats. The normal rats were fed on the usual laboratory diet. The rats on a fat diet were given butter, the essential salts and water. The amount of butter eaten each day varied from 3 to 7 g. After the 4th day of fat feeding, the rats were generally in poor physical condition. For this reason, the majority of experiments were made on animals that had been on butter diets for 2 or 3 days only. The rats were killed by a blow on the head. Portions of the liver were removed as quickly as possible for the glycogen determinations. The remainder of the liver was sliced for the manometric or other experiments.

Manometric methods. The method developed by Dixon and Keilin [1933] was used for the determinations of the respiratory quotient and the O_2 consumption.

Two major difficulties complicated the determination of the respiratory quotient and Q_{O_2} of the fatty livers. In the first place, it was noticed that fat separated from the tissue and collected on the sides of the vessel. Owing to this separation of fat, it was impossible to obtain the exact weight of the tissue used in each vessel. In our later experiments, this difficulty was overcome by weighing several slices of tissue before and after drying, in order to obtain the ratio for that particular liver. The slices for the manometric method were cut with a razor blade slightly moistened with Ringer's solution and were placed on a watch-glass in a covered dish which had moistened filter-paper on the sides and top until enough slices had been collected for the experiment. The slices were weighed and transferred to the vessels as quickly as possible. This gave an accurate measure of the wet weight of the tissue, and having obtained the ratio of the wet to the dry weight for that liver, the dry weight was calculated for the tissue used in the vessel of the manometer. When the calculated value of dry tissue was compared with the observed value of the tissue taken from the vessel, washed in water and dried in an oven, the calculated value was always much higher than the observed. The difference was due to the amount of substance lost by the usual procedure for obtaining the dry weight of the tissue. Since we determined the true ratio for the wet and dry tissues only in our later work, we are unable to give Q_{O_2} values for the earlier experiments.

The second major difficulty was the formation of acetoacetic acid. If aceto acetic acid is formed by the slices from a fatty liver, oxygen will be absorbed, but no corresponding amount of CO_2 will be liberated. We determined the amount of acetoacetic acid formed, using the manometric method, and we found that considerable quantities of this acid were produced in 2 hours by the fatty liver slices. A manometric method was devised by Ostern [1933] for the determination of oxaloacetic acid and it was later used by Quastel and Wheatley [1933] for their study of the production of acetoacetic acid by the liver. Krebs (unpublished experiments) has recently improved this method by using aniline citrate in place of the aniline hydrochloride. We have adopted this modification in our work. The initial value of this substance in the liver was practically zero. Liver slices from the liver of rats on normal diet produced very little acetoacetic acid. Unfortunately our observations on acetoacetic acid formation were made before we obtained a definite ratio of wet to dry tissue in each experiment. Therefore, we are unable to give absolute values of the acetoacetic formation per mg. dry tissue per hour. We can say, however, that there is a definite formation in the livers of fat-fed rats, and that this formation would affect the respiratory quotient. In the manometric method, aniline citrate was used to liberate carbon dioxide from the acetoacetic acid. This fact suggested that hydrochloric acid used in the Dixon-Keilin method might also liberate carbon dioxide in a similar way. Several experiments were made to study this reaction, using separately aniline citrate and HCl on pure solutions of acetoacetic acid. The results of one experiment are given in Fig. 1. The carbon dioxide was quantitatively liberated by HCl, as well as by the aniline citrate, but the time courses of the two processes were very different. These experiments were made at 37°. There was a delay of 15 minutes on account of the preliminary shaking to ensure thermal equilibrium. During this time, small amounts of acetoacetic acid may be broken down, especially in the presence of the citric acid, which would account for the recovery of only 80 % of the theoretical yield. The same results were obtained when similar experiments were made on normal tissue to which acetoacetic acid had been added. Thus, the routine procedure of Dixon and Keilin may be used for determining the respiratory quotient of the fatty livers provided that a sufficiently long period be allowed for the breakdown of the acetoacetic acid. This period was, in our experiments, generally about 5 hours after spilling over the hydrochloric acid.

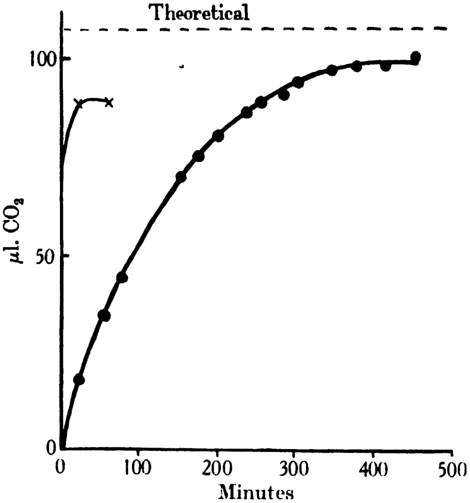

Fig. 1. Liberation of CO_2 from acetoacetic acid after adding aniline citrate and HCl. ×——× Aniline-citric acid, 80 % recovery. •——• HCl, 94 % recovery.

The remainder of the procedure for the manometric experiments was identical with the original description of Dixon and Keilin. We observed, however, that the readings, after the KOH had been admitted to the vessels, did not become constant for several hours. Elliot and Schroeder [1934] have observed similar changes, lasting for two or more hours.

Chemical methods. The Hubbard [1921, 1] method was used for the determination of total acetone bodies in the urine and the method described by Good *et al.* [1933] was used for the glycogen estimations. The glycogen estimations were made in duplicate. Only one acetone determination was made, as the amount of urine collected from a rat rarely exceeded 10 ml. for the 24-hour sample. The total fermentable carbohydrate in liver slices was determined by the method described by Cori and Cori [1933] for muscle. Estimations of β-hydroxybutyric acid in the liver slices were made by grinding the tissue in ice-cold water and carrying out the procedure described by Hubbard [1921, 2] for determining this substance in blood.

For the determination of the total fermentable carbohydrate and the β-hydroxybutyric acid in the tissue slices the following procedure was used. The tissue was cut in the same manner as for the manometric method. Alternate slices were taken for each series in order to ensure a good sampling of the liver tissue. The tissue was weighed and was placed in a small flask containing 3 ml. of bicarbonate-Ringer solution. Generally about 1·00 g. of slices was used for each determination. The solution had previously been saturated with 5 % CO_2 in oxygen. The small flask was closed with a rubber stopper through which passed two tubes, so that 5 % CO_2 in oxygen could be passed through the vessel while it was shaken in the water-bath. The gas mixture was passed through the vessels for 10 minutes. The stop-cocks were then closed and they were shaken for an additional 5 minutes before the contents of one vessel were taken for the initial value.

RESULTS.

Respiratory exchange: The results obtained on normal and fatty liver slices are given in Tables I and II and in Fig. 2. The respiratory quotients of liver slices taken from rats on a normal diet were between 0·61 and 0·87 with an average of

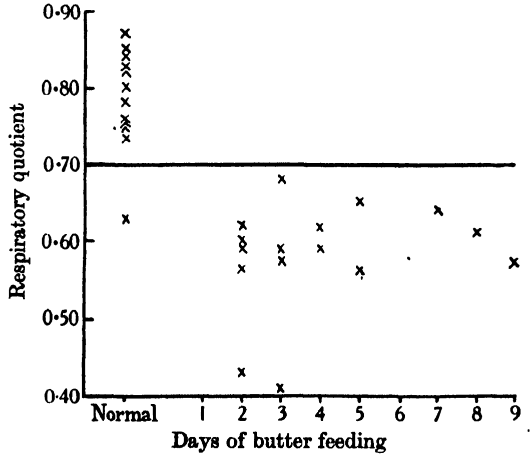

Fig. 2. Respiratory quotients of normal and fatty livers.

0·79, although only one determination, that of August 2nd, gave a value less than 0·70. Therefore, the majority of the respiration quotients for normal tissue fell within the normal limits of tissue oxidation. The range of these determinations is shown in graphic form in Fig. 2. When, on the other hand, determinations were made with the liver slices taken from fatty livers, the respiratory quotient was always below the normal level for fat oxidation, the lowest value observed was 0·41 and the highest 0·68, giving an average of 0·58. These results are given in Table II and in Fig. 2. This series of determinations on fatty livers was made after we had overcome the difficulties of obtaining accurate weights of the wet and dry tissue and was made in such a way as to eliminate the error involved in the fixation of oxygen in acetoacetic acid. The Q_{O_2} values, therefore, can be given for this series. They show some variation, not only from experiment to experiment but also in the same experiment. For example, in the experiment of November 8th, where the respiratory quotients of those determinations on the same liver were 0·55, 0·56 and 0·62, the Q_{O_2} values were 6·20, 4·13 and 7·48. However, closer agreement was obtained in other experiments.

A previous series of respiratory quotient determinations was made before we realised the necessity of waiting 4 or 5 hours to ensure the complete breakdown of acetoacetic acid. They fall within a somewhat lower range than those reported in Fig. 2, although the difference is not very great. This is certainly accounted for by the fact that, in this series, there was a retention of O_2 by reason of the formation of acetoacetic acid.

It is interesting to note that the ratio of wet to dry weights was different for the normal and fatty tissues. The ratio for normal tissue averaged 3·5, while that for the fatty tissue averaged 2·9.

In order to determine whether the formation of β-hydroxybutyric acid had any effect on the lowering of the respiratory quotient, two determinations of this substance were made. The results are given in Table IV. They show that the formation of 0·37 mg. β-hydroxybutyric acid per g. tissue would bind only 8 μl. O_2 per 0·3 g. of wet tissue per 2 hours. This is a negligible amount compared with the total uptake of over 1000 μl. observed in these experiments.

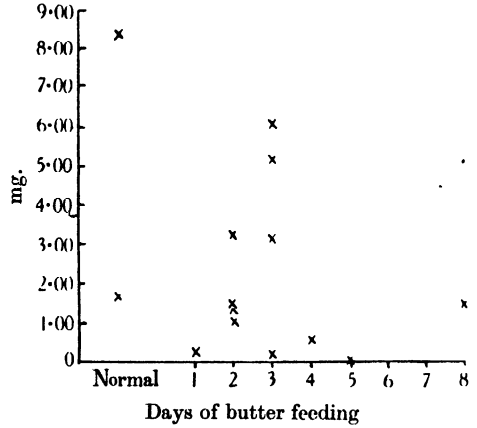

Fig. 3. Increases in total carbohydrate per g. of tissue.

Total fermentable carbohydrate. These results are given in Table IV and in Fig. 3. In order to see if comparable results could be obtained for the total fermentable carbohydrate in two series of liver slices, cut from the same liver, determinations were made on two such batches, shaken in the water-bath for the same length of time. The results of these determinations show close agreement both for the initial and final values (Table IV), illustrating that this method is adequate for determining changes in the carbohydrate content of the tissues. After these preliminary experiments, determinations were made in which one series was removed at the end of 15 minutes in the water-bath for the initial value and the other series at the end of 3 hours. Two determinations on normal

tissue gave an increase in carbohydrate during this period of shaking. These results are in contrast to those of Takane [1926]. Takane found a decrease in total carbohydrate in normal tissue and only observed an increase in the presence of added lactate. We determined the lactic acid content of the tissue at the beginning of three experiments (Table IV). The maximum initial lactic acid content was 1·14 mg. per g. tissue. If all the lactic acid were converted into fermentable sugar, it would account for a rise of the same amount. We did not determine the content of lactic acid at the end of our experiments. If lactic acid had disappeared, there would be no evidence that it had passed into carbohydrate and thus no correction could be applied to the carbohydrate increase. We then turned our attention to the livers of fat-fed animals. Again, an increase in carbohydrate was observed. The most marked increase was obtained on November 13th, where the increment was 6 mg. per g. tissue. In this experiment, the initial lactic acid value was only 0·64 mg. per g. tissue. Therefore the conversion of lactic acid into carbohydrate could account for only a small proportion of the total increase. In a few of our experiments the carbohydrate increase could be explained by assuming that all the initial lactic acid was converted into fermentable carbohydrate, as in the experiment of November 14th. The majority of our experiments gave increases greater than 1 mg. per g. wet tissue, therefore the increment of carbohydrate must have come from some other source. Taken in conjunction with the low respiratory quotients, we regard this as most important evidence for the formation of carbohydrate from fat.

Glycogen. The changes in the liver glycogen of the rats on a butter diet are given in Fig. 4. These results are stated in terms of g. glucose per 100 g. wet tissue. The values of the glycogen content of livers from rats on a normal diet varied between 1·52 % and 5·25 % with one exception. This value was very low, 0·10 %. On the diet of butter, the liver glycogen practically disappears on the 1st day and then gradually returns, reaching an average value of about 1 %. A high value was obtained for the liver glycogen of a rat fed for 9 days on butter. The averages for our 7, 8 and 9-day experiments are not as conclusive as for the 2nd, 3rd and 4th days, owing to the smaller number of experiments made on the longer periods of fat feeding. Our results show an increase of glycogen under

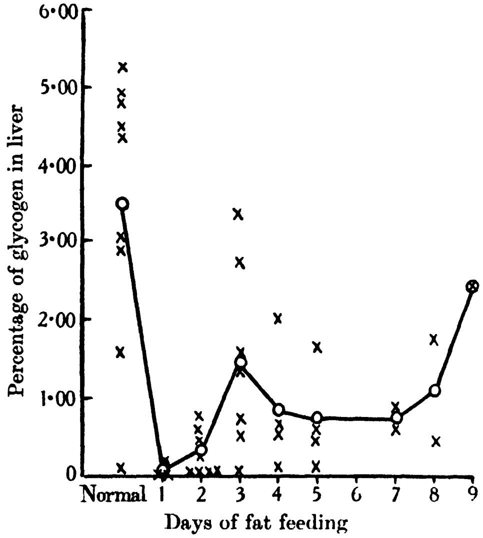

Fig. 4. Variation of liver glycogen on normal and fat diets. The circle gives the average value in each case.

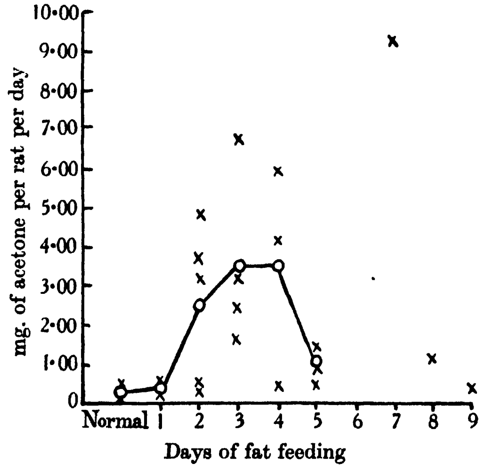

Fig. 5. Total acetone bodies excreted per rat per 24 hours.

these conditions. In one experiment, we kept a rat on butter diet for 7 days and then on the normal diet for 2 days. This rat gave an exceptionally high value for liver glycogen, 9·5 %.

Total acetone bodies. The results are given in Fig. 5 in terms of mg. acetone per rat excreted in the urine during the 24 hours before the animal was killed. There is a slight correlation between the appearance of glycogen in the liver and the disappearance of the total acetone bodies from the urine. The results in both series are so scattered that it is difficult to draw any conclusions from the averages. In general the acetone bodies showed an initial rise, starting on the 2nd day, reaching a peak on the 3rd and 4th days and then falling again, although the one experiment on the 7th day gave a very high value. Wigglesworth [1924] has observed similar changes in the acetone bodies of rats on a diet of butter.

An attempt was made to determine the changes in the fat content and the iodine number of liver slices in order to see if any increase in desaturation or if any decrease in fat content could be detected during a 3-hour period of metabolism. The results were so variable for two series of slices shaken for the same period of time that this procedure was discontinued.

Discussion.

The experiments described in this paper offer good evidence in favour of the hypothesis that fat can be converted into carbohydrate in the liver of the rat. In view, however, of the sharp controversy which the question has raised in the past, we are anxious to define as precisely as possible exactly what we believe our experiments to have proved. We have shown that, on a fat diet but not on a normal one, the respiratory quotient of rat liver slices *in vitro* is well below 0·7. Therefore there is a causal connection between fat feeding and low respiratory quotients. Further, we have shown that carbohydrate can be synthesised by liver slices *in vitro*. The matter may, perhaps, be put into more general terms, as follows. The respiratory quotient in our experiments is a function of the fat diet: carbohydrate synthesis also takes place under these conditions. Since we have eliminated by direct experiment many of the fallacies which surround the determination of the respiratory quotient, we feel that there is strong presumptive evidence that the low quotients do, in fact, indicate carbohydrate synthesis; this presumption is greatly strengthened when we find such a synthesis actually occurring. We should feel that neither finding, taken by itself, would be very conclusive; on the other hand, both taken together, represent a strong case.

One or two further points merit attention. In the livers of two rats on a normal diet, we found carbohydrate synthesis, and in one case this synthesis was larger than any found in the livers of the fat-fed animals. If gluconeogenesis were a process occurring only in animals fed on an entirely abnormal diet of pure fat, it would probably be of little importance. It has, on the contrary, been assumed by many authors, without experimental proof, to occur in normal animals. The R.Q. of the normal liver slices may be assumed to have been in the neighbourhood of 0·79, the average figure for normal livers, and one which does not indicate the formation of carbohydrate from fat. We have, in fact, no evidence to show that the carbohydrate was not formed in these cases from protein. Supposing, however, that it was formed, in whole or in part, from fat, it is quite possible that in a carbohydrate-rich liver the process would result in a lowering of the R.Q. from unity to a level which was still well above that of fat oxidation. On the other hand, in carbohydrate-poor livers, such as are those on the 2nd and

3rd days of a fat diet, the liver is probably oxidising fat, and carbohydrate synthesis would lower the R.Q., starting from a base line, not of 1·0, but of 0·7. We have calculated, in fact, that the synthesis of 3·0 mg. carbohydrate per g. liver slices would lower the R.Q. from 0·79 to 0·63 in our respiratory experiments. Although some of our experiments showed a synthesis of carbohydrate of less than 3·0 mg. per g. tissue, in four experiments the carbohydrate synthesis was greater than 3·0 mg. Similarly, in a number of experiments, the R.Q. was less than 0·63. Our average value was in fact 0·58.

The increase in liver glycogen in the rats fed on butter occupies an intermediate position between the results of those observers who have reported large increases and those who have found very small changes. The averages for our determinations for each day show a decided increase on the 3rd day in contrast to the absence of glycogen on the 1st and 2nd days. Without our other data, it might be assumed that this increase is due to the glycerol fraction of the fat, an assumption made by Gregg [1931] to explain similar results. With the lowered respiratory quotient and the determination of an actual increase in carbohydrate in liver slices the more probable explanation for this rise is that part of the carbohydrate is coming from fat.

SUMMARY.

1. The respiratory quotient of slices of liver from a rat fed on a normal diet averages 0·79, while that from a rat fed on butter averages 0·58.

2. The carbohydrate content of liver slices taken from a liver of a rat fed on butter shows a definite increase after 3 hours' shaking in bicarbonate-Ringer medium at 37°.

3. The glycogen content of the liver of rats fed on butter falls to practically zero on the 1st day of this diet. It gradually rises reaching a level of almost 1·00 % on the 4th and 5th days of butter feeding.

4. The acetone bodies in the urine of rats increase, reach a maximum on the 3rd or 4th day of butter feeding and then decrease.

5. The lowering of the respiratory quotient and the increase in carbohydrate of the liver slices indicate that conversion of fat into carbohydrate takes place in the liver of a rat fed on butter. The same conversion may take place in a normal liver.

XLII. PROTEIN AND THE DIETARY PRODUCTION OF FATTY LIVERS.

By HAROLD JOHN CHANNON and HARRY WILKINSON.

From the Department of Biochemistry, The University, Liverpool.

(*Received December 20th, 1934.*)

The observation by Best *et al.* [1932] that fatty livers could be produced in rats which received a diet consisting of mixed grain with 40 % of beef fat provided a means whereby the curious action of choline in preventing and curing such dietary fatty livers has been extensively studied [Best and Huntsman, 1935]. On a number of occasions however use of this diet has failed to produce in our rats fatty livers of an intensity similar to that recorded by the Toronto workers, while its deficient nature may cause weight losses in the experimental animals. Since the amount of liver fat is changed by starvation, it may also be influenced by this type of undernutrition and complicating factors in the interpretation of results may thereby be introduced.

A governing factor in fatty liver production on diets containing 40 % of fat has been shown to be the choline content [Best and Huntsman, 1935]. With this finding in mind an attempt was next made to produce dietary fatty livers in rats under conditions in which no loss of body weight occurred. For this purpose a diet of caseinogen 20, starch 30, beef fat 40, salt mixture 5, marmite 5 and vitamins A and D was given. Both the caseinogen and starch had been exhaustively extracted by alcohol and ether and save for the small amount of choline present in the marmite—1·75 mg. per rat per day—this diet was choline-free. Fatty livers did not result. This amount of choline is of no importance since the mixed grain diet of Best, Hershey and Huntsman [1932] which causes fatty livers in rats contains enough choline to give each animal about 8 mg. per day. This failure suggested that some factor other than the choline content was influencing the production of fatty livers on diets containing 40 % of fat, and consideration of various results in the literature suggested the level of protein intake as the most probable. In this connection the wide variations in the relative amounts of glyceride and cholesteryl ester appearing in the "cholesterol" fatty liver caused by feeding diets containing 1–2 % of cholesterol were considered. Calculation of the approximate compositions of the diets used by different workers [Okey, 1933, 1, 2; Chanutin and Ludewig, 1933; Best *et al.*, 1934; Channon and Wilkinson, 1934] indicated that the protein content of the diets might be a factor in the control of the amount of liver glyceride. Accordingly the effect of varying the protein content of the diet at the expense of the carbohydrate, with a constant fat content (40 %) and an adequate supply of vitamins and salts, has been studied. The object was to evolve a diet which would cause fatty livers without loss of body weight if possible and to study the part played by protein in fatty liver production. Further, in order to study any effect of protein in controlling the fatty liver produced by feeding rats on pure sucrose [Best and Huntsman, 1935], two further diets were included; these were fat-free and contained 5 and 30 % of protein respectively with 85 and 60 % of glucose hydrate. All the diets used have been substantially choline-free.

These experiments have been used at the same time to attempt to elucidate a further point in fatty liver production. Great variations in the percentage of liver fat among individual rats under the same fatty liver-producing dietary regime often occur and the extent of these variations can be readily seen by reference to the paper of Best and Huntsman [1935] where variations from 5·5 to 26·6 % among individuals from one experiment are recorded. This degree of variation must have some significance. The frequency of its occurrence is such as to make the use of large numbers of animals necessary, apart from rendering interpretation of results somewhat uncertain. The degree of fat infiltration occurring in the liver in starvation in rats and rabbits has been shown to be related to the amount of fat present in the depôts [Dible, 1932; Dible and Libman, 1934]. It was possible that the variations in the amount of fat in the fatty livers of rats on a high fat diet were related to the amount of depôt fat. This has been investigated by a study of the fat content of the liver and carcass of each individual animal in these experiments.

EXPERIMENTAL.

The general plan of the experiment was to feed groups of rats on various diets for 21 days. The animals were then killed by a blow on the head 12 hours after the last meal. The livers were removed and weighed for analysis, the gastro-intestinal tracts removed and the carcasses stored in a refrigerator until they could be analysed.

The diets used are described in Table I. The caseinogen was B.D.H. "fat-free casein" which had been further extracted three times with boiling industrial alcohol. The choline content of the constituents of the diets was determined by assay on the isolated rabbit intestine after hydrolysis and acetylation. Save for the marmite, the constituents were choline-free. The marmite contained 350 mg. of choline per 100 g. and since it constituted 5 % of all the diets, each animal in the different groups ingested about 1·5 mg. of choline per day. The average actual amounts of choline ingested by the animals in each group are recorded in Table II.

Table I. *Description of the diets.*

Group ...	A	B	C	D	E	F	G	H
Diet								
Caseinogen	0	5	10	20	30	50	5	30
Beef dripping	40	40	40	40	40	40	0	0
Glucose hydrate	50	45	40	30	20	0	85	60
Marmite	5	5	5	5	5	5	5	5
Salt mixture	5	5	5	5	5	5	5	5
Cod-liver oil	One drop per rat every 3 days							

The fat content of the individual livers was determined by ethereal extraction after acidification of the livers following saponification with aqueous NaOH. After evaporation to dryness of the washed ethereal extract the weight of the "fat" was obtained. Separation of this material into its constituent fatty acids and unsaponifiable matter was not carried out because experiments showed that the combined weights of unsaponifiable matter and fatty acids obtained by further alcoholic saponification were in all cases 98 % of that of the original material. The fat content of the carcasses was determined either by a similar method or by saponification of the alcoholic extract of the minced carcass. In the latter cases the minced carcasses were treated many times with successive volumes of boiling alcohol and the combined extracts saponified and treated as already described.

Results.

In Table II are recorded data concerning the number of rats used in each group, their changes in weight during the experiment, the average food intake per rat per day, the caloric value of this food and its choline content.

Table II. *Weight records of the animals and the food intake.*

Group	A	B	C	D	E	F	G	H
Protein % of diet ...	0	5	10	20	30	50	5	30
No. of animals ...	6	6	6	6	6	5	6	6
Av. weight at beginning of experiment (g.)	141	143	141	136	139	148	141	136
Av. weight at end of experiment (g.)	122	147	153	179	182	186	140	146
Gain or loss (g.)	−19	+4	+12	+43	+43	+38	−1	+10
Av. food intake per rat per day (g.)	8·3	9·2	8·0	9·0	9·0	8·5	11·7	13·5
Caloric intake per rat per day (Cals.)	48·0	53·4	46·4	52·5	52·5	50·6	44·5	51·1
Choline intake per rat per day (mg.)	1·46	1·70	1·42	1·59	1·59	1·50	2·07	2·38

Diets A to F contained 40 % fat; G and H were fat-free.

In Table III the percentages of "fat" (total fatty acids and unsaponifiable matter) present in the livers and the carcasses of the individual animals are set out.

DISCUSSION.

1. *Diets (B–F) containing 40 % of fat with varying percentages of protein.* The wide variations in the percentages of fat in the individual livers are seen in Table III. For discussion purposes the mean values are recorded in that table, although the limitations caused by the relatively small numbers of animals are recognised. The average figures for the "fat" content of the livers of the animals receiving 5, 10, 20, 30 and 50 % of protein are 12·49, 7·35, 6·50, 6·12

and 5·60 % respectively. These diets were substantially choline-free, for the choline intake of each rat in the different groups varied only between 1·42 and 1·70 mg. per day. As mentioned in the introduction, this amount of choline is considered to be of no significance in the interpretation of the results and further, since it is virtually constant at 1·5 mg. per rat per day, any possible effect is the same for all the groups. It is clear therefore that the amount of protein in the diet is a factor controlling the amount of fat appearing in the liver irrespective of any effect of choline, the degree of fat infiltration increasing with decreasing protein content. The 12·49 % of fat in the livers of animals which received 5 % of protein is similar to the figure often recorded by the Toronto workers as occurring in rats receiving the mixed grain diet with 40 % of fat. Such a diet would on our calculations contain 6 % of protein. The decreasing amount of fat appearing in the liver with increasing protein intake explains also our previous failures to produce fatty livers in rats on diets of high fat content but choline-free, because in all these cases protein constituted at least 20 % of the diet. These investigations further provide a method for producing fatty livers in rats by dietary means on diets free from choline without the possibility of complications due to weight loss. Thus the diet containing 5 % of protein and 40 % of fat resulted in the livers of the animals containing 12·49 % of fat at the end of 3 weeks with an average weight increase of 4 g. per animal.

This control of the glyceride content of the liver by the protein content of the diet has been further confirmed in experiments on the "cholesterol" fatty liver. We administered to one group of rats a diet containing caseinogen 5, fat 20, glucose 65, marmite 5, salt mixture 5, vitamins A and D, with 2 % cholesterol. To a second group the same diet was given save that the protein content was raised to 30 % at the expense of the sugar, which was reduced to 40 %. After 3 weeks the animals were killed and their livers analysed. The results obtained are recorded in Table IV.

Table IV. *The liver lipoids of rats fed on a diet containing 20 % fat and 2 % cholesterol, but free from choline.*

(g./100 g. liver.)

Group ...	J	K
Percentage protein in diet	5	30
Phosphatide	1·79	2·54
Glyceride	25·42	5·54
Free cholesterol	0·294	0·452
Cholesteryl oleate	4·42	7·91

The figures in Table IV appear amply to confirm the finding of the control of glyceride deposition in the liver by the level of the protein intake, for whereas the glyceride content of the livers of animals receiving 5 % of protein (group J) is 25·42 %, that of group K, which received 30 % of protein, is only 5·54 %. It is of interest to note that the amount of cholesteryl esters is some 80 % higher in group K, compared with group J, but at this stage no interpretation of this finding can be provided.

These results show therefore that in the "cholesterol" fatty liver the relative amounts of glyceride and cholesteryl esters depend in the case of choline-free diets on the protein content of the diet, the glyceride fraction being far more extensively involved and in the reverse direction. They explain the varying degree to which these two constituents occur in the livers of rats fed on diets containing cholesterol as reported by different workers, a question which has been discussed in a previous paper [Channon and Wilkinson, 1934]. A number of other points arise from consideration of Table IV and other data concerning this experiment: (*a*) The total fatty acid content of the livers of group J (protein 5 %, fat 20 % with cholesterol 2 %) is 27·5 %. On the other hand that of group B in Table III (protein 5 %, fat 40 % without added cholesterol) is 12·49 %, a figure half as great. This increase does not seem to be related in any way to the cholesteryl ester content of the livers, because the livers of group K in Table IV contained 80 % more cholesteryl esters than those of group J. (*b*) In group J the phosphatide percentage, 1·79 %, is the lowest which we have yet encountered in any group of fatty livers, just as the "fat" content is the highest. (*c*) The liver weights expressed as a percentage of the body weights were, in group J 5·55 % and in group K 3·54 %; the former figure again is the highest we have encountered and is to be compared with the normal figure of about 3 %. (*d*) The normal iodine value of rat liver fatty acids is about 115. Those of group J (total liver fatty acids 27·5 %) had an iodine value of 78·7, while in group K (total liver fatty acids 10·52 %) the iodine value was 80·7. These figures illustrate the fact that under the conditions of these experiments the iodine value does not fall in proportion to the degree of fat infiltration. Thus in group J where the livers contained about nine times the normal amount of fatty acids, the iodine value has fallen only from 115 to 78·7, while in group K (liver acids three times the normal amount) the iodine value was 80·7. Admixture of one part of the original liver acids (I. V. 115) with 8 parts of those of the food (I. V. 40) would yield a mixture of acids having iodine value 48. Clearly therefore the liver acids of group J have not been derived by direct absorption of the mixed food acids. Further they contained 29·5% of solid acids of iodine value 13 (Twitchell) a percentage differing little from the normal. Whether the unsaturated liver acids, which in group J amount to 1·58 g. per animal, of iodine value 106, have been derived by preferential absorption of the unsaturated acids of the food or depôt fats, cannot be determined. More detailed evidence along these lines may however throw light on any possible desaturation process.

The general finding that the protein content of the diet controls the degree of glyceride infiltration of the liver may have a number of explanations, of which mention will be made of one only. In view of the known action of choline and of betaine in preventing fat infiltration [Best and Huntsman, 1932] it may imply that certain amino-acids may be converted into these substances in the tissues. Best and Huntsman [1935] draw attention to the fact that Engeland [1909] suggested that betaines might arise in the tissues by methylation of amino-acids. It is possible that a number of other compounds of types similar to betaine and choline, which might have physiological actions in controlling the liver fat level, may arise from different amino-acids, although at the present time choline and betaine themselves are alone known to be active. Thus choline itself might be derived from glycine, as was suggested by Rosenfeld [1930] as a result of his study of the synthesis of lecithin by chickens. Another possible precursor of choline might be serine. It is of interest however that the protein used in our experiments, caseinogen, contains very little glycine or serine. We are therefore continuing these studies by producing fatty livers in rats on a diet containing 5 % caseinogen and are adding to the diets supplements of these and other amino-acids. In a previous paper [Aylward *et al.*, 1935] studies were made of the changes in the lipoids of the livers of rats following a fat- and cholesterol-containing meal free from and with added choline. The diets used contained 20 % of caseinogen and the decrease in liver phosphatide at the seventh hour in the livers of the animals receiving the choline-free diet was much greater than on the diet which contained choline. If this finding be confirmed, it would imply that the action of protein in preventing fat infiltration was much slower than that of choline itself and may suggest that the conversion of some precursor into a substance having the same action as choline is being relatively slowly effected.

A further point of interest is that although the percentage of liver fat decreases with increase of the protein percentage in the diet, even in group F (protein 50 %) it is still 5·66 %, a figure which is to be regarded as about 1 % higher than the normal.

It will be observed from Table III that in the animals of group A, which received no protein in the diet, the livers contained 8·95 % of fat, *i.e.* substantially less than did those of rats which received 5 % of protein. We do not propose to discuss this figure because the weight losses of the animals, an average of 19 g. in 21 days, are too great to permit of any deductions being made with certainty.

With the results recorded in Table III are to be compared those of Best *et al.* [1935]. These workers obtained fatty livers in rats receiving a diet of 15 % of protein and 20 % of fat for 21 days (average figure 10·5 %). According to our results such a diet should not produce fatty livers, for the figures in Table III suggest that, if 15 % of protein were present in the diet with as much as 40 % of fat, the fat content of the liver would be about 7 %, whereas the fat content of their diet was only 20 %. It is not unlikely that these discrepant findings are to be ascribed to the weight losses of the animals of Best *et al.*, which were 9 g. per animal in a period of 21 days, the diet used being deficient in vitamins. The experiments of Best and Ridout [1933] in which rats received a grain diet with 20 % of fat did not result in fatty livers. Since the protein content of this diet would be only 8 %, it might have been expected from our data that fatty livers should have resulted, even though the fat content of the diet was only 20 %. These particular results cannot be compared with our own, however, because the average weight loss of the animals was 23 g. in 31 days, while the diet was such that each animal received about 8 mg. of choline per day, facts which complicate any comparison.

2. *Diets (G–H) containing no fat with 5 % and 30 % of protein.* No difference in the fat contents of the livers of these groups occurred, nor did fatty livers result, the average value being 4·65 %. From the point of view of future experiments it should be pointed out that the individual variation among the livers of the animals which received 30 % of protein was very much less than in any of the groups in this experiment. This suggests such a diet to be very suitable as a preparatory one for ensuring the greatest possible constancy of the fat content of the liver before further dietary treatment.

Best and Huntsman [1935] found that normal animals receiving exclusively sucrose developed fatty livers. The present results show that a diet of 5 % protein and glucose does not cause fatty livers. We think the explanation of these differences is again to be found in complicating factors of weight loss, for whereas our animals had an average weight loss of 1 g. in 21 days, the rate of weight loss of those of Best and Huntsman was rapid.

3. *The relationship between the amount of depôt fat and the amount of liver fat.* The figures recorded in Table III show that no relationship exists between the amount of depôt fat and that of liver fat. If the ratios of the percentage of the carcass fat to that of the liver fat be calculated for the animals which received a 40 % fat diet with 0, 5, 10, 30 and 50 % of protein, the average figures re-

sulting are 1·38, 1·40, 2·17, 2·94 and 2·77; if the individuals of one particular group are considered (group B, 40 % fat, 5 % protein) the ratios of carcass fat to liver fat are 0·70, 2·25, 1·14, 2·62, 2·11, 1·28. It is clear therefore that these results provide no evidence for the view that fat infiltration in the liver under these particular dietary conditions is influenced by the amount of depôt fat, and in this they are to be contrasted with the starvation experiments referred to in the introduction. This question of individual variation must be of significance and needs further investigation.

SUMMARY.

1. Groups of rats have been fed on complete diets containing 40 % fat with varying amounts of protein (from 5 to 50 %) for a period of 3 weeks and their livers and carcasses analysed for fat content. The diets were substantially choline-free, but each rat actually received 1·5 mg. of choline per day, which was present in the yeast extract used to supply vitamin B complex.

2. The amount of fat appearing in the liver was conditioned by the amount of protein in the diet irrespective of any action of choline.

3. The diet containing 40 % of fat and 5 % of protein is adequate for weight maintenance and for the production of livers containing 12·49 % of fat in 3 weeks.

4. This control of the glyceride content of the "fat" fatty liver has been confirmed by experiments on the production of the "cholesterol" fatty liver, for livers of animals receiving a diet containing 5 % of protein, 20 % of fat and 2 % of cholesterol contained at the end of 3 weeks 25·42 % glyceride and 4·42 % cholesteryl esters. On the other hand the livers of another group receiving the same amounts of fat and cholesterol but with 30 % protein, contained 5·54 % glyceride and 7·91 % cholesteryl esters.

5. The possibility of the action of the protein in controlling liver fat being due to its providing amino-acid precursors which are converted either into choline or betaine or substances of similar physiological action is discussed.

6. No relationship exists between the amount of fat infiltration in the liver and the amount of the depôt fat.

The expenses of this research were defrayed from a grant from the Medical Research Council, to whom we express our thanks.

XLIII. A STUDY OF CYSTINURIA IN TWO SISTERS.

BY EVELYN MARION HICKMANS AND
WILLIAM CAREY SMALLWOOD.

From the Children's Hospital, Birmingham.

(*Received December 10th, 1934.*)

THE subjects of this investigation are sisters, one of whom, the younger, was first referred to the Birmingham Children's Hospital by Dr Burns of Redditch for the investigation of albuminuria. She was admitted and on examination was found to have cystinuria. A subsequent examination of a specimen of urine from the sister revealed cystine crystals and she, also, was admitted for investigation and observations on metabolism.

Family history.

Cystinuria is one of a group of disorders which have been aptly described by Sir Archibald Garrod in the picturesque phrase "inborn errors of metabolism". An enquiry was instituted, therefore, into the occurrence of the derangement in other members of the family, and with the co-operation of the patients' doctor and parents many specimens of urine were collected from each of seventeen blood relatives, at intervals of several weeks, and examined by us for cystine. The tests applied were:

(1) Microscopical examination of sediment: (*a*) from the fresh specimen, (*b*) after acidifying with dilute acetic acid and standing for one week, and (*c*) from acidified specimens concentrated by evaporation.

(2) The Sullivan reaction as modified by Brand *et al.* [1930].

(3) The cyanide-nitroprusside reaction described by the same authors.

These investigations revealed well-marked cystinuria in one other relative, whose position in the genealogical tree is shown in Fig. 1. The positions of the two subjects of this investigation are indicated by the encircled figures, while crosses denote the existence of members who were not examined. In addition to the discovery of one other definite cystinuric it was found that the urine of several other members of the family gave faintly positive results with one or other of the chemical tests for cystine, and a few showed one or two hexagonal crystals after prolonged microscopical examination of an acidified specimen of urine concentrated by evaporation.

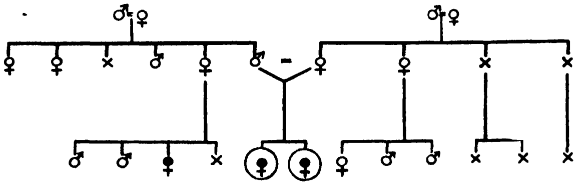

Fig. 1. Genealogical tree.

♂ ♀ male and female normals respectively; **♀** female cystinurics.

These findings, together with the results of tests for albumin and estimations of total amino-acids, appear in Table I. It will be seen that the presence of traces of cystine in the urine of one individual was not constant and that specimens in which, on microscopy, two or three hexagonal crystals were found did not always yield positive chemical tests and *vice versa*.

Various writers [Loewy and Neuberg, 1907; Lewis and Simon, 1902] have suggested that the degree of cystinuria may vary considerably from time to time and even disappear temporarily. At first we were tempted to believe that these other members of the family were occasional or mild cystinurics and that the union of two such individuals had resulted in two florid examples of the metabolic error. We do not feel justified, however, in advancing this thesis on such slender evidence. There was no consanguinity of parentage in any of the families and no family history of stone or of nephritis known to the parents of the two children investigated.

Clinical history.

W.B. Aged 12 years. First child in family of two. Admitted to Birmingham Children's Hospital on April 26th, 1932.

History. Quite well until 6 months previously; since then vaguely unwell; easily tired, frequently complaining of backache referred to both loins and relieved by lying down. For 3 months prior to admission scalding micturition but no increased frequency of micturition or other urinary symptoms. Occasional headaches for many years.

Examination. A tall slender girl: weight 5 stone 6 pounds: nutrition moderately good and general appearance one of health. Mentality normal. No abnormality of cardiovascular, respiratory, alimentary or nervous systems. B.P. 125/80. Kidneys neither enlarged nor tender.

Urine. S.G. 1030. Reaction slightly alkaline to litmus. Albumin: light cloud. Sugar: nil.

Deposit. Cystine crystals in large numbers in specimens which were allowed to stand, both before and after acidifying with acetic acid. Sullivan and nitroprusside tests both strongly positive for cystine.

X-ray of renal tract—no evidence of stone.

Blood.	Urea	(fasting)	30·9	mg./100 ml.
	Non-protein-nitrogen	,,	30·3	,,
	Uric acid	,,	2·81	,,
	Amino-acid-nitrogen	,,	11·48	,,
	Chlorides	,,	459	,,
	Cholesterol	,,	182	,,
	Creatinine	,,	1·26	,,

Urea concentration test (*Calvert's*) showed normal renal function:

15 g. urea given.
Specimen A. Volume 500 ml.: Urea 2·32 g./100 ml.
Specimen B. Volume 930 ml.: Urea 0·39 g./100 ml.

J.B. Aged 10 years. Second child in family. Admitted to Birmingham Children's Hospital, April 6th, 1932.

History. Always a delicate child though never suffering from any definite disease of any system. One year before admission commenced to complain of backache, was easily tired and had frequent frontal headaches. These symptoms continued. In November 1931 the child was noticed to be passing very little urine, was seen by Dr Burns of Redditch and found to have albuminuria. No history of haematuria or other urinary symptoms. She was thought to be abnormally thirsty at this time. Twelve months before admission the child had an acute febrile illness in which she vomited and developed a scarlatiniform rash but never peeled. The albuminuria persisted and the child was sent to hospital for investigation of renal function.

Examination. A tall slender girl—weight 4 stone 4 pounds—of healthy appearance, normal mentality and moderately good nutrition. Cardiovascular, respiratory and nervous systems normal. Many carious teeth present: alimentary tract otherwise normal. Kidneys neither enlarged nor tender.

Uric acid	,,	2·15	,,
Amino-acid-nitrogen	,,	6·18	,,
Cholesterol	,,	170	,,
Chlorides	,,	482	,,
Creatinine	,,	1·27	,,

A twenty-four hour specimen of urine—volume 373 ml.—collected when the child was having ordinary hospital diet showed:

Urea	1·72	g./100 ml.
Uric acid	0·051	,,
Creatinine	0·098	,,
Total nitrogen	1·60	,,
Chlorides	0·61	,
Amino-acid-nitrogen	0·0297	,,
p_H	7·05	,,

Silver articles placed in contact with the skin of both children for periods of five days showed no discoloration, an observation which suggests that sulphur compounds were absent from the sweat of our patients. The urine of both children developed a greenish colour and gave off hydrogen sulphide and ammonia on standing.

Presence in the urine of tyrosine, leucine, putrescine and cadaverine.

The urine of both patients was examined repeatedly for the presence of leucine and tyrosine and for the diamines cadaverine and putrescine. Specimens were concentrated by evaporation *in vacuo* and the following tests performed:

Examination of the concentrate for crystals of leucine and tyrosine.

Tests with Millon's reagent.

Treatment of the concentrate with β-naphthalenesulphonyl chloride (method of Abderhalden and Shittenhelm [1905]).

Benzoylation method of Baumann and Udransky [1889].

Phenyl isocyanate method of Loewy and Neuberg [1904].

These tests failed to reveal the above amino-acids and diamines.

Test for the presence of a precursor of cystine in fresh specimens of urine.

A perusal of the literature on cystinuria reveals frequent references to the presence in the urine of cystine precursors, which usually break down quite rapidly with the liberation of free cystine, especially after the addition of dilute acetic acid. These may, however, from time to time prove more stable and resist the action of the somewhat hypothetical urinary ferments which are supposed to bring about the necessary chemical changes. Wallis and Garrod [quoted by Garrod, 1923] reported a case in which cystine could not be found by the Gaskell method, and which showed cystine crystals in the urine only after six months' standing. Garrod remarks "the inference cannot be avoided that under certain conditions cystinurics excrete a sulphur compound which is not free cystine but a compound or unoxidised derivative thereof".

From time to time various workers [Klemperer and Jacoby, 1915; Looney *et al.*, 1923] have reported a diminution in the cystine excretion (as determined colorimetrically) after the prolonged administration of alkali without significant changes in the neutral sulphur values, and these findings have been regarded as further evidence in favour of the excretion in freshly voided urine of a cystine complex and as an explanation of the phenomenon of intermittent cystinuria. This subject receives careful consideration by Brand *et al.* [1930] who, in their observations on a cystinuric, found that the freshly voided urine of their patient gave a negative Sullivan reaction, but after standing for 24 hours the brilliant red colour indicating a positive reaction had developed and this colour continued to increase in intensity for a further 24 hours before fading. In a similar experiment we have observed an almost exactly similar phenomenon in both of our patients. The red colour commenced to develop at the end of the first hour, deepened gradually during the next 48 hours and then slowly faded.

Metabolism experiments.

The source of the cystine excreted in the urine, whether of endogenous or exogenous origin, and the effect of diet on the amount of this excretion have been the points studied by various workers. The investigations here recorded were undertaken in order to test the effect of various diets on the excretion of urinary cystine, in an endeavour to discover a diet sufficient for the requirements of these growing children which was least productive of cystinuria and therefore less likely to lead to stone formation; simultaneously an attempt was made to locate the source of the cystine.

The feeding experiments carried out were as follows:

(1) Ordinary hospital diet.
(2) Ordinary hospital diet *plus* pure cystine.
(3) Low cystine, medium protein diet.
(4) High cystine, medium protein diet.
(5) High cystine, high protein diet.
(6) Ordinary hospital diet *plus* pure cystine for estimation of faecal loss of cystine.

Method. The experiments were carried out concurrently on the two patients and on a normal control—a boy aged 12 years, who had recovered from pneumonia a few weeks earlier and appeared to be in good health at the time of the investigation. Throughout the experimental period all these children were allowed to play in the ward and garden each day. All urine passed was collected in 24-hour specimens under toluene and subjected to the following estimations. Total nitrogen (micro-Kjeldahl method using Koch and McMeekin's modification of Nessler's solution, as quoted by Peters and Van Slyke [1932], ammonia (Folin's aeration method), urea (urease), uric acid [Folin, 1930], creatinine [Folin, 1914], amino-acid-nitrogen [Folin, 1922], cystine (Looney's method using Folin's [1930] uric acid reagents), sulphur in all forms [Fiske, 1921] and p_{H} (electrometrically, using the quinhydrone electrode or by indicators).

A summary of the results obtained is shown in Figs. 3, 4 and 5.

When this work was completed and the figures for the various periods analysed, it was found that there were well-marked daily variations in the output of various urinary constituents, particularly in total nitrogen, uric acid, creatinine, cystine and neutral sulphur. These diurnal variations were all in the same direction so that the graphs for each showed great similarity. Further, these daily variations coincided in the three children, suggesting that the same factor was operating in all three, and as this could not be of a dietetic nature it was thought to be the result of changes in metabolism associated with differing amounts of exercise. Consequently we readmitted the younger child, J.B., for investigation of this point.

Effect of exercise. The patient was given a generous varied diet containing similar foodstuffs in the same amounts each day and supplying approximately 86 g. of protein and 2000 Calories daily. In addition to fluids taken with meals she was given 4 pints of lemonade daily, to ensure a diuresis and consequent rapid elimination of metabolic products.

The metabolism period commenced at 9 a.m. after a preliminary period of 21 hours in bed on the diet. During the first 48 hours the child remained at rest in bed. For the first 9 hours of the next 24-hour period she played around the ward without indulging in any strenuous games (indicated in Fig. 2 as "light exercise"). On the following day she was made to run around the garden and to skip until tired (indicated as "moderate exercise"). After a further period of complete rest in bed she was again exercised and the metabolism period was completed with 48 hours in bed. Fig. 2 shows the excretion of various waste products during this 8-day period. The first 24 hours yielded high total nitrogen and low sulphur values, and we regret that the child was not given a longer time to become stabilised before the urine was collected. The urea-nitrogen figures remained at a very constant level over the whole period, indicating the constant nitrogen intake. Light exercise was associated with increased excretion of cystine and neutral sulphur but did not affect the uric acid or creatinine figures. Moderate exercise resulted in a greatly increased excretion of uric acid, creatinine, cystine and neutral sulphur, so that the graphs for the output of these various bodies are almost identical. The figures for total nitrogen tend to show similar variations. The increased uric acid and creatinine excretions must result from an

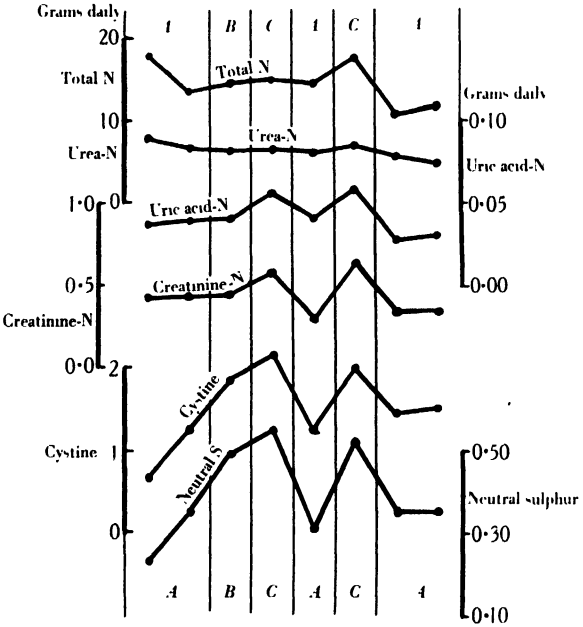

Fig. 2. J.B. Analyses of urine to demonstrate the effect of exercise.

A, at rest in bed; *B*, light exercise; *C*, moderate exercise.

increased tissue metabolism associated with exercise and it seems highly probable that the increased cystine excretion was also of endogenous origin. In the investigation of a case of cystinuria, Brand *et al.* [1930] noted an increased creatinine excretion on the day when their patient had 2 hours' exercise (handball) and mentioned that Alsberg and Folin [1905] also discovered an increased excretion of creatinine associated with exercise. They did not comment on the fact that associated with this increased creatinine excretion there was a well-marked increase in the output of cystine in their patient. Robson [1929] also noted well-marked daily fluctuations in another case, in spite of careful control of the protein intake, which he was unable to explain. He did not mention whether his patient was in bed or not throughout the metabolism period and it may be that exercise was the factor responsible for his results.

The importance of the exercise factor was not appreciated at the time when our feeding experiments were carried out and the children were not confined to bed. The exercise taken, although varying a little from day to day, was never strenuous and, in our opinion, was not sufficient to affect seriously the average figures for a 5-day period.

Feeding experiments.

Experiment 1. Hospital diet with a medium protein and low cystine content. After a preliminary period of 2 weeks on this diet the metabolism of nitrogen and sulphur was followed over a 5-day period and it was then noticed that the albuminuria which was present in both cystinurics on admission to Hospital had almost disappeared. The cystine excretion at this time was low and a remarkable feature of the investigation was the increased albuminuria which occurred later when the patients were having a high protein diet and the output of cystine was increased. This phenomenon was observed in both children, the degree of albuminuria reflecting quite accurately the degree of cystinuria. The control child was always albumin-free. Orthostatic tests carried out on the cystinurics were negative.

Another striking feature was the high p_H of the urine of both cystinurics throughout the whole of the metabolism period. The 24-hour specimens of urine were collected under toluene, kept under exactly the same conditions, and the p_H was estimated at the earliest possible opportunity. The figures for the control child varied between 5·2 and 7·3, with an average of about 6 for the whole period, and the ammonia values were low. The urines of the cystinurics were much more alkaline, occasionally reaching figures as high as p_H 9. The highest figures corresponded with the peaks in the graph for ammonium compounds, although even when the ammonia values were low and corresponded with those of the control child, p_H values of between 7 and 8 were frequently found; further, the alkalinity of any specimen from the cystinurics increased considerably on standing, although fresh specimens of urine examined from time to time showed this same tendency to alkalinity. We are unable fully to explain this phenomenon. The children were observed over a long period of time, their urinary tracts appeared to be free from infection, they were not given medicines or other preparations which might have contained alkalis, and the experiment was adequately controlled. This peculiarity may have been of very great practical importance in preventing calculus formation in the two children.

The excretions of nitrogen and urea are very similar in the cystinurics and the control. The sisters show high amino-acid-nitrogen and neutral sulphur values, as would be expected.

Experiment 2. Hospital diet plus *cystine.* To Diet No. 1 pure cystine (prepared from animal hair and supplied by B.D.H. Ltd.) was added in the following amounts:

1st day	1 g.	14 g.
2nd day	2 g.	
3rd day	4 g.	
4th day	7 g.	

On the 5th, 6th and 7th days no cystine was added.

The average figures for the first 5 days of this period, described here as the "cystine ingestion period", together with those for the following 2 days when the children were again on hospital diet only, are shown in the figures. In the case of W.B. (Fig. 4) the output of cystine was raised very slightly during the ingestion period and still higher figures were found on the 2 subsequent days, but this small increase is probably of no significance, especially as the figures for neutral sulphur were not increased. The output of inorganic sulphur was doubled during the ingestion period but returned to a level lower than the average for that period on the 2 following days. A calculation shows that about 60 % of the added cystine was metabolised during the 7 days. The fate of the residual 40 % formed

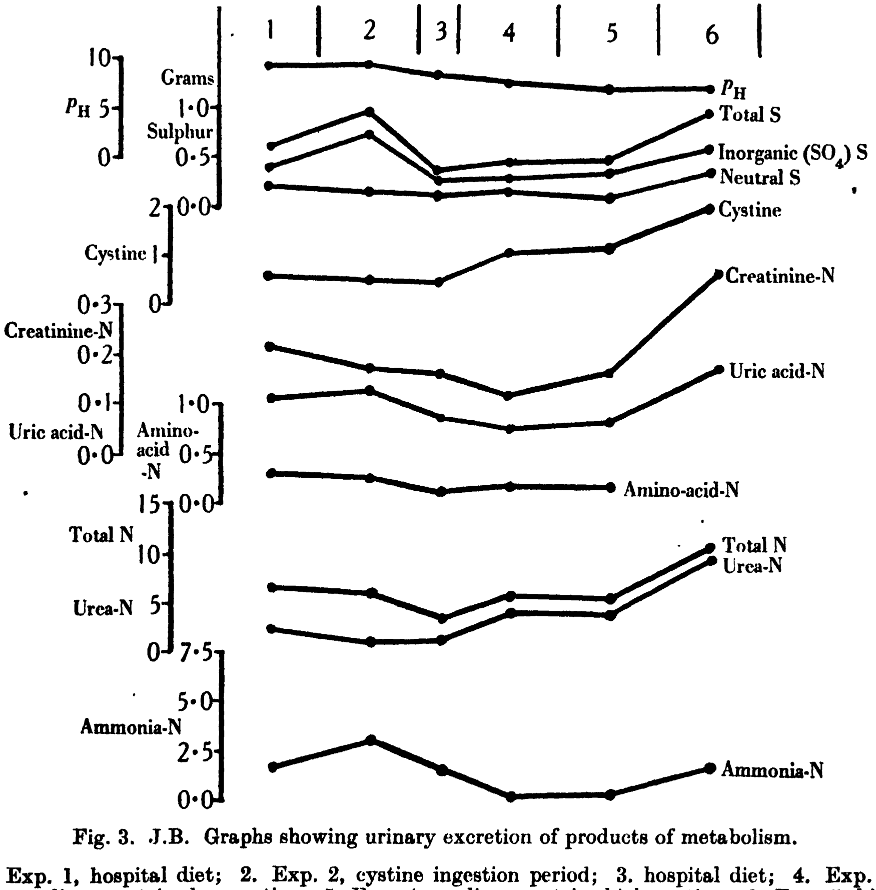

Fig. 3. J.B. Graphs showing urinary excretion of products of metabolism.

1. Exp. 1, hospital diet; 2. Exp. 2, cystine ingestion period; 3. hospital diet; 4. Exp. 3, medium protein, low cystine; 5. Exp. 4, medium protein, high cystine; 6. Exp. 5, high protein, high cystine.

the object of an experiment carried out when all the dietetic investigations were completed, but which may conveniently be mentioned here. W.B. was given the weighed hospital diet and after a period of several days on this regime, in which to become stabilised, 4 g. of cystine were given by mouth. The increased output in the faeces, estimated colorimetrically, amounted to 1·43 g., representing 36 % of that ingested. It would appear, therefore, that cystine given as such was oxidised quantitatively to inorganic sulphate and that the mechanism of oxidation was not at fault.

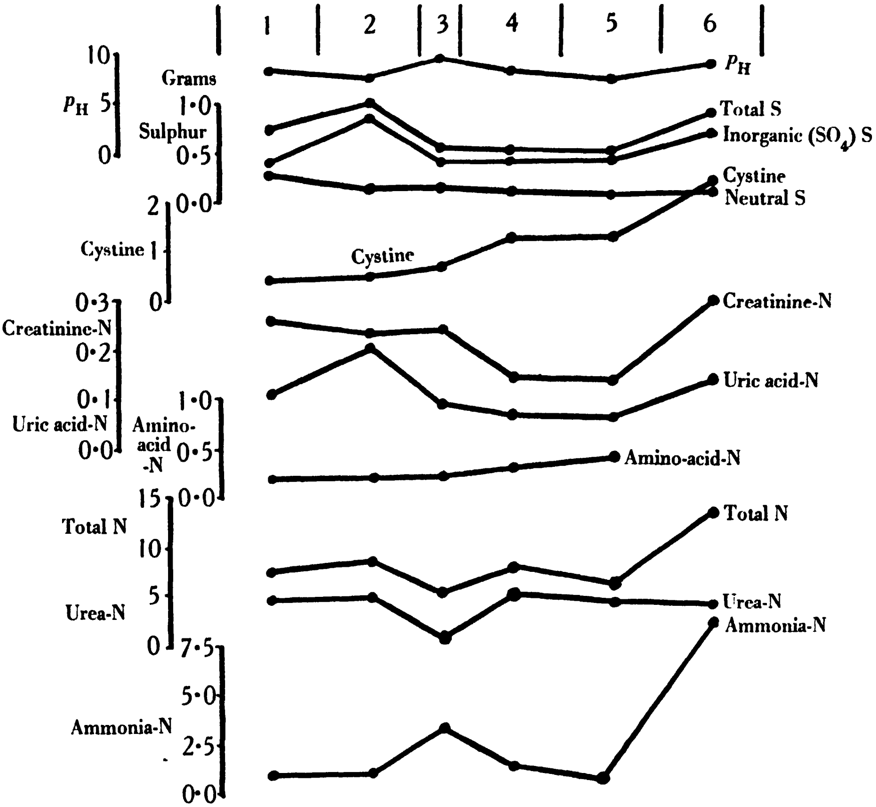

Fig. 4. W.B. Graphs showing urinary excretion of products of metabolism 1, 2, 3, *etc.* as in Fig. 3.

In the case of J.B. (Fig. 3) the output of cystine was slightly less than in Exp. No. 1 and only 47 % of the amount ingested was metabolised. The control (Fig. 5) oxidised 77 % of his ingested cystine and in addition showed a slight increase in neutral sulphur excretion. On 2 days his urine gave a slight coloration with the nitroprusside test for cystine.

Robson [1929], in a similar investigation of a male cystinuric aged 23 years, who was given 20 g. of cystine by mouth over a period of 4 days, found that 85 % of the ingested cystine was broken down and excreted as inorganic sulphate. The absence of any increase in urinary cystine during the ingestion period is in accord with the findings of most other investigators. Lewis and Lough [1929] calculated that the cystinuric investigated by them was able to oxidise about

64 % of the pure cystine ingested, the remainder being lost by failure of absorption or by destruction in the bowel by micro-organisms. Our results demonstrate the failure of absorption from the bowel but do not suggest any breakdown of cystine by micro-organisms.

Experiment 3. Low cystine, medium protein diet. After a few days' return to hospital diet the patients were given one consisting of one pound of apples and three pints of milk daily. This provides 5·8 g. protein, 0·6 g. sulphur (including, at most, 0·40 g. cystine) and 1390 Calories. After 3 preliminary days on the diet urine was collected for a further period of 5 days. On this low cystine but medium protein intake the output of cystine was considerably raised in both cystinurics, resulting in a negative cystine balance of 0·8 g. per day in W.B. and 0·6 g. per day in J.B. Our results are in accord with those of Lewis and Lough [1929] who conducted a similar experiment, and additional evidence is furnished of the endogenous origin of a significant portion of the cystine excreted.

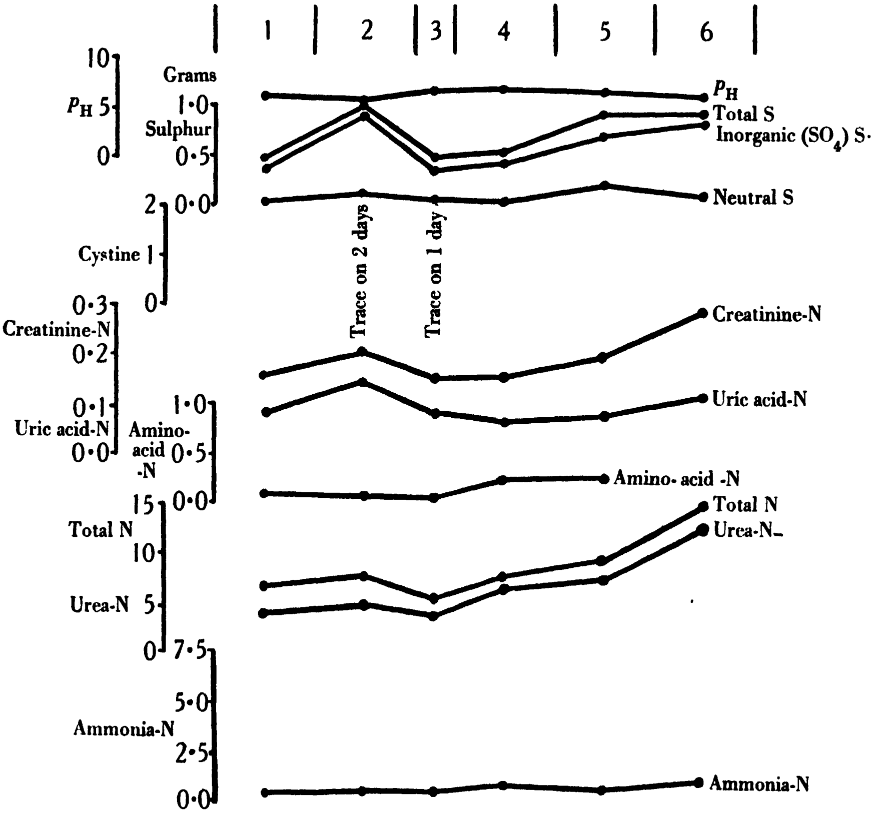

Fig. 5. Control. Graphs showing urinary excretion of products of metabolism. 1, 2, 3, *etc.* as in Fig. 3.

In the case of W.B. there was a lessened excretion of total and neutral sulphur but approximately the same output of inorganic sulphate as on the basal diet. J.B. did not appear to absorb the milk protein as well as that of a mixed diet, indicated by a lessened urinary nitrogen output. At the same time poor absorption of protein cystine resulted in a diminished inorganic and total sulphur excretion. On this diet, therefore, both patients appeared to be excreting very largely endogenous cystine, the low cystine intake being reflected in the low sulphur output.

That the excretion of endogenous cystine was stimulated by increased protein intake is confirmed by the results of feeding with a high protein diet.

Experiment 4. High cystine, medium protein diet. This consisted of one pint of milk, four eggs, half-a-pound of apples, four ounces of brown bread and one ounce of butter daily, and provided 53 g. of protein, 1271 Calories and 0·76 g. of sulphur—mostly cystine sulphur. The protein content was very similar to that of the previous diets. The average figures for the 5-day period show neither increased amino-acid nor cystine output. The control appeared to metabolise the added sulphur to inorganic sulphate, but either the cystinurics failed to absorb the extra cystine of the sulphur molecule, as the amino-acid itself or as some precursor, or, alternatively, they absorbed and stored it. In any case, the cystine output was not affected by the cystine intake.

The fall in the figures for uric acid and creatinine in Exps. 3 and 4 may be explained as the result of a vegetarian diet.

Experiment 5. The protein intake was doubled by adding eight ounces of cooked lean meat to Diet No. 4, the cystine content remaining practically at the same level. The cystine output was doubled in the two sisters and at the same time more sulphur was oxidised, as indicated by the rise in total and inorganic sulphur values. These rises were associated with similar increases in the figures for total nitrogen, urea, uric acid and creatinine. The results of this experiment are in conformity with those obtained by Robson [1929], who found that on a high protein diet the increased elimination of cystine was in almost direct proportion to the increased nitrogen excretion. We are unable to calculate the cystine intake on this diet, but it seems highly probable that there was again a negative cystine balance and that the output was of endogenous origin and increased by a high protein diet. Lewis and Lough [1929] reached a similar conclusion in a comparison of the effects of diets on varying cystine and protein values; these workers found that the excretion of cystine varied with the total nitrogen excretion and did not appear to be related to the cystine content of the diet.

It is generally recognised that diets rich in animal protein have a decided effect in stimulating tissue metabolism and raising the metabolic rate: this effect is thought to be due to the action of certain of the amino-acids resulting from such protein digestion which stimulate cellular activity. Further evidence on this point is furnished by our cases which show increases in uric acid and creatinine excretion more than twice as high as those obtained on the previous diet (No. 4) of half the protein value and therefore, partially at least, of endogenous origin, the result of increased tissue breakdown. The figures for neutral sulphur in the child W.B. showed no rise corresponding to the increase in the figures for cystine as estimated colorimetrically—in fact the graph for neutral sulphur throughout the metabolism period shows a steady fall. In the case of J.B. the graphs for neutral sulphur and cystine correspond more closely. The cystine-sulphur excretion as calculated from the cystine (estimated colorimetrically) was, on the whole, higher than the total neutral sulphur; an observation made by many previous workers, each of whom concluded that the colorimetric estimation tends to give unduly high readings. Estimation of cystine in the previous 24 hours' urine was carried out each day at approximately the same time; hence, at the time of the examination, the breaking down of any cystine precursors present in the freshly voided specimens should have proceeded to about the same extent. We therefore regard these figures as a more reliable indication of cystine excretion than those for neutral sulphur, even though they may give inaccurate absolute values. The neutral sulphur figures for W.B. are probably inaccurate.

The undetermined nitrogen varied throughout the metabolism periods. Figures as high as 33 % were reached by W.B., 25 % by J.B. and 29 % by the control, and over the whole period the undetermined nitrogen was somewhat higher in the control child than in either cystinuric.

DISCUSSION.

The subjects of this investigation show many interesting features in common. Both were admitted with albuminuria which was not of the orthostatic type or associated with clinical evidence of renal insufficiency or other evidence of kidney damage, and which increased or decreased (to the point of disappearing) with increased and diminished output of urinary cystine. These observations are of great interest and may be of importance in view of the work of Cox *et al.* [1929], Newburgh *et al.* [1925], and Curtis and Newburgh [1926; 1927], who fed young rats on synthetic diets containing free cystine and produced in their animals an acute nephritis from which many of them died. Newburgh and Curtis [1927], by feeding rats on diets rich in caseinogen, beef protein and lactalbumin, were able to demonstrate the markedly nephropathogenic nature of the lactalbumin—a protein with a very high cystine content (4 %).

Abderhalden [1903] described an infant, one of a family of cystinurics, who died of malnutrition at the age of 21 months. At autopsy the internal organs were found to contain crystalline deposits of cystine visible to the naked eye and in many ways similar to the deposits of sodium biurate in gout. The same writer [1922] observed kidney damage in rats ingesting free cystine and tyrosine and was able to demonstrate crystals of these amino-acids in the kidney tubules. It is difficult to reconcile these animal experiments with the results of feeding cystine to normal adults and to cases of cystinuria. Nevertheless, it seems probable that, in our patients, the excretion of the greater quantities of this abnormal urinary constituent, possibly associated with deposition of crystals in the renal tubules, was associated with some renal damage and a leak of protein into the kidney tubules. The urinary cystine in our patients we believe to be entirely endogenous. The exercise experiment demonstrates the importance of this factor in affecting the cystine output. Feeding isolated cystine showed that the amino-acid is completely oxidised to inorganic sulphate, even when administered in large quantities, a finding which is in agreement with those of other writers [Hele, 1909; Looney *et al.*, 1923; Robson, 1929]. Feeding with a diet which contained a high content of cystine sulphur in the natural foodstuff did not result in any greater output of cystine than when the children were given one with a low cystine value and similar protein content, but there is no evidence that the extra cystine of the diet was absorbed or in any way metabolised. We submit that the increased excretion of urinary cystine on a diet high in animal protein is of endogenous origin, the result of increased tissue metabolism due to the specific dynamic action of that protein and not derived from the cystine of the ingested protein molecule. The practical importance of this observation is obvious and our patients were sent home on a diet of low protein content, which they had taken conscientiously until they were seen again recently—two years after the original investigations were carried out. Both children were apparently quite well and free from any symptoms referable to the urinary tract. There was no evidence of stone formation or urinary infection.

With the co-operation of the parents, 24-hour specimens of urine were collected from each of the two girls when they were at home taking their usual diet and indulging in their normal activities. That from the elder child, W.B., was free from albumin and contained 9·45 g. of total nitrogen and 0·585 g. of cystine (colorimetric). The specimen from J.B. showed a faint haze of albumin (far less than when first seen two years previously), 5·1 g. of total nitrogen and 0·442 g. of cystine—all of them reasonably low figures.

The high p_H of the urine, which formed such a notable feature of this investigation, has already received consideration, and in view of this finding it was considered unnecessary to try the effect of administration of alkalis. For this reason also, many specimens of urine had first to be acidified with dilute acetic acid and allowed to stand before cystine crystals appeared, and the greater solubility of cystine in an alkaline solution may explain the fact that the subjects of this study, although passing relatively large amounts of the amino-acid, remain free from calculus formation.

SUMMARY.

Two cases of cystinuria occurring in sisters are recorded, together with the results of the examination for cystinuria in other members of the family.

With the aid of the Sullivan reaction, evidence is presented which indicates that in these patients a precursor of cystine was excreted into the urine, which later decomposed with the liberation of free cystine.

Other abnormal constituents—tyrosine, leucine, putrescine and cadaverine—were absent from the urine of these subjects.

Both passed urine with an abnormally high p_H and it is suggested that this may explain their freedom from stone.

Evidence is brought forward to show that the excretion of large amounts of cystine may bring about a certain amount of kidney damage, producing an albuminuria which varies with the amount of cystine excreted.

Cystine prepared from hair when administered by mouth did not produce an increased excretion of cystine in the urine but was oxidised quantitatively to sulphates. Much of it was unabsorbed and excreted in the stool.

Foodstuffs with a high cystine content did not cause increased cystinuria; the extra cystine may have remained unabsorbed or have been absorbed and stored but was neither oxidised to sulphate nor excreted in the urine as such.

The endogenous origin of some of the excreted cystine is demonstrated, and the effect of a high animal protein diet in increasing the cystinuria is explained as the result of a stimulation of tissue metabolism with liberation of more endogenous cystine.

We suggest that cases of cystinuria should be given a diet containing only small amounts of animal protein.

It is a pleasure to acknowledge the debt of gratitude we owe to Miss Eva L. Tonks for her help in carrying out much of the laboratory work recorded in this paper, to Prof. L. G. Parsons for his stimulating interest in the work and permission to record the investigation of his cases and to the Medical Research Council for a personal grant to one of us (E.M.H.), and a further grant towards defraying the cost of the investigation.

XLIV. SOME BIOLOGICAL PROPERTIES OF EQUILIN.

BY KÁROLY DAVID AND SAMUEL ELZEVIER DE JONGH.
From the Pharmaco-Therapeutic Laboratory of the University of Amsterdam.

(Received December 19th, 1934.)

EQUILIN, an important member of the large group of oestrogenic substances discovered in recent years, is chemically related to menformon (oestrone).

Equilin was originally prepared from the urine of pregnant mares by Girard [1932] and co-workers; the empirical formula ($C_{18}H_{20}O_2$) had 2 hydrogen atoms less than that of oestrone; it had M.P. 238–240° (corr.) as against 255·5–256·5° for oestrone, and $[\alpha]_D^{20^\circ}$ was +308° (in dioxan) as against +163°. We obtained very similar figures for our own preparations, *viz.* M.P. 236–237·5° uncorr. and $[\alpha]_D + 307^\circ$ in dioxan.

The biological examination of equilin is justified by the fact that it constitutes the chief impurity even of crystalline commercial oestrone. For comparison of the various biological actions of pure equilin with pure oestrone equal quantities of both have been investigated in comparative assays. By equal quantities we mean not identical weights but quantities which produce the same oestrogenic effect in mice, this animal being the one with which our routine estimations are always performed. The following comparative assays were made: (*a*) oestrus in the castrated rat, (*b*) genital growth in the young female rat, (*c*) opening of the vagina in the young rat, (*d*) "antimasculine" action in the rat, (*e*) "paradoxical" effect in the castrated rat (growth of seminal vesicles), (*f*) nipple growth in the adult male guinea-pig, (*g*) epithelial metaplasia in the genitalia of the male castrated mouse.

We only determined which of the two substances under consideration would produce the stronger reaction per given number of mouse units. To establish a quantitative ratio in each case would have rendered the investigation too laborious and was not attempted.

We first determined as nearly as possible the exact dose of equilin required to induce oestrus in the castrated mouse, injecting oestrone 3 × 0·1 ml. into one group and equilin into another group of mice and next week performing a cross-test on the same subjects (summary in Table I). The letters *a*–*g* represent graded types of vaginal smear, progressing in alphabetic sequence towards oestrus, *a*–*d* being negative, *e*–*g* positive types [de Jongh *et al.*, 1932]. The oestrone used in our experiments was tested on several hundred animals and found to be equal in oestrogenic potency to the International standard preparation. Accordingly it contains one I.U. in 0·1 γ whether comparison is made in rats or in mice. This

Table I. *Number of animals and stage of cycle achieved or surpassed.*

		$\geqslant a$	b	c	d	e	f	g	Positive
I.	0·1γ oestrone	21	21	21	21	21	18	5	21/21 = 100 %
	0·12γ equilin	21	21	21	17	16	12	6	16/21 = 76 %
				Also 0·12γ equilin <0·1γ oestrone					
II.	0·1γ oestrone	48	46	45	43	42	33	15	42/48 = 87·5 %
	0·15γ equilin	48	46	44	41	37	36	22	37/48 = 77·1 %
				0·15γ equilin <0·1γ oestrone					
III.	0·1γ oestrone	24	24	20	20	19	13	6	19/24 = 79 %
	0·18γ equilin	24	24	24	24	23	16	10	23/24 = 96 %
				0·18γ equilin >0·1γ oestrone					

international unit of oestrone will as a rule yield positive smears in 70 % of our animals when given in oil solution (3 injections of 0·1 ml. within 36 hours).

Evidently from Table I the dose of equilin equivalent to 1 international unit in mice is not less than 0·15γ. A similar effective dose-ratio was obtained when equilin and oestrone were given to mice by mouth (Table I *a*), the actual quantities being 1·5γ equilin and 1·0γ oestrone in 3 equal portions of oil solution.

Table I *a*.

	⩾*a*	*b*	*c*	*d*	*e*	*f*	*g*	Positive
1·5γ equilin	23	18	13	12	12	8	3	12/23 = 52 %
1·0γ oestrone	23	18	13	13	12	10	3	12/23 = 52 %

In subsequent experiments oestrone and equilin were therefore given in the ratio of 2 : 3 by weight.

(*a*) *Oestrus in rats.*

1γ oestrone and 1·5γ equilin were given in 3 subcutaneous injections; 26 rats were used and cross-tested with the following result:

	⩾*a*	*b*	*c*	*d*	*e*	*f*	*g*
Oestrone	26	21	16	14	8	6	3
Equilin	26	24	23	22	20	20	18

Clearly the action of equilin was stronger than could have been anticipated from its effect on mice, and this was confirmed by a further experiment on 53 rats using half the dose of equilin and the full dose of oestrone.

	⩾*a*	*b*	*c*	*d*	*e*	*f*	*g*
Oestrone	53	46	34	33	28	25	16
Equiline	53	50	41	39	30	27	15

In the rat equilin is four-thirds as oestrogenic per mg. as oestrone, which does not agree with Girard's [1933] finding of only one-seventh.

The I.U. of equilin, when tested in mice, is 0·15 γ, while when tested in rats it is 0·075 γ. From these data we draw the important conclusion that it is not sufficient to describe a preparation as containing a certain number of I.U. without reference to the kind of animals used for the testing. For more intensive discussion of this question see Laqueur [1935].

(*b*) *Growth of genitalia.*

Small doses (0·05γ oestrone and 0·075γ equilin) in 0·1 ml. were given twice daily for 14 days (May 29th–June 12th) for fine differentiation of the relative activities. Rats from 3 litters were castrated and equally divided between the

two groups. Increase in body weight was very irregular despite the use of litter-mates.

The increases in weight of the uterus and vagina were greater, though the average body weight was lower, in the equilin group. The weight of the vagina is less significant, because less accurately determinable, than that of the uterus. The action of equilin on the preputial glands is negligible, that of oestrone apparently stronger, largely on account of the exceptional reaction of animal 3816. The confirmatory experiment (June 26th–July 24th) differed from the former only in its greater duration (4 weeks).

4019	44	82		36		68		26		
4020	37	90		17		59		26		

Two animals died in the oestrone group. With the exception of the vagina and to a less extent of the preputial glands, the increase of organ-weight was less than appeared in the former experiment; obviously because, the dose remaining constant throughout both experiments, the tissue hormone concentration became further reduced in the second experiment *pari passu* with greater increase of total body weight. The action of equilin on the uterus is again superior, and this time the preputial glands have also reacted.

The conclusion is that as a stimulus to the growth of secondary sex organs in the female rat equilin is certainly no less powerful than oestrone.

(*c*) *Opening of the vagina.*

Immature rats were used at about 3 weeks old. Five injections of 0·1 ml. were given (each containing either 2γ oestrone or 3γ equilin), two on June 5th, two on the 6th, one on the 7th. The weight was approximately the same in all cases (25 g.); observation continued until June 15th.

Table IV.

Rat	Oestrus	Vagina opening	Substance	Rat	Oestrus	Vagina opening	Substance

3883	,,	9. vi		3889	?	—	
3884	?	—		3890	?	—	

Clearly, equilin provoked opening of the vagina more regularly and consistently earlier than oestrone. Subsequent vaginal smears were in all cases negative, in agreement with Girard's observation [1933] that equilin and oestrone in equal doses by weight produce approximately the same effect.

(*d*) *Antimasculine effect.*

(1) *Experiments on young rats.* Three groups of five rats were used, 22–23 days old, comprising as many litter-mates as possible. One group was a control, the other two received respectively 0·5γ oestrone and 0·75γ equilin daily for 4 weeks in 0·1 ml. oil solution.

The antimasculine action is partially counteracted by the "paradoxical" effect (see section (*e*)), though the latter is weak at such low dosage. The average weight of the seminal vesicles decreased in the oestrone group, though not in the equilin group owing to the exceptional reaction of rat 3826.

The growth of preputial glands was stimulated in the oestrone group ("paradoxical" effect) and unaffected in the equilin group (*cf.* the female preputial glands in section (*b*)). A distinct "antimasculine" action on the testis, epididymis and remaining genitalia was seen in both groups but was more pronounced in the equilin-treated.

Table V.

3836	30	85		1160		179		14		22		490		

(2) *Experiments in adult rats.* These are uncomplicated by the "paradoxical" effect and require no longer than 2 weeks. In young rats we determine the retardation of the spontaneous genital growth with reference to control animals; this requires time. In adult rats an artificial atrophy is provoked.

Three groups of five rats were used (from unknown litters) receiving respectively 3·75γ equilin, 2·5γ oestrone and control oil.

"Antimasculine" action was clearly evident in all organs weighed and was more pronounced in the equilin group. The "antimasculine" activity of equilin, therefore, is at least as great as that of oestrone.

(e) *Paradoxical effect.*

This is a term which we have applied to the capacity of oestrone and allied substances to stimulate growth in certain parts of the genital tract of the male, especially the castrated male. We have already shown elsewhere [Freud *et al.*, 1933] that, apart from the preputial glands and their stratified epithelium, the reaction principally concerns the organs containing smooth muscle.

We used three groups of young recently castrated rats, some 26 days old (litter A) and some 24 days (litter B). The dose was 5γ oestrone and 7·5γ equilin twice daily in the respective groups. Duration of the experiment, 3 weeks.

Table VII.

3851	28	59		4	4	14	

By "prostate" is meant only the easily dissected ventral part of the gland; this grew very little, as expected, whereas the seminal vesicles grew very considerably in both treated groups. The preputial glands were augmented only by oestrone, as in some of the other experiments. The growth of the preputial glands, particularly in the male, is apparently stimulated by equilin less than by oestrone in oestrogenically equivalent unitage.

(f) *Growth of nipples.*

Stimulation of nipple-growth by oestrone and allied substances is most readily seen and measured in the (male) guinea-pig. The present experimental dose (1·5γ equilin, or 1·0γ oestrone, twice daily for 3 weeks), based on our former experience, was expected to be just sufficient to cause a distinct reaction, thereby demonstrating fine differences in activity. Table VIII states in millimetres the actual measurements obtained and shows almost mathematically identical activities for the two substances. However, two of the three animals in the equilin group secreted "milk" from the 4th or 5th to the 8th day after the last injections (which is remarkably late), whereas the oestrone group, as would be expected with so low a dosage, showed no secretion.

Equilin, therefore, stimulates the mammary gland at least as strongly as oestrone. The delayed secretion invites speculation concerning possible tissue storage of the hormone, on which point experience is lacking.

Table VIII.

(*g*) *Epithelial metaplasia of the male genital tract.*

This was noted after use of oestrone almost simultaneously by Lacassagne [1933, 1, 2], de Jongh [1933, 1934] and Burrows and Kennaway [1934]. Five prepubertally castrated adult male mice received 0·75γ equilin subcutaneously twice daily for 3 weeks, while four more received 0·5γ oestrone twice daily. The genitalia were examined by serial section with the following results.

(1) Stratified epithelium appeared in certain parts of the prostate (Lacassagne, de Jongh) of all mice, somewhat more conspicuously in the equilin group.

(2) The excretory ducts of the seminal vesicles showed similar changes (de Jongh) to a similar extent in both groups.

(3) Connective tissue changes in the ampulla of the vas deferens [Heringa and de Jongh, 1934] were of the same order in all treated animals.

(4) "Paradoxical" thickening of the vesicular smooth muscle (see section (*e*)) was somewhat weaker, though still distinct, in the equilin group. Similar experiments using rats produced the same order of change in both groups treated. The seminal vesicles were entirely used for serial section and therefore not weighed.

DISCUSSION.

The comparative biological activities of equilin and oestrone have been examined under varying experimental conditions and on various test objects, the minimum dose causing oestrus in mice being adopted as a basis of comparison in preference to a weight basis, for practical reasons.

Equilin is as active as or more active than oestrone in nearly every instance. Two exceptions are the growth of preputial glands (especially in the male) and, in less degree, the "paradoxical" growth of seminal vesicles in the mouse. Neither of these being material to the human subject, our results do not speak against the clinical use of equilin.

The possibility of course remains that human sensitivity may differ from mouse sensitivity in an opposite direction from that of the rat; in which case oestrone would naturally be preferable. The regrettable paucity of quantitative data concerning the action of oestrone in human subjects renders actual comparison impossible. As matters stand, equilin might even prove a more suitable therapeutic agent than oestrone. On the pharmacological evidence, equilin cannot be regarded as a harmful or even undesirable impurity in commercial oestrogenic preparations, which are standardised in mouse units (though were the comparative basis to be the minimum oestrogenic rat unit, equilin might be expected to show weaker antimasculine and uterine growth-promoting activity).

SUMMARY.

1. Equilin, compared with oestrone in equivalent dosage (calculated from their oestrogenic activities in mice), was more active in producing oestrus in the castrated rat, uterine and to some extent vaginal growth, vaginal opening in the young female rat, inhibition of the testes and male secondary sex organs of the male rat (with the few exceptions mentioned below), stimulation of the mammary gland of the guinea-pig and metaplasia of prostatic epithelium in the mouse.

2. The activities of equilin and oestrone were approximately equal as regards inhibition of preputial glands and seminal vesicles in the entire rat, "paradoxical" stimulation of the growth of seminal vesicles in the young castrated rat or of nipples in the guinea-pig, metaplasia of the vesicular duct epithelium of the mouse and changes in the connective tissue of the vas deferens of the mouse.

3. Oestrone was a more effective stimulus to the growth of preputial glands in the young female and to a greater extent in the male rat; and to the growth of seminal vesicles in the castrated mouse.

4. Equilin, when present in commercial oestrogenic preparations, cannot be regarded as an undesirable contamination.

XLV. THE OXYTOCIC HORMONE OF THE POSTERIOR LOBE OF THE PITUITARY GLAND.

V. RECOGNITION AS AN OXIDATION-REDUCTION SYSTEM.

By JOHN MASSON GULLAND
and SYDNEY STEWART RANDALL[1].

From the Biochemical Department, The Lister Institute, London.

(*Received December 20th, 1934.*)

In continuation of the study of the effects of chemical reagents on the physiological activity of the oxytocic hormone, it was important to examine its behaviour with reducing agents. Amongst such reagents electrolytic hydrogen and hydrogen sulphide suggested themselves as being peculiarly suitable for trial on account of the mildness of the conditions under which they can operate. This communication describes the partial inactivation of the hormone by electrolytic hydrogen and by hydrogen sulphide; the changes which the hormone then undergoes when freed from the reagents or when treated with oxidising agents such as molecular oxygen or the oxidised forms of certain dyes; and finally the examination of the equilibria developed in mixtures of the hormone and indicators of known oxidation-reduction potentials.

Description of results.

The physiological activity of the hormone was diminished to about 55 % of its initial value by electrolytic reduction for 4 hours. No immediate change in activity occurred when the reduced solution was preserved from contact with air for some hours, but when oxygen was passed into the solution, the activity first rose to about 85 % and then fell to some 60 % of the initial value (Fig. 1).

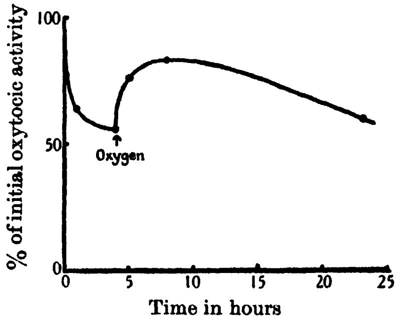

Fig. 1.

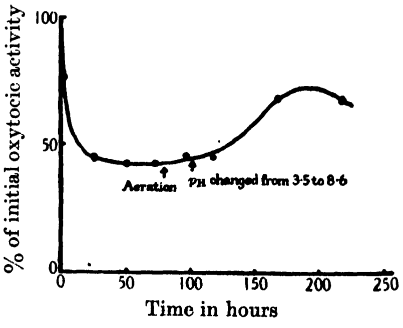

Fig. 2.

---

[1] Lister Institute Research Student in Biochemistry.

Hydrogen sulphide, when added to a solution of the hormone at p_{H} 3·5, caused the physiological activity to fall at a moderate rate to 42 % of its initial value. At this point the activity then remained constant (Fig. 2 and Table I). Aeration of such solutions with currents of moist air to remove excess of hydrogen sulphide was followed in acid and in alkaline solutions by a slow temporary recovery of oxytocic activity, which probably rose to its maximum (about 75 % of the initial value) in the course of 100 hours. The activity then slowly decreased again, and the experiments were stopped. It might have been expected that the progressive gain in activity would have complicated the assays, but in practice no difficulty was experienced, since the rate of reactivation was so slow.

A different picture was presented by the results of the next series of experiments. Hitherto, no precautions had been taken to exclude air from the reduction, and all the solutions had been prepared from distilled water containing dissolved air. The reductions with hydrogen sulphide were therefore repeated using solutions which had been boiled to expel air. This modification did not greatly affect the value to which the oxytocic activity fell as the result of the reduction (about 45 %), but when samples were diluted with distilled water containing air, the physiological values rose so rapidly that it was quite impossible to assay the solutions by the customary method of arranging the contractions of the guinea-pig uterus in groups of four [Gulland and Newton, 1932]. A method of assay, elaborated in the experimental section, demonstrated clearly (Fig. 3) that the activity rose during 1 hour from about 45 % to about 80–90 %, that it then fell to about 55 % during the course of a further hour, and that it then remained apparently constant.

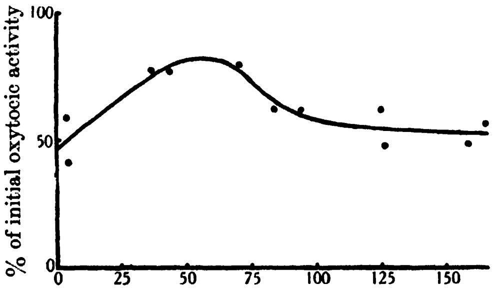

Fig. 3.

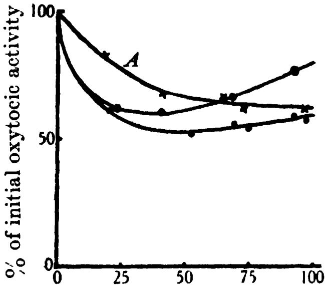

Fig. 4.

Both in this and the preceding series of experiments, the dilution of the reduced hormone solutions with ordinary distilled water resulted in a temporary gain in activity followed by a decrease. In the first series (reduction in presence of air) the gain and fall were slow, occupying together about 200 hours. In the second series, the gain and fall were rapid, occupying together about 2 hours. These divergences must be attributed to the presence or absence of air during the reduction, but no information is at present available as to the identity, or otherwise, of the changes responsible for the increases and subsequent decreases of activity in these experiments.

In view of the complicated results described above which might have been due to the effects of oxygen on the products of the reduction by hydrogen sulphide, it was necessary to study the reduction and subsequent behaviour of the hormone under conditions which remained anaerobic until the doses were introduced into the testing-bath for assay. Such conditions were realised by the use of boiled solutions cooled in nitrogen and by carrying out the reductions and dilutions in atmospheres of pure nitrogen. Under these circumstances and when the assay was performed immediately, the oxytocic value of a partially purified hormone solution decreased to about 55–60 % of its value after the reduction had proceeded for 40 hours and thereafter began slowly to increase again (Fig. 4). In exactly similar experiments with a less highly purified hormone solution containing more proteinoid material, the reduction proceeded less rapidly; the experiment was not prolonged sufficiently to ascertain the final value or to determine whether the activity again increased (Fig. 4, curve *A*). Evidently the course of the reduction was influenced by the presence of other substances.

Experiments were then made to ascertain whether the oxytocic activity was affected by the mere removal under anaerobic conditions of hydrogen sulphide from the reduced hormone solutions (55–60 %, above) and its replacement by pure nitrogen. Assays were made of diluted samples of reduced solutions immediately after the dilution. The solutions were then freed from hydrogen sulphide by repeated evacuations and fillings with nitrogen, and second assays made at intervals varying between 1 and 2½ hours from the first assays gave values for the activities which were different from those of the first assays. At first sight, it appeared as if hydrogen sulphide were affecting the response of the uterus to doses of the hormone, but this explanation was ruled out by demonstration that comparable and even much greater doses of hydrogen sulphide, introduced directly into the bath, did not modify the response to standard doses of hormone solution.

A study was therefore made of the changes in oxytocic value which occurred with passage of time when reduced hormone solutions were freed from hydrogen sulphide and kept under anaerobic conditions (Figs. 5 *a* and 5 *b*). The activity first increased, and the extent and rate of this reactivation in the case of a hormone solution which contained relatively much physiologically inactive material (Fig. 5 *a*) were greater than in the case of a purer solution (Fig. 5 *b*), indicating that reactivation was possibly due, at any rate in part, to interaction of the hormone with other substances present in the solution. The value to which the activity rose in the reactivations was less than 100 %, and this change was followed by a loss of activity, of which the final result was a value of about 50 %. In the case of the less pure hormone solution (Fig. 5 *a*), however, the

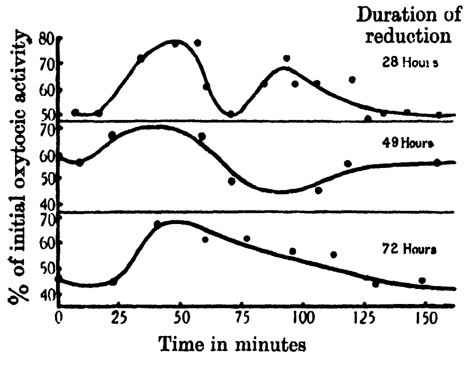

Fig. 5 *a*. Hormone solution 2.

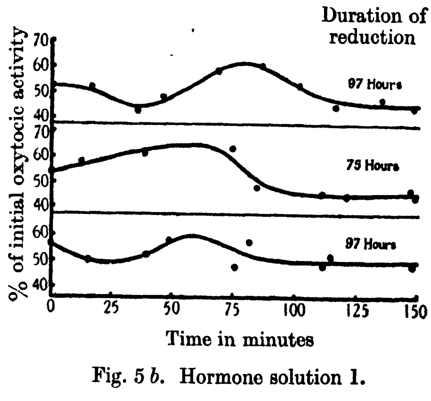

Fig. 5 *b*. Hormone solution 1.

exact progress of the changes of activity after the peak of reactivation is not clear. The curves of Fig. 5 *a* have been drawn as closely as possible to the experimental points, and it may be seen that when the duration of reduction was short there is evidence of a second peak, which became smaller and finally disappeared as the duration of the reduction with hydrogen sulphide was increased. It has not been possible to carry out sufficient experiments to establish this fact, and it is not necessary to investigate it further at present. If this peculiar behaviour is correct and is a property of the hormone, it must be investigated later with a purer specimen; if it is due to the action of other substances present in the solution, its full investigation is not a matter of immediate importance for this communication.

The experiments described above indicate that oxidation or reduction of at least one group in the hormone molecule was accompanied by, and presumably caused, variations in the oxytocic activity. A preliminary investigation of the oxidation-reduction potential of this system was made by studying the action of oxidised dyes on the hormone reduced by hydrogen sulphide. Methylene blue, for example, completely restored the activity of the reduced hormone, presumably by oxidation of the reduced group. Neutral red, on the other hand, effected only partial reactivation at p_H 3·6 and seemed to have little action at p_H 6·6 and 8·5. The examination of the redox system by this method was unreliable, however, partly because hydrogen sulphide itself is unsatisfactory as an indicator of redox potential, and partly because it might attack the molecule otherwise than by straightforward reduction. Moreover, neutral red is unsuitable as an indicator since its reduced form is unstable [Clark and Perkins, 1932]. Reliable results, however, were to be expected from assays of the oxytocic activity at equilibrium of mixtures of hormone solutions and the oxidised and leuco-forms of reversible oxidation-reduction indicators. Fig. 6 shows how the oxytocic activity of the hormone varies with changes in the electrode potential of the medium between +0·04 and −0·26 v. at p_H 6. The left-hand portion of the curve represents the theoretical relationship between the percentage of the oxidised form of a redox system and the potential in volts, drawn in this case to a scale such that the values representing the oxidised and reduced forms correspond to those denoting the highest and lowest oxytocic activities determined. The right-hand section of the curve is the mirror image of the left-hand portion. Equilibrium was rapidly attained, except at potentials of −0·12 and −0·16 v., when an upward drift towards increased activity oc-

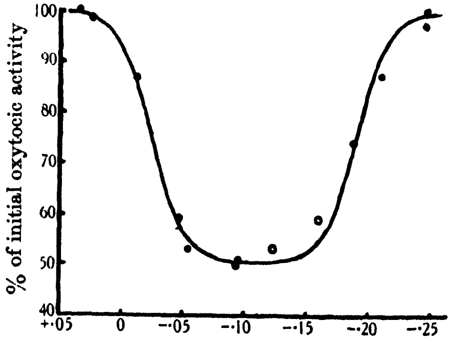

Fig. 6.

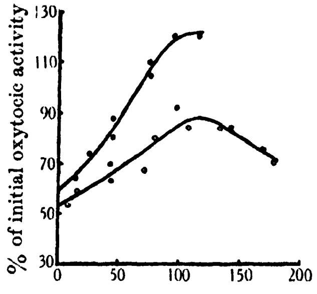

Fig. 7.

curred so rapidly that assay by the normal procedure was impossible. These drifts (Fig. 7) were followed by the method of assay developed in the reactivations after reduction by hydrogen sulphide, and the values denoted by open circles in Fig. 6 were estimated by extrapolating these curves to zero time.

At potentials of $+0{\cdot}35$ (phenolindophenol) and $-0{\cdot}45$ v. (methyl viologen) (not shown in Fig. 6) the oxytocic activity was 100 %.

Discussion.

The experiments described above demonstrate that the oxytocic hormone contains one oxidation-reduction system, having $E_0'-0{\cdot}025$ v. at p_H 6. When the system is oxidised the oxytocic activity is 100 %, when reduced, 50 %. It is interesting to recall that Johnson *et al.* [1927] concluded that oxidation-reduction processes constitute an important factor in the regulation of the tone of uterine muscle.

The results might also be interpreted as showing that the hormone molecule contains a second oxidation-reduction system having $E_0'-0{\cdot}190$ v. at p_H 6. On this view, the oxytocic activity would be 100 % when both systems are oxidised or reduced, and 50 % when one is oxidised and the other reduced. The existence of the second system is possible, but there are certain objections to its unqualified acceptance, and these are discussed below.

The oxytocic activity remains at 100 % after treatment of the hormone with methyl viologen at a potential of $-0{\cdot}45$ v. or with alkaline glucose. On the other hand, electrolytic reduction for 4 hours lowers the activity to 56 %. These facts are not in harmony if the reagents only attack the oxidation-reduction systems. If the hormone contains two redox systems, as seems to be indicated by the experiments with redox potential indicators and alkaline glucose, electrolytic reduction should not have decreased the activity. Possible explanations of the apparent anomaly are that the duration of the electrolytic reduction was insufficient to allow both systems to be reduced or that its effect was complicated by exposure of the reduced hormone to air at the surface of the liquid in the reduction vessel. In the hope of settling this point, the hormone was reduced catalytically with hydrogen and platinum black for many hours; the activity fell rapidly, and remained at 50 %. This fact seemed at first to support the results of the electrolytic reduction and to show that the hormone contained only one redox system, the activity being 50 % when this was reduced. In that case, the increasing oxytocic activities corresponding to increasingly negative potentials, as shown by the right-hand portion of Fig. 6, might be the result of oxidation of the reduced system of the hormone through a rapid transfer of oxygen by the more negative redox potential indicators when the dose is introduced into the oxygenated Ringer solution in the testing bath.

It was demonstrated in the following ways that transfer of oxygen is not alone responsible for the higher activities at the more negative potentials. The hormone was reduced to an activity value of 50 % by indigodisulphonate at a potential of $-0{\cdot}09$ v. (Fig. 6) and was then mixed anaerobically with an air-free solution of oxidised methyl viologen. No marked change in the potential of the solution occurred, as would have been shown by a large increase in the blue colour of the solution, but the oxytocic activity rose to 74 %. In an exactly similar experiment in which rosinduline replaced methyl viologen the activity rose to 59 %. These results indicate that transfer of oxygen to the hormone by the dye may occur to some extent, and the mutual relationship of the values in the two experiments supports this view. It was expected, however, that complete reactivation of the hormone would have occurred if transfer of oxygen were the sole cause of the increasing oxytocic activity with the more negative indicators.

Further attempts were made to investigate the question of oxygen transfer by making assays under conditions in which the supply of available oxygen was considerably reduced. Johnson *et al.* [1927] record that when the isolated guinea-pig uterus is suspended in Ringer solution through which nitrogen, instead of oxygen, is passing, it contracts and remains in that state of tonus until oxygen is admitted. Attempts to repeat these observations were unsuccessful, even when nitrogen, freed from oxygen as described in this communication, was used and when the Ringer solution was covered with a layer of medicinal paraffin to exclude air. Spontaneous contractions of the uterine horn did occur, only to be followed by relaxation in the usual manner. We do not wish to stress this difference between our observations and those of Johnson *et al.*, or to offer any adverse criticism of their results. It has, however, been possible to make completely satisfactory assays of hormone solutions using a uterine horn suspended in Ringer solution covered with paraffin and saturated by a rapid stream of pure nitrogen. The only oxygen available must either (*a*) have been absorbed by the horn during its momentary exposure when the bath was emptied between doses or subsequently from the fresh Ringer solution, or (*b*) have remained dissolved in the Ringer solution in the bath at 37° for about 8 or 10 minutes in a rapid stream of nitrogen. This method was utilised to assay some hormone solutions which had been reduced with hydrogen sulphide or used in electrode potential experiments. No difference within the limits of experimental error could be detected between the activities of solutions assayed in this and in the normal way, except in the case of the indigodisulphonate-methyl viologen experiment described above; in this case, the activity was 61 %, instead of 74 % determined by the normal method.

It seems therefore that transfer of oxygen by the more negative indicators may cause oxidation of the hormone and consequent increase in oxytocic activity, but that this transfer is insufficient to account for the apparent activity of 100 % exhibited by the hormone at potentials of −0·247 v. and lower.

This conclusion strengthens the possibility that the hormone molecule contains two oxidation-reduction systems, and support for this view might be derived from the course of anaerobic reduction by hydrogen sulphide—initial decrease of activity to 50–60 %, followed by a slow increase. The chief evidence to the contrary was that catalytic or electrolytic reduction lowered the activity to about 50 %, instead of leaving it unchanged at 100 %. It was shown as follows that this was probably due to adsorption of the hormone or to its destructive reduction. A hormone solution which had been reduced by platinum black and hydrogen and exhibited 50 % of its initial activity was mixed anaerobically with oxidised methylene blue in order to convert the redox system completely into its oxidised form as in the experiments after reduction with hydrogen sulphide. The activity first fell, a value of about 33 % being recorded, and then rose again to 50 %, where it remained constant. These changes would have been predicted on the assumption that two redox systems in half the hormone molecules present in the solution had been fully reduced, resulting in an activity of 100 % as regards those molecules, and that the other half of the hormone molecules had been adsorbed on the catalyst or destroyed. In agreement with this view, it was found that oxidised rosinduline, added anaerobically to the reduced hormone solution (activity 50 %), did not alter the activity. Further, an attempt to restore full activity to an electrolytically reduced solution (value 70 %) by adding oxidised methylene blue only raised the activity to 83 %, indicating that some hormone molecules had been destroyed. These facts are in agreement with the existence of two redox systems. On the other hand, the addition of reduced rosinduline to the catalytically reduced hormone solution lowered the activity from 50 % to about 20 %, a fact which is not in harmony with these views.

Our present opinion is that the hormone contains one oxidation-reduction system, that it may also contain a second group which readily undergoes reduction, and that the states of oxidation of these groups are intimately connected with the physiological activity of the hormone. In addition, transfer of oxygen to the reduced hormone may occur in the testing bath through the agency of the more negative redox potential indicators.

The decision as to whether the drift of the oxytocic activity of the hormone at electrode potentials between about $-0 \cdot 11$ and $-0 \cdot 18$ v. or after reduction by hydrogen sulphide is an inherent property of the molecule or results from the presence of other substances must be postponed until purer hormone solutions are available. The subsequent inactivations which follow these increases in activity are also intimately linked with this question. Whatever the explanation may be, it is clear that molecular oxygen is not a necessary factor, since both these changes can occur in its absence. On the other hand, oxygen may well take part in the aerobic reactivations, and undoubtedly it is responsible for the existence of the hormone in its oxidised state in posterior pituitary extracts. It would be unwise to attempt an explanation of these activations and inactivations without a knowledge of the simultaneous electrode potentials of the solutions in which they were occurring. Possibly measurements of these may throw light on these questions.

EXPERIMENTAL DETAILS.

Hormone solutions.

Three solutions of the hormone were used in this investigation. One, called hormone solution 1, was prepared according to Kamm *et al.* [1928], and corresponded in its state of purification to that used by Gulland and Newton [1932]. It contained 300 oxytocic units per ml., associated with 5·65 mg. of solid when dried to constant weight.

The second solution, called hormone solution 2, was prepared by extracting dried, powdered posterior lobe (1·5 units per mg.) with 0·25 % acetic acid, concentrating the extract and precipitating by saturation with ammonium sulphate as described by Kamm *et al.* [1928]. The precipitate was then thoroughly extracted with 98 % acetic acid, and the extract was mixed with ether (2·5 vols.) and light petroleum (5 vols.). The solid thus precipitated was washed with a mixture of ether and light petroleum and was dissolved in a convenient volume of water at p_H 3. This solution therefore contained more inactive material than hormone solution 1, the actual content being 28·3 mg. of solid when dried to constant weight associated with 450 units per ml. The amount of ammonium sulphate was 3·9 mg. per ml., based on estimations of sulphate ion as barium sulphate, so that the weight of glandular material was 24·4 mg. per ml.

The third solution, hormone solution 3, prepared as described by Kamm *et al.*, contained 900 units per ml., associated with 3·67 mg. of solid.

Electrolytic reduction and reactivation by oxygen (Fig. 1).

The apparatus used was a rectangular three-compartment cell of the type used for electrodialysis. The electrodes were platinum foil, each measuring

2·5 × 2·5 cm. and the compartments were cooled by glass coils containing flowing water. The dividing membranes consisted of cellophane No. 400, and each compartment contained 10 ml. of liquid. Experiments on the electrodialysis of the hormone will be described at an early date in another communication.

The following description is typical of several experiments. The cathode chamber contained a mixture of hormone solution 2 (0·2 ml. containing 90 units) and $M/10$ sodium acetate solution (0·1 ml.) diluted to 10 ml. The centre compartment was filled with water (9 ml.) and $M/10$ acetate buffer at p_H 3·5 (1·0 ml.), and the anode chamber contained $N/1000$ acetic acid (10 ml.). The current was maintained at 50 milliamps, the voltage across the cell being 60 v. in the early part of the experiment and somewhat higher after the first half-hour. The temperature remained at 15°. The cathode solution was kept adjusted to p_H 9 by passing in carbon dioxide as required.

After the reduction had proceeded for 1 hour, the cathode solution was transferred quantitatively to a 25 ml. flask, brought to p_H 3·5 by the addition of 0·5 ml. of $N/10$ hydrochloric acid and diluted to 25 ml. When diluted and assayed, it had 66 % of the total activity, and this value remained unchanged when the undiluted solution, which still contained dissolved hydrogen, was kept in a cooled vessel for 18 hours.

When the reduction was prolonged for 4 hours and the cathode solution was treated as before, it contained only 56 % of the total activity. In both cases the liquid in the anode compartment exhibited no activity, and the centre compartment contained less than 1 % of the total number of units.

A stream of moist oxygen was passed for 1 hour through the cathode solution which had been reduced for 4 hours. The assay of a sample, taken at the end of this period and tested at once, showed that the activity had risen to 76 %, but after this oxygenated solution had been kept at 0° for 18 hours, the activity had fallen to 60 %. In a parallel experiment, the activity after oxygenation for 1 hour was 75 % and 3 hours later 83 %.

Aerobic reduction by hydrogen sulphide and reactivation by aeration (Fig. 2).

Mixtures of hormone solution 1 (0·1 ml. containing 30 units), $M/10$ acetate buffer at p_H 3·5 (0·5 ml.) and hydrogen sulphide solution (1·0 ml. saturated at 20°) were diluted to 2·5 ml. and kept at room temperature. The results are summarised in Table I.

It is evident that the reactivation occurs very slowly in acid or alkaline solution. In order to ascertain whether the rate of reactivation would increase and the activity be restored completely if the formation of hydrogen peroxide were avoided or its amount, if formed, were diminished, a portion (1·0 ml.) of the solution from Exp. 2, which had been reduced for 25 hours and then aerated was adjusted to p_H 8·2 with $N/10$ sodium hydroxide and then mixed with borate buffer at p_H 8·2 and a suspension of cerous hydroxide prepared from $M/50$ cerous sulphate (1·0 ml.). The suspension was shaken, and samples (not shown in Table I) were taken at 49 and 73 hours, centrifuged, diluted and assayed; the values for activity were 60 and 46 % respectively. The results of this experiment seemed to indicate that reactivation was more rapid in presence of cerous hydroxide. This point must not be stressed, however, since it is possible that the rate of oxidation was accelerated at the surface of the finely divided cerous hydroxide. In addition, no information could be obtained as to the adsorptive effect of cerous hydroxide on the reduced hormone or on the oxidised hormone formed in its presence.

Anaerobic reduction with hydrogen sulphide and reactivation.

The oxygen-free nitrogen used in all the anaerobic experiments was prepared by storing nitrogen (from a cylinder) over alkaline pyrogallol, scrubbing it thoroughly with alkaline pyrogallol immediately before use, passing it through a roll of reduced copper gauze in an electric furnace at a low red heat, and then washing it with air-free water. When purified in this way, the nitrogen gave no coloration with alkaline pyrogallol.

All solutions used in the anaerobic experiments were rendered free from oxygen as follows: they were either boiled and cooled quickly while a rapid stream of nitrogen passed through them, or if that procedure were unsuitable, they were repeatedly evacuated and saturated with nitrogen.

Reduction. The hormone solution (0·1 ml.) was mixed with $M/10$ acetate buffer at p_H 3·5 (0·5 ml.) and water (0·9 ml.). Part (0·3 ml.) of this solution was then freed from air and mixed with a saturated solution (0·2 ml.) of hydrogen sulphide in air-free water in a small tube swept out by nitrogen. The tube was then tightly stoppered and placed in a thermostat at 20°. A number of tubes prepared in this way at the same time formed the material for one experiment. After the reduction had proceeded for the desired time, one tube was introduced into a separating funnel containing air-free water (24·5 ml.) in an atmosphere of nitrogen. By evacuating the funnel, the stopper of the small reduction tube was released, care being taken not to allow hydrogen sulphide to escape from the funnel; the contents of the tube and funnel were thoroughly mixed, and the funnel was again filled completely with nitrogen. These experiments were repeated many times using hormone solutions 1 and 2, and some of the results, which differed slightly, are recorded in Fig. 4. These assays were not complicated by changes due to reactivation, presumably because these, if they occurred at all, were slow in presence of hydrogen sulphide.

Aerobic reactivation. In the early experiments on the reduction described above, the contents of the small tubes were diluted with air-containing water (24·5 ml.) and not as described above. Under these conditions it was observed that the activity seemed to have increased during the first hour after the dilution and then to have fallen at the end of 2 hours to approximately the original value of the reduced solution. The rate of change was too rapid to allow assays to be made by the customary procedure of arranging contractions of the uterus in groups of four [Gulland and Newton, 1932], but it was possible to obtain a moderately accurate estimate of the activity at any given time after dilution (*a*) by making assays simultaneously on two uterine horns previously brought to a satisfactorily sensitive condition by doses of standard hormone solution; and (*b*) by arranging doses of the solutions either in the order experimental,

experimental, standard, standard, or in the order experimental, standard, standard, experimental. From the charts thus obtained, the activity values of the experimental solutions were estimated by direct comparison of the heights of contractions evoked by them and by the adjacent doses of standard solution. It is evident that the results obtained by this procedure cannot be so reliable as those reached by the customary method of assay.

A number of experiments were made in this way, and in some cases the assays were made by two observers working simultaneously, but independently, with different uterine horns. These changes are illustrated by Fig. 3, from which it is clear that after reduction with hydrogen sulphide and dilution with aerated water the activity rose during 1 hour and then fell to a steady value close to that of the original reduced solution.

Anaerobic reactivation. A series of reductions of hormone solutions 1 and 2 was carried out as described above, and the reduction tubes were exploded as before in air-free water in an atmosphere of nitrogen. As soon as the contents of the separating-funnel had been mixed, a dose was withdrawn without exposing it to the air and inserted immediately into the testing-bath. After some practice it was possible to arrange that this dose should cause a contraction of which the height lay between two adjacent doses of standard solution. The activity of the reduced sample was thus ascertained with some measure of certainty, since in these experiments only those uterine horns were used which at the beginning of the assay were not only giving uniform responses to identical standard doses but which also exibited a satisfactory degree of sensitivity.

The anaerobic removal of doses of the experimental solutions from the tube below the tap of the separating funnel was easily accomplished by means of a 1 ml. hypodermic syringe graduated in 1/100 ml.

The remainder of the solution was at once freed from hydrogen sulphide by four successive evacuations and replacements by nitrogen, and the changes in activity were followed simultaneously in two uterine horns as described in the case of the aerobic reactivation experiments. Some results are given in Figs. 5 *a* and 5 *b*.

Action of dyes on the hormone after anaerobic reduction (*Table II*).

Hormone solution 2 (0·1 ml.), $M/10$ acetate buffer at p_{H} 3·5 (0·5 ml.), and hydrogen sulphide solution (1·0 ml., saturated at 20°) were mixed in a flask swept out by nitrogen. The mixture was diluted to 2·5 ml. with air-free water, and kept in a thermostat at 20°; the period of reduction varied between 24 and 48 hours in different experiments.

Methylene blue at p_H *4·2 and neutral red at* p_H *3·6.* The reduced hormone solution (1·0 ml.) was transferred without being exposed to air to a specially constructed tube swept out by nitrogen and containing air-free water (8 ml.). The tube was then evacuated and refilled with nitrogen four successive times, and whilst it was still under slightly reduced pressure an air-free, $M/50{,}000$ aqueous solution (1·0 ml.) of the oxidised form of the dye was added from a burette fixed in the stopper. Some minutes later (accurately timed), the p_{H} was determined, and a sample was removed anaerobically by a tap in the bottom of the tube and diluted for assay. Difficulties due to changes in activity were not experienced in making assays in the presence of these dyes, which seemed to stabilise the oxytocic value.

A control experiment was carried out simultaneously on another portion of the same reduced solution; the dye solution was replaced by water, and care was taken to ensure that the conditions as to time during which the dye acted and rates of evacuation and refilling were copied as faultlessly as possible. These precautions were necessary in view of the reactivation which occurs when the hydrogen sulphide is removed.

Neutral red at p_H *6·6 and 8·6.* These experiments were carried out similarly to those described above, except that the dye was added as a mixture of $N/10$ sodium hydroxide (0·1 ml.) and 2·0 ml. of $M/50{,}000$ neutral red in $M/5$ sodium phosphate buffer at p_H 6·6 or in Palitzsch's borate buffer [Clark, 1928] at p_H 8·6 respectively. Control experiments were made in the same way.

* During the assays of these experiments the activity drifted upwards, and these values were estimated by extrapolating to zero time the curves representing the drifts.

† Anthraquinone-β-sulphonate is practically colourless, and it was assumed that the oxidised form was present to an extent of 20 % of the total dye in the reaction mixture, since this was the average figure for a series of experiments made with coloured indicators at the same period.

‡ 0·5 ml. of the oxidised dye solution was mixed with the hormone solution, and 0·5 ml. of the leuco-dye solution was added from the burette.

§ This assay was made under as completely anaerobic conditions as possible. Nitrogen, free from oxygen, was substituted for the oxygen passing through the Ringer solution in the testing-bath, and a layer of medicinal paraffin covered the surface of this Ringer solution.

Oxidation-reduction potential of the hormone system (Table III).

These experiments were made in an apparatus in which the following series of operations could be carried out in an atmosphere of air-free nitrogen with solutions which had previously been freed from air. A $M/5000$ aqueous solution of the leuco-dye, prepared by reduction with platinised asbestos and hydrogen, was filtered through a sintered glass plate into a burette. 1·0 ml. was added to a mixture of the hormone solution (1·0 ml. of a 1/100 dilution of solution 2 or 0·5 ml. of a 1/100 dilution of solution 3, 4·5 units in each case), $M/10$ buffer solution (1·0 ml.) and water (7·0 or 7·5 ml.), the final volume being 10·0 ml. In every case oxidation of the leuco-dye occurred, and the percentage of oxidised form present in the reaction mixture was estimated colorimetrically. The total molarity of the dye in the mixture was 1/50,000. Temperature was 18° approximately. The samples for assay were removed at a tap in the reaction vessel without being exposed to air and were introduced immediately into the testing bath, the dilutions having been suitably arranged to enable this to be done. Equilibrium appeared to be attained immediately in most cases, but at potentials of $-0{\cdot}12$ and $-0{\cdot}16$ v. the activity value drifted rapidly (see footnote to Table III), and a slow drift was also observed at $-0{\cdot}19$ v.

The effects of adding oxidised potential indicators to the hormone reduced with indigodisulphonate.

A $M/5000$ aqueous solution (1·0 ml.) of leuco-indigodisulphonate was added to an air-free mixture of a dilution of hormone solution 3 (0·5 ml., 4·5 units) $M/10$ acetate buffer at p_H 6 (1·0 ml.) and water (6·5 ml.) in the apparatus used in the previous experiments. An air-free $M/5000$ aqueous solution (1·0 ml.) of methyl viologen was then added, and assays of oxytocic activity were made in the normal way and in a stream of nitrogen (see Discussion). The values were 74 and 61 % respectively.

Addition of a $M/5000$ aqueous solution (1·0 ml.) of oxidised rosinduline 2 G instead of methyl viologen gave a solution which assayed at 59 %.

Reduction with hydrogen and platinum black.

The catalyst was a strip of platinum foil (8 × 0·5 cm.) coated electrolytically with a thin film of platinum black and washed by electrolysis in dilute sulphuric acid and then distilled water. A mixture (20 ml.) of a dilution of hormone solution 3 (2·22 ml., 20 units), $M/10$ acetate buffer at p_H 6 (2·0 ml.) and water was shaken mechanically with the catalyst in an atmosphere of hydrogen. After 1¼ hours an assay showed the activity to be 59 %, and after a further period of reduction of 11 hours the activity was 50 %.

Equal volumes of this reduced hormone solution and $M/5000$ solutions of potential indicators were mixed anaerobically and the results are summarised in Table IV.

Table IV.

Potential indicator	% of initial activity	Time elapsed from mixing indicator with reduced hormone mins.
Oxidised rosinduline	50	3
	50	30
Oxidised methylene blue	33	6
	50	60
Reduced rosinduline	20	6
	20	60

Electrolytic reduction and reactivation by methylene blue.

Hormone solution 2 was reduced electrolytically, as described previously, until an assay showed that the activity was 70 %. The reduced solution (5 ml.) was freed from dissolved hydrogen by repeated evacuation and saturation with nitrogen and was mixed anaerobically with a $M/5000$ aqueous solution (2·0 ml.) of methylene blue. An assay showed the activity to be 83 % of its initial value.

SUMMARY.

1. The oxytocic activity of the hormone falls to about half its initial value when the molecule is reduced by hydrogen sulphide. The reduced hormone is completely reactivated by oxidised methylene blue.

2. The hormone is also reduced by catalytic or electrolytic hydrogen, the activity again falling to about 50 %. Part of this decrease in activity is probably due to destruction of the hormone or to its adsorption by the catalyst or electrode.

3. The reduced hormone is partially reactivated when it is exposed to air or when the hydrogen sulphide is removed under anaerobic conditions, These reactivations are followed by inactivations. These processes vary according to the circumstances in which they occur and the conditions under which the hormone was reduced.

4. Assays of the oxytocic activity of the hormone in presence of indicators of known oxidation-reduction potential indicate that the hormone molecule contains a redox system having $E_0' \mp 0{\cdot}025$ v. at p_H 6. The activity is 100 % when this is oxidised and 50 % when it is reduced.

5. Assays of the oxytocic activity of the hormone at potentials between $-0{\cdot}10$ and $-0{\cdot}25$ v. show that the activity increases from 50 to 100 % over this range. This may indicate the presence in the molecule of a second group which readily undergoes reduction, but the interpretation of the results is complicated by the possibility that some oxidation of the reduced hormone in the testing bath may occur through a rapid transfer of oxygen to it by the more negative redox potential indicators.

We are much indebted to Dr B. C. J. G. Knight and Dr G. M. Richardson for valued advice and criticism and to Dr K. G. Stern and Mr G. D. Greville for specimens of rosinduline and methyl viologen respectively.

XLVI. THE OXYTOCIC HORMONE OF THE POSTERIOR LOBE OF THE PITUITARY GLAND.

VI. FURTHER STUDIES OF THE ACTION OF OXIDISING AND REDUCING AGENTS.

By JOHN MASSON GULLAND
AND SYDNEY STEWART RANDALL[1].

From the Biochemical Department, The Lister Institute, London.

(*Received January 1st, 1935.*)

In Part V [Gulland and Randall, 1935] it was shown that the molecule of the oxytocic hormone certainly contains one, and may possibly contain two, oxidation-reduction systems, although the existence of the second is not definitely established.

The present communication describes the actions on the hormone of some oxidising and reducing agents, which were studied in the hope that they might throw light on the nature of the groups forming the oxidation-reduction system, or systems.

EXPERIMENTAL.

Sulphur dioxide and sodium sulphite (Fig. 1). Sodium sulphite at p_H 8·4 caused irreversible and complete inactivation of the hormone in 5 minutes. Sulphur dioxide at p_H 3·5, on the other hand, caused a slower inactivation to about 60 %, which was followed by reactivation and finally by inactivation to 3·6 % after 24 hours.

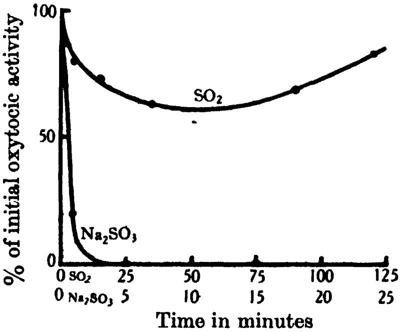

Fig. 1. Action of sulphur dioxide and sodium sulphite.

SO_2 at p_H 3·5 Na_2SO_3 at p_H 8·4

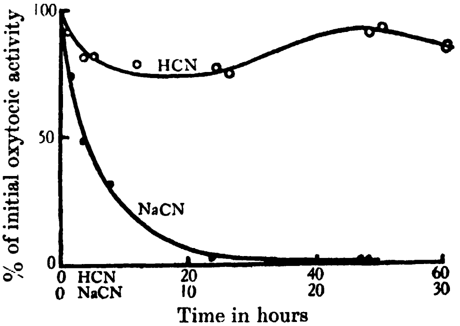

Fig. 2. Action of sodium cyanide and hydrogen cyanide.

HCN at p_H 3·5 (2 exps.) NaCN at p_H 7·8 (2 exps.)

At p_H *3·5.* The following solutions were placed in this order in a 2·5 ml. graduated flask: $M/10$ sodium acetate buffer at p_H 3·5 (0·5 ml.), $N/10$ hydrochloric acid (0·25 ml.), water (0·9 ml.), $N/10$ sodium sulphite (0·5 ml.), and a

[1] Lister Institute Research Student in Biochemistry.

Kamm[1] solution of the hormone (0·1 ml.), containing 300 oxytocic units associated with 5·65 mg. of solid per ml. (called Kamm solution 1 throughout this paper). The mixture was diluted to 2·5 ml. with water, the final p_H being 3·5, and the stoppered flask was placed in a thermostat at 20°. Samples were diluted to a convenient volume for assay[2].

At p_H *8·4.* Palitzsch's sodium borate buffer [Clark, 1928] at p_H 8·4 (0·5 ml.), $N/10$ sodium sulphite (0·5 ml.), water (1·0 ml.) and Kamm solution 1 (0·1 ml.) were mixed, diluted to 2·5 ml. (p_H 8·4) and placed in a thermostat at 21°.

Sodium cyanide and hydrogen cyanide (Fig. 2). The hormone underwent a slow, irreversible and probably complete inactivation when treated with sodium cyanide at p_H 7·8. Hydrogen cyanide at p_H 3·5 slowly caused a temporary decrease in activity; this was followed by a slight reactivation and then by a fall to an oxytocic value of about 82 %, at which level the activity seemed to remain constant. In both series of experiments the samples were freed from hydrogen cyanide by aeration at p_H 3·5, a procedure adopted before the susceptibility of the reduced form of the hormone had been recognised. It is possible that some alteration of activity may have occurred during this aeration in the case of the experiments at p_H 3·5, though probably not in the case of those at p_H 7·8. Even if this were so the essential nature of the results at p_H 3·5 remains clear.

At p_H *3·5.* $M/10$ sodium acetate buffer at p_H 3·5 (0·5 ml.), $N/10$ hydrochloric acid (0·45 ml.), $N/10$ sodium cyanide (0·5 ml.) and Kamm solution 1 (0·1 ml.) were mixed, diluted to 2·5 ml. and placed in a thermostat at 20°. The p_H was 3·5. Samples were aerated with a current of moist air for 30–45 minutes until free from cyanide (Prussian blue test; sensitivity, 1 in 5×10^4) and were suitably diluted and assayed.

At p_H *7·8.* Palitzsch's sodium borate buffer at p_H 8·2 (0·5 ml.), $N/10$ hydrochloric acid (0·37 ml.), $N/10$ sodium cyanide (0·5 ml.) and Kamm solution 1 (0·1 ml.) were mixed, diluted to 2·5 ml. and kept in a thermostat at 20°. Samples were adjusted to p_H 3 by means of $N/10$ hydrochloric acid and were then aerated as before, diluted and assayed.

Hydrogen peroxide (Fig. 3). The general character of the interaction of the hormone with hydrogen peroxide was the same at p_H 3·5 and at p_H 8·2. A period of inactivation was followed by one of reactivation, after which the activity again declined. The only essential difference between the courses of these reactions was the increased rate at which the changes occurred in the alkaline medium. It should be noted that estimations of the concentrations of hydrogen peroxide made by the permanganate method [Treadwell and Hall, 1928] throughout the experiments showed that the concentrations remained unchanged within the limits of the experimental error of the method.

At p_H *3·5.* $M/10$ sodium acetate buffer at p_H 3·5 (0·5 ml.), $M/10$ hydrogen peroxide (0·2 ml.) and a Kamm hormone solution (0·1 ml.) containing 90 units associated with 0·37 mg. of solid were mixed and diluted to 2·5 ml. The mixture was kept in a thermostat at 21°, and samples were diluted for assay.

At p_H *8·2.* The procedure was similar to that used above, except that Palitzsch's borate buffer at p_H 8·2 (0·5 ml.) replaced the acetate buffer.

---

[1] For definition of this term, see Gulland and Newton [1932].

[2] Assays were carried out by the guinea-pig uterus method, following the "bracketing" technique described by Gulland and Newton [1932]. It should be mentioned that throughout the work described in this paper the response of the isolated uterus was not influenced by the introduction into the testing bath of the reagents or their decomposition products in amounts much greater than those actually used in the experiments. The sole exception to this statement is discussed in the description of the experiments with hydroxylamine.

Iodine (Fig. 4). An aqueous iodine solution at p_{H} 3·5 caused the oxytocic activity to fall to 7 % of its initial value, at which it remained constant.

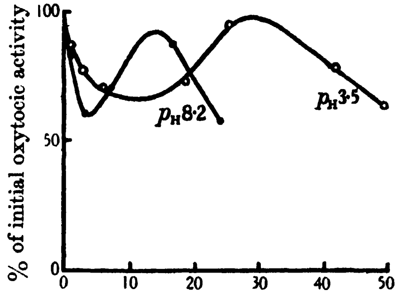

Fig. 3. Action of hydrogen peroxide.

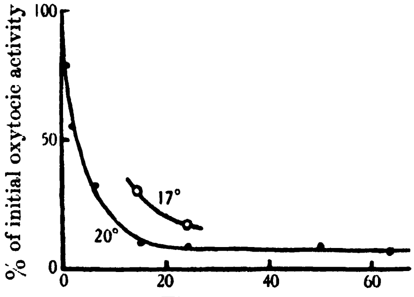

Fig. 4. Action of iodine at p_{H} 3·5.

A mixture of $M/10$ sodium acetate buffer at p_{H} 3·5 (0·5 ml.), aqueous iodine solution saturated at 20° (1·0 ml., 0·28 mg. of iodine) and Kamm solution 1 (0·1 ml.) was diluted to 2·5 ml. and kept in a thermostat at 20°. Samples were suitably diluted for assay. An excess of iodine, as shown by the starch-iodide test, was present throughout the experiments. The temperature coefficient of this reaction appeared to be considerably higher than those of the other reactions which have been studied.

Chlorine. An aqueous chlorine solution completely inactivated the hormone in acid solution in the course of 15 hours at 0°.

A mixture of $M/10$ sodium acetate buffer at p_{H} 3·5 (0·9 ml.), Kamm solution 1 (0·1 ml.) and freshly prepared chlorine water (1·0 ml., 5·6 mg. chlorine) was kept at 0° overnight. A sample was aerated with moist air till free from chlorine (starch-iodide test) and was then adjusted to p_{H} 7 with sodium hydroxide and suitably diluted for assay. The activity of the experimental solution was less than 0·3 % of the initial value.

Semicarbazide had no action on the hormone.

A mixture of a Kamm solution (5·0 ml., containing 10 units associated with 0·1 mg. solid), $M/3$ sodium phosphate buffer at p_{H} 7 (1·0 ml.) and semicarbazide hydrochloride (22·3 mg.) was diluted to 10 ml. at p_{H} 7. The concentration of semicarbazide was thus $M/50$. After the mixture had remained at 0° for 48 hours, the assay of a sample showed that no inactivation had occurred.

Hydroxylamine. The analysis of the effect of hydroxylamine at $M/50$ dilution at p_{H} 7 was not so straightforward as in the case of semicarbazide [*cf.* Gulland, 1933]. In some experiments an apparent inactivation of about 20 % or even 40 % was observed, whereas in others no inactivation could be detected. These discrepancies were finally explained by demonstrating that the responses of some, but not all, uterine horns to a series of standard doses of hormone solution or of histamine were depressed by the simultaneous introduction of hydroxylamine into the testing bath at a dilution of $M/50{,}000$, or sometimes even less. The conclusion was therefore drawn that hydroxylamine has no chemical action on the hormone.

DISCUSSION.

Several of the reagents of which the effects are described in this communication have already been employed by Guha and Chakravorty [1933] and by Das and Guha [1934, 1, 2]. Their results, however, can only be of qualitative value for the following reasons.

In the first place, these authors use the "equality" method of assay; thus Guha and Chakravorty state that "the comparison was made by finding the suitable dose which could produce a contraction in a virgin guinea-pig's uterus equal to that produced by the standard dose", and adherence to this technique is confirmed in the later papers. In our opinion, and we believe that here we share the view of others who have long experience of oxytocic assays, the "equality" method is unreliable and may lead to false conclusions. Its sole recommendation is the fact that the performance of an assay occupies relatively little time and trouble. The only satisfactory method of assay is the "bracketing" method; in this, the least dose of standard clearly greater than the unknown and the greatest dose of standard clearly less than the unknown are ascertained, and the activity of the sample is taken as the mean determined from these values [Burn and Dale, 1922; Burn, 1928; Gulland and Newton, 1932].

Secondly, although Guha and his collaborators recognise the obvious desirability of using hormone solutions which are as free as possible from material which has no oxytocic activity, such, for example, as the preparation of Kamm *et al.* [1928], they do in fact use what must be far less pure solutions of the hormone. There are two objections to the use of hormone solutions which contain much inactive material. In certain reactions the course of the changes undergone by the hormone varies according to the ratio of activity/solid, and in general, the risk is run that the concentration of a reagent may decrease markedly during a reaction owing to preferential interaction with concomitant substances. The consequences are, of course, that the true effect of the reagent on the hormone may not be discerned. Unfortunately, the Indian authors state neither the solid content nor the number of oxytocic units in their solutions, so that exact comparisons are impossible. Nevertheless, to illustrate the point at issue it may be mentioned that in our hands a Kamm solution prepared according to Kamm *et al.* [1928] contained 3·67 mg. of solid (dried at 105° to constant weight) per ml. with which were associated 900 oxytocic units. On the other hand, a solution prepared as described by Guha and Chakravorty [1933] contained 450 units per ml. associated with 28·3 mg. of solid, of which 3·9 mg. were ammonium sulphate.

Thirdly, the practice adopted by Guha and his collaborators of exposing the hormone to the chemical reagent for an arbitrary period of time can only show what the activity is at the end of that period. The observations recorded in this communication alone, to make no mention of the results quoted in previous members of the series, provide ample evidence that experiments made in this way cannot record correctly the progress of a reaction and may give a false impression of its final result. The oxytocic activity must be assayed at suitable intervals of time throughout the reactions.

However desirable it may be to develop at as early a date as possible a distinctive name for the oxytocic hormone, it is unfortunate that Das and Guha [1934, 1, 2] should attempt to designate it as "oxytocin", since this name was given by Messrs Parke, Davis and Co., to one of their commercial preparations of the hormone. It would be regrettable from various standpoints if a chemical entity were to share its name with a commercial preparation, and we prefer to continue to refer to the "oxytocic hormone" until sufficient is known of its properties to permit a rational name to be proposed.

The observations described in this communication cannot be correlated to any degree of probability with a definite structure for the oxidation-reduction systems of the hormone molecule, but it is noteworthy that none is actually opposed to the presence of a disulphide linkage; in fact, several of the results could have been predicted on such an assumption, by analogy with the effects of the same reagents on cystine. Although we do not feel justified in making a definite suggestion that a disulphide linkage is present, it is of interest to compare the action of the reagents on the hormone and on cystine, all the more because Sullivan and Smith [1928] observed that high oxytocic activity of posterior pituitary preparations could be correlated with high content of labile sulphur, and Du Vigneaud *et al.* [1933] found that increasing activity in a series of pitocin (oxytocic hormone) preparations was accompanied by an increase in the sulphur content. The results of these authors may indicate that the sulphur-containing substances from which the hormone is formed are available in larger amounts in active posterior lobes and that the more fully developed forerunners of the hormone molecule resemble it in such a way that their elimination is not readily achieved by processes of purification.

Sodium sulphite and sodium cyanide both inactivate the hormone completely and irreversibly. Their action on cystine is to rupture the disulphide linkage, producing one molecule of cysteine and one molecule of sodium cysteine-*S*-sulphonate [Clarke, 1932; Lugg, 1932] or sodium α-amino-β-sulphocyanopropionate respectively [Pulewka and Winzer, 1928; Lugg, 1933; Bodansky, 1929]. Moreover, Clarke [1932] found that a solution of ammonium sulphite and cystine which was exposed to air ultimately contained cysteine-*S*-sulphonic acid but no cysteine, and he concluded that the cysteine initially formed underwent oxidation to cystine, which in turn reacted with more ammonium sulphite, and so on until the conversion was complete. If the hormone contained a disulphide linkage, analogous changes might lead to disruption of the molecule and consequent total loss of activity with both reagents.

Iodine effected marked inactivation of the hormone, chlorine complete loss of activity. The halogens oxidise cystine to cysteic acid by way of the corresponding sulphinic acid, thus again destroying the disulphide linkage [Shinohara, 1932, 1, 2; Lucas and King, 1932; Simonsen, 1933].

The correlation of the effects of the other reagents with the presence of a specific group is less simple. The successive changes in the activity of the hormone when treated with sulphur dioxide or hydrogen cyanide—decrease, increase and final decrease of activity—might be regarded as evidence for the presence of two oxidation-reduction systems; the reagents could then be regarded as reducing these systems and ultimately as destroying a disulphide-sulphydryl system. Since these reagents have little or no action on cystine, it would be necessary to invoke the well-known lability of sulphur linkages when combined in peptides as compared with the stability in cystine. On the other hand, such arguments lose their value when it is realised that hydrogen peroxide, an oxidising agent, effects the same series of changes—decrease, increase and finally decrease of activity. Hydrogen peroxide oxidises cystine to cysteic acid [Schöberl, 1933].

Finally, it is evident that the oxytocic hormone and insulin exhibit similarities in some of their reactions [see for the insulin reactions: Blatherwick *et al.*, 1927; Freudenberg *et al.*, 1931; 1932; Kuhn *et al.*, 1931; Du Vigneaud *et al.*, 1931–32]. There is, however, one marked difference between these hormones: so far, all attempts to reactivate reduced insulin have proved unsuccessful.

SUMMARY.

1. The action of the following reagents on the hormone has been studied: sodium sulphite, sulphur dioxide, sodium cyanide, hydrogen cyanide, chlorine, iodine, hydrogen peroxide, semicarbazide and hydroxylamine.

2. The results are discussed from the standpoint of the presence of a disulphide linkage in the hormone molecule.

XLVII. CORRELATION OF THE SPERMICIDAL EFFICIENCIES OF AROMATIC ALDEHYDES WITH THEIR CHEMICAL REACTIVITIES, AND ELECTROMETRIC ALKALINE TITRATIONS OF GELATIN IN PRESENCE OF AROMATIC ALDEHYDES.

By JOHN MASSON GULLAND and THOMAS HOBSON MEAD.

From the Biochemical Department, The Lister Institute, London.

(*Received January 2nd, 1935.*)

In a previous communication [Gulland, 1932] it was shown that a series of *p*-benzoquinones arranged in order of their lethal action on guinea-pig spermatozoa resembles closely a series of the same, or similar, quinones placed in order of their chemical reactivities. At the same time the results of a few experiments with aromatic aldehydes were quoted, from which it was evident that certain simple derivatives of benzaldehyde are considerably more effective than others in immobilising guinea-pig spermatozoa. These observations have now been extended to cover a series of closely related aromatic aldehydes, in order to ascertain to what extent their spermicidal efficiency, regarded as a measure of their effect on cells, may be correlated with the chemical reactivities of their aldehyde groups.

The biological tests were made essentially as described by Baker [1930; 1931, 1; 1932] but with one important alteration, which is described in the experimental section. This modification confers the following advantages. (*a*) Substances in pairs may be compared directly with each other, using one and the same sperm suspension. (*b*) Decisive results may be obtained at sublethal, instead of lethal, concentrations, a point which becomes important when sparingly soluble substances are examined. (*c*) It is possible to classify substances which differ but slightly in spermicidal efficiency. (*d*) Fewer animals are needed. The three former advantages were of greater value in the present investigation than in Baker's researches.

The aldehydes now examined were mono- and di-methoxybenzaldehydes; phenolic derivatives were not included, since their acidity disturbed the buffering effect of the fluid in which the sperms were suspended and consequently introduced a second variable factor into the experiments. A method has been devised, however, to enable the spermicidal efficiency of such acidic substances to be tested at the standard p_H value.

The following experimental relationships were established between the lethalities of the aldehydes, formaldehyde being included for comparative purposes: formaldehyde > 2:5-dimethoxybenzaldehyde > 2:3-dimethoxybenzaldehyde > 2-methoxybenzaldehyde ≧ 2:4-dimethoxybenzaldehyde ≧ 3-methoxybenzaldehyde > 3:4-dimethoxybenzaldehyde.

Since the carbonyl group is the only chemically reactive centre in these aldehydes, it is obvious that the amino-groups of the cell proteins or amino-acids are probable points of attack by the aldehydes. It will be shown elsewhere that some aromatic aldehydes condense readily with glycine in presence of baryta or barium acetate, whereas others do not, and in the present connection it may be stated that the isolation of the barium salt of the arylidene glycine was found to be an indication that the aldehyde in question would prove spermicidally efficient. In the same paper it is demonstrated that 2:5- and 2:3-dimethoxybenzaldehydes, both of which are of relatively high lethality towards sperms, enter into reversible condensation with *d*-phenylalanine more rapidly and to a greater extent than does 3:4-dimethoxybenzaldehyde, which has only feeble lethality. Such condensations, however, are less closely related to those occurring in cells than are interactions of the aldehydes with a protein, and the chemical reactivities of the same aldehydes which were examined for spermicidal efficiency have therefore been compared as regards their capacities for condensation with gelatin.

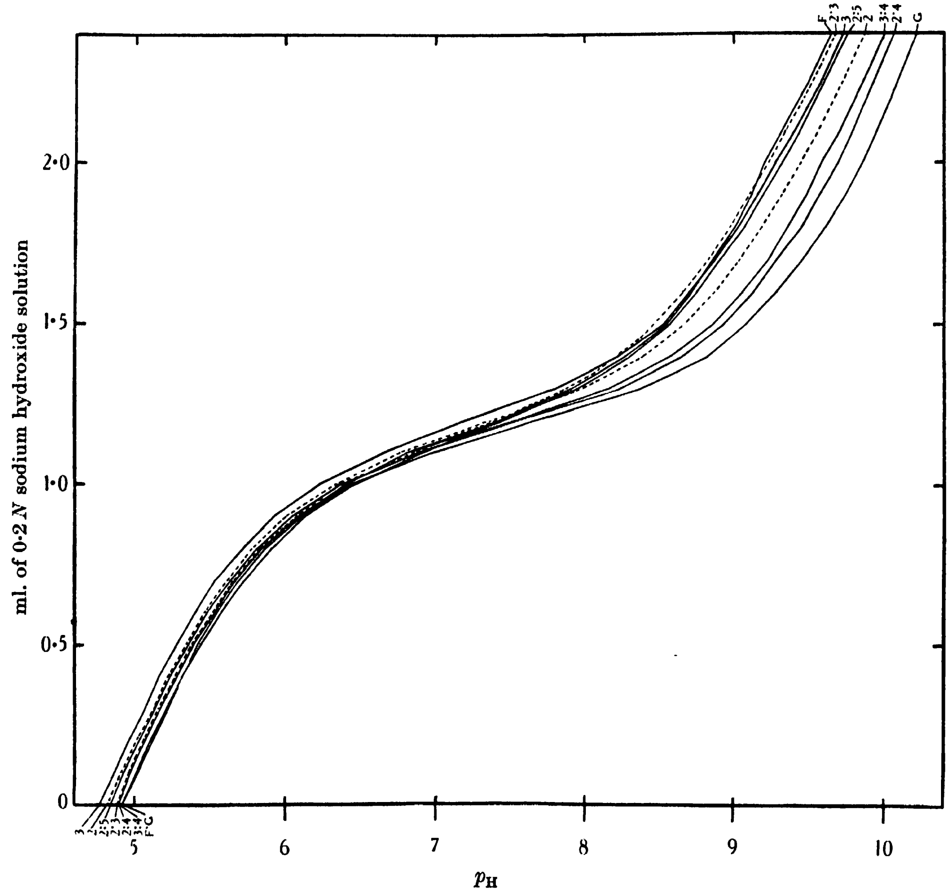

Fig. 1. Titration of gelatin (G) alone and in presence of formaldehyde (F) and 2-, 3-methoxybenzaldehydes, 2:3-, 2:4-, 2:5-, 3:4-dimethoxybenzaldehydes.

Birch and Harris [1930] compared the titration curve of a gelatin solution with that of a similar solution containing formaldehyde and showed that the acidic portion of the curve is unaltered by the addition of the aldehyde whereas in the alkaline range displacement occurs in the direction of decreased p_H value.

This effect is due to the combination of the aldehyde with undissociated basic groups of the gelatin anions. As a result, the effective concentration of gelatin anions is reduced, and the solution becomes more acid [Levy, 1933; Richardson, 1934]. It follows that the extents of the displacements in alkaline titrations of a protein in solutions of different aldehydes at the same concentration provide a measure of the tendencies of the aldehydes to condense with the undissociated amino-groups of the protein anion.

Titration curves were prepared under standard conditions over the range p_H 5–10 for gelatin alone and in presence of a constant fraction of a molecular proportion of each of the aldehydes (Fig. 1). Absolute accuracy was not attempted, but as the conditions of each experiment were identical, the results obtained were strictly comparable among themselves. These curves almost coincide at about p_H 6·5, and closely approach the gelatin curve. They are deflected from the gelatin curve towards increased acidity at higher and lower p_H values (shown more clearly in Fig. 2). These portions of the curves are considered separately below. The curve obtained using 3-methoxybenzaldehyde is apparently abnormal and is discussed later.

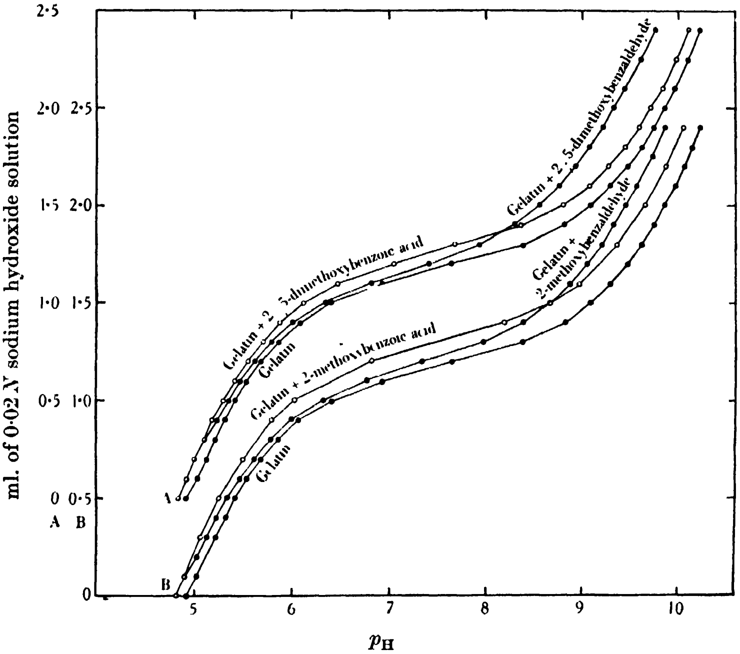

Fig. 2. Titrations of gelatin alone and in presence of:

A { *M*/100 2:5-dimethoxybenzaldehyde
2:5-dimethoxybenzoic acid

B { *M*/100 2-methoxybenzaldehyde
2-methoxybenzoic acid

Consideration of the more alkaline sections of the titration curves shows that condensation occurred progressively over approximately the same p_H range as that in which the amino-groups of the lysine residues and the "terminal" amino-groups of peptide chains dissociate [*cf.* Jordan-Lloyd, 1933]. This suggests that these groups are involved in this condensation.

From the standpoint of the relative capacities of the aldehydes for condensation, the displacements of the titration curves may be compared at p_H 8·2, the reaction of the fluid in which the sperms are suspended in the biological tests, or more easily at $p_{\rm H}$ 9·6, where the spatial differences are greater; the curves do not intersect, with the exception that that of formaldehyde crosses that of 2:3-dimethoxybenzaldehyde at $p_{\rm H}$ 9·1–9·2. By this means the aldehydes were arranged in the following order of decreasing capacity for condensation with gelatin anions: 2:3-dimethoxybenzaldehyde > (formaldehyde) > 3-methoxybenzaldehyde > 2:5-dimethoxybenzaldehyde > 2-methoxybenzaldehyde > 3:4-dimethoxybenzaldehyde > 2:4-dimethoxybenzaldehyde. The position of formaldehyde in the series is doubtful on account of the intersection mentioned above, and 3-methoxybenzaldehyde occupies an unexpectedly high place (see below).

3-Methoxybenzaldehyde autoxidises with great ease, and it was shown by titration that the sample used contained 0·3 % of the corresponding acid, although all possible precautions had been taken to prevent aerial oxidation during its purification. Moreover, the amount of acid may well have increased beyond 0·3 % during the preparation of the aldehyde-gelatin solution before the titration was begun. It was therefore suspected that the position of the titration curve in Fig. 1 was due to the presence of 3-methoxybenzoic acid and not to a superior capacity for condensation by this aldehyde, and confirmation of this view was obtained in two experiments. 2-Methoxybenzoic acid or 2:5-dimethoxybenzoic acid respectively was added to the gelatin solution before titration in amounts sufficient to lower the $p_{\rm H}$ to that of the corresponding aldehyde-gelatin mixture at the isoelectric point of gelatin. The subsequent titration of the mixture of gelatin and acid then followed a course parallel with the gelatin curve and quite different from the aldehyde-gelatin curve (Fig. 2).

By transposing the position of the 3-methoxybenzaldehyde-gelatin curve so that it coincides with the curves of the other aldehyde complexes at $p_{\rm H}$ 6·6, that is, by making allowance for the presence of 3-methoxybenzoic acid, it may be shown that at alkaline reactions 3-methoxybenzaldehyde has a capacity for condensation approximately equal to that of 2-methoxybenzaldehyde, and that it also reacts with gelatin at $p_{\rm H}$ values acid to $p_{\rm H}$ 6·6, in common with the other aromatic aldehydes. These aldehydes thus fall into the following order of decreasing capacity for condensation with gelatin anions at the reaction at which the spermicidal tests were made (Table I). It is also possible that in the spermicidal tests the facile autoxidation of 3-methoxybenzaldehyde reduced its true lethality slightly by decreasing its concentration as a result of conversion into 3-methoxybenzoic acid. Attention was given to these corrections in drawing up Table I, which in our opinion shows the arrangement of the aldehydes in decreasing order (*a*) of spermicidal efficiency, (*b*) of capacity for condensation with gelatin anions.

Table I.

Spermicidal efficiency	Capacity for condensation with gelatin
2:5-Dimethoxybenzaldehyde	2:3-Dimethoxybenzaldehyde
2:3-Dimethoxybenzaldehyde	2:5-Dimethoxybenzaldehyde
2-Methoxybenzaldehyde	2-Methoxybenzaldehyde
3-Methoxybenzaldehyde	3-Methoxybenzaldehyde
2:4-Dimethoxybenzaldehyde	3:4-Dimethoxybenzaldehyde
3:4-Dimethoxybenzaldehyde	2:4-Dimethoxybenzaldehyde

Thus, the series of aldehydes arranged in order of spermicidal efficiency closely resembles the series of the same aldehydes arranged in order of their capacity for condensation with gelatin anions.

The arguments used above are based on the assumption that in no case is the aldehyde present in such amount that all, or even most of those groups in the gelatin molecule which can react have in fact condensed with the aldehyde molecule. That the gelatin was capable of far more extensive condensation was shown (Fig. 3) by the very marked additional displacement of the curve in presence of 0·5 % formaldehyde as compared with that using $M/100$ formaldehyde.

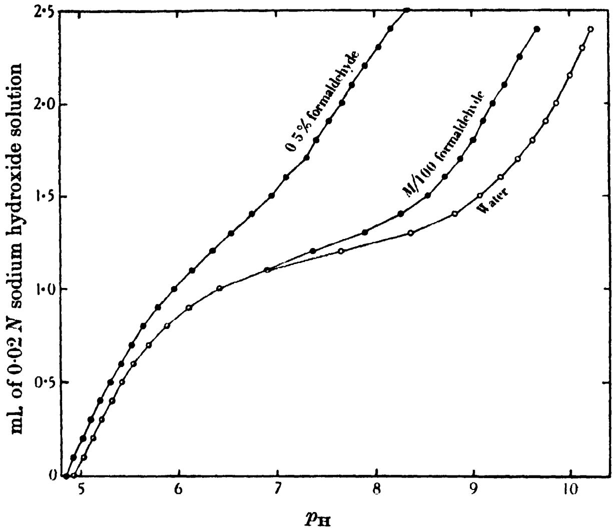

Fig. 3. Titrations of gelatin in 0·5 % and $M/100$ formaldehyde solutions and in water.

The more acidic sections of the titration curves, except in the case of that determined in presence of formaldehyde, are deflected away from the gelatin curve towards greater acidity between p_{H} 6 and 4·9, the isoelectric point of gelatin. These changes are clearly shown in Fig. 2. It is improbable that these deflections are due to the presence of small amounts of the corresponding acids, partly because these aldehydes, excluding 3-methoxybenzaldehyde, do not autoxidise very readily and partly because the curves almost coincide at p_{H} 6·7 as mentioned above. It was shown above that the presence of the corresponding acid prevented this coincidence. It may be inferred, therefore, that the aromatic aldehydes, but possibly not formaldehyde at the same concentration, combine with gelatin between its isoelectric point and about p_{H} 6–7 to form compounds which may be resolved into their components as the reaction of the medium approaches neutrality. This condensation might conceivably be associated with the iminazole group of histidine residues, for which Neuberger [1934] has determined p_{K} 5·99 [*cf.* Jordan-Lloyd, 1933], and in this connection it is interesting to note that when salicylaldehyde and histidine condense in the presence of brucine, the resulting brucine salt contains salicylaldehyde and histidine in the ratio of 2:1 [Bergmann and Zervas, 1926]. We do not, however, advance any explanation of the deflections at acid p_{H} values, since further investigation is necessary.

EXPERIMENTAL.

Technique of biological tests.

The technique described in great detail by Baker showed the least concentration (weight/volume) in the series 1:50, 1:100, 1:200, 1:400, 1:800 *etc.*, which sufficed to immobilise in 30 minutes in four consecutive experiments all guinea-pig sperms suspended in a glucose-saline fluid buffered at p_H 8·1 at 37°. The early experiments of the present investigation were made according to this technique, but it soon became evident that modifications of Baker's procedure were necessary. These are described below, and should be regarded as supplementary to his description and not in any way in opposition to it.

Preparation of buffered glucose-saline solution. It is undesirable to store alkaline stock solution containing glucose and phosphate, owing to the instability of glucose under these conditions. In order, therefore, to avoid the necessity of frequent preparations of small quantities [Baker, 1931, 2] two solutions were employed, one containing the saline constituents, the other the glucose. The first solution consisted of disodium hydrogen phosphate dihydrate (5·96 g.), dihydrogen potassium phosphate (0·20 g.) and sodium chloride (4·00 g.) in 1 litre of aqueous solution; this was preserved at 0° and mixed as required with an equal volume of a solution of glucose (6·0 g.) in freshly prepared aqueous solution (100 ml.). Sodium phosphate dihydrate was used instead of the dodecahydrate [Baker, 1931, 2], since the latter effloresces and is therefore of inconstant composition.

Preparation of aldehyde solutions. These were prepared in terms of molarity, instead of percentage, so that the activities of aldehydes with different molecular weights could be readily compared.

Neutralisation of acidic substances before the biological test. It is well known that sperm-cells are susceptible to changes in the reaction of the medium in which they are suspended, and that the mobility of guinea-pig sperms is much reduced if the medium becomes acid. Measurements of the p_H values of control sperm suspensions made with a B.D.H. capillator before and after a number of experiments showed that an increase in the acidity of the medium from p_H 8·2 to 7·8 might be expected and did not interfere with the mobility of the cells. This change is presumably the result of cell metabolism and respiration and possibly of slight absorption of carbon dioxide from the atmosphere.

Several phenolic aldehydes were examined during this work, and as these substances are acidic, it was possible that part of their spermicidal activities and those of acidic substances in general might be due to insufficient buffering by the glucose-saline medium when the higher concentrations of substances were tested. For example, at the end of an experiment with resorcylaldehyde, the sperm suspension containing this aldehyde at $M/200$ concentration was at p_H 6·8. It was thus essential to neutralise such acidic substances, and this had to be effected without disturbing the isotonicity of the solutions. The following modification of the usual procedure, namely solution of the substance in 0·9 % sodium chloride, was therefore adopted in experiments with acidic compounds. On the assumption that in dilute solution sodium chloride and sodium hydroxide are dissociated to the same extent, an aqueous solution of 6·15 g. of sodium hydroxide in 1 l. was regarded as being isotonic. A solution of the acidic substance (x g.) in 0·9 % sodium chloride (y ml.) at the strength needed for the experiment was titrated with this isotonic sodium hydroxide to p_H 8·0, and the volume of alkali required (z ml.) noted. The solution for the experiment was then prepared by dissolving the substance (x g.) in 0·9 % sodium chloride

(y–z ml.) and isotonic sodium hydroxide (z ml.). This procedure involves the assumption that the sodium salt of the acidic substance was dissociated to the same extent as sodium chloride in dilute solution. This assumption is justified for the purpose of these experiments.

Comparison of biological activities. Baker's technique involves the comparison of the lowest concentrations at which the substances being examined immobilise all sperms under the experimental conditions. There are three objections to this procedure from the standpoint of the present investigation. First, the sparing solubility of several aldehydes prevented lethal or highly active concentrations from being reached. Secondly, the recognition of small differences in activity was extremely difficult, especially when these were encountered in experiments on different days. Thirdly, sperm suspensions vary considerably in the number of cells they contain, and this might affect the results. The following method of performing the tests was therefore adopted.

The effects of two aldehydes, each at two concentrations, were compared simultaneously on one sperm suspension in each experiment. The usual concentrations were $M/200$ and $M/300$, because the stronger solution had some lethal action in each case. Baker's technique was followed closely, with the modifications described. Three slides were used for the microscopic examination, each having two hollows in it, denoted *a* and *b* respectively. Slide I *a* and *b* contained the control suspension. Slide II *a* contained substance x at a dilution of $M/300$, whereas II *b* contained substance y at $M/300$. Slide III contained the two aldehydes at $M/200$ dilution. Thus, by comparing the mobilities of the sperm suspensions *a* and *b* after the standard time of 30 minutes, a direct comparison of the relative activities of the two aldehydes could be made, without relying solely on the records of the grades of activity. Duplicate experiments were made for each pair of aldehydes, and the aldehydes could then be arranged in the order of their activities in immobilising sperms. Quotation of grades of activity recorded and dilutions used in the many experiments would occupy too much space for them to be stated here, although these data were also used in drawing up the series on p. 397. The following list, however, summarises the results of the comparative experiments.

Comparison of the spermicidal efficiencies of pairs of aldehydes.

The activity of:	was	that of:
3-Methoxybenzaldehyde	$<$	2-Methoxybenzaldehyde
3:4-Dimethoxybenzaldehyde	$<$	2:4-Dimethoxybenzaldehyde
2:4-Dimethoxybenzaldehyde	$=$	2-Methoxybenzaldehyde
3:4-Dimethoxybenzaldehyde	$<$	2-Methoxybenzaldehyde
3:4-Dimethoxybenzaldehyde	$<$	3-Methoxybenzaldehyde
3-Methoxybenzaldehyde	$=$	2:4-Dimethoxybenzaldehyde
2-Methoxybenzaldehyde	$<$	2:3-Dimethoxybenzaldehyde
2:3-Dimethoxybenzaldehyde	$\leqq$	2:5-Dimethoxybenzaldehyde
2:3-Dimethoxybenzaldehyde	$<$	Formaldehyde
2:5-Dimethoxybenzaldehyde	$<$	Formaldehyde

Preparation of materials.

Aromatic aldehydes and acids were prepared by customary methods and were purified by repeated recrystallisation, with changes of solvent where possible.

Formaldehyde was prepared by distilling in a slow current of steam a mixture of pure hexamethylenetetramine (14 g.) and dilute sulphuric acid (7 % weight/volume; 300 ml.). Six fractions (40 ml. each) were collected, and the first three (formaldehyde concentration greater than 4 %) were mixed, shaken with calcium carbonate and redistilled in presence of calcium carbonate. The first 40 ml. to be collected were boiled gently in a long-necked flask and cooled *in vacuo*. The residual solution was neutral, was free from carbon dioxide and contained 4·8 % of formaldehyde, estimated by oxidation with neutralised perhydrol in alkaline solution and back-titration of the excess of alkali with standard hydrochloric acid, using phenolphthalein as indicator.

Water free from carbon dioxide was obtained by distilling laboratory distilled water in an apparatus fitted with efficient spray-trap and silica condenser, the first third of the distillate being rejected. The water was collected and stored in a Jena-glass bottle which had been soaked in similar water for some weeks and which was fitted with a soda-lime tube and siphon.

Sodium hydroxide solution. A solution of hydroxide in its own weight of water was left in a resistance glass vessel until the carbonate had separated. The solution was filtered through prepared filter-paper, and diluted with carbon dioxide-free water to give a $0{\cdot}2N$ solution of sodium hydroxide. This solution was preserved in a wax-lined bottle connected to the burette (see later) and protected by a soda-lime tube; its strength was checked at intervals by titration with $0{\cdot}1N$ hydrochloric acid.

Gelatin. Preliminary titration experiments with different samples of "Gold Leaf" gelatin gave inconsistent results, and the gelatin ultimately used was a commercial powder purified as described by Smith [1921]. The final product, a readily soluble powder, was kept in a tightly-stoppered bottle and did not change in composition during the period of the experiments. It contained 9·5 % of moisture when dried to constant weight for 11 hours at 100–105°, and a sample weighing 0·4065 g. left less than 0·1 mg. of residue after ignition.

Purified hydrogen. Hydrogen was obtained from a cylinder connected with a small gas-holder which helped to maintain a steady flow. The gas was scrubbed by passing up two towers, the first filled with glass beads over which flowed concentrated sodium hydroxide, the second filled with beads over which passed water free from carbon dioxide. Traces of oxygen were removed by passing the hydrogen over copper gauze heated at a dull red heat in an electric furnace.

Electrometric titrations of gelatin alone and in presence of aldehydes.

Apparatus. The use of rubber tubing in conveying the hydrogen supply was avoided as far as possible, connections between glass tubes being arranged so that the tubes met in the joint. All rubber stoppers and tubes were purified by treatment with sodium hydroxide and water in the usual way.

The cell consisted of a pyrex boiling-tube, 5 cm. in diameter and 12·5 cm. long, having a working capacity of 100 ml. The tube was closed by a rubber bung pierced with seven holes, through which passed a glass stirrer in a tight sleeve, a thermometer, inlet and exit tubes for hydrogen, and closely fitting glass sleeves through which passed the tip of the burette, the agar potassium chloride bridge and the hydrogen electrode respectively. These sleeves enabled the easy insertion or withdrawal of the parts in question. The stirrer was operated manually and could be raised to remove drops adhering to the tip of the burette.

The hydrogen electrode vessel was of the Bunker type [1920], so designed that the entire platinum surface (about 1 cm. of wire) was bathed in hydrogen as each bubble escaped, and was then covered with liquid before the next bubble formed. The electrodes were replatinised before each titration, and occasionally a fresh electrode was inserted during a titration in order to make certain that poisoning was not occurring. After a suitable interval for saturation, the fresh electrode was always at the same potential as that which it had replaced.

The reference electrode was a 3·5N potassium chloride-calomel half-cell connected to the hydrogen electrode cell by a vessel containing saturated potassium chloride and the agar-potassium chloride bridge. Fresh surfaces of the bridges were exposed before use, and bridges gave concordant results when interchanged.

The electrodes were connected to a Tinsley potentiometer by unsupported wires, and the null point was determined by a capillary electrometer. Two determinations of E.M.F. were made, the null point being approached from both sides.

Before reaching the cell, the hydrogen passed through a presaturator containing pure water for all experiments except those with solutions containing formaldehyde, when the presaturator contained a formaldehyde solution of the same strength as that in the cell. Condensation in the tube between the presaturator and the cell was prevented by an adjacent carbon-filament lamp.

The cell, presaturator, saturated potassium chloride vessel and calomel electrode were immersed in a paraffin thermostat at 37° ± 0·1°.

The burette was protected by soda-lime tubes and was fitted with two jets, one which could be lowered into the cell, the other arranged outside the thermostat for adjusting the zero level and for checking the strength of the sodium hydroxide.

Procedure. Purified gelatin (1 g.) and the aldehyde (0·1 millimol) in water (100 ml.) were used for each experiment, except in one instance when more concentrated formaldehyde solution was used. The total volume of 0·2N sodium hydroxide required in each titration was 2·4 ml., and the range p_H 5–10 was covered. The aldehyde and gelatin were either dissolved simultaneously by warming their suspension in the water to 90° and then cooling to 38°, or the gelatin was dissolved first in this way and the aldehyde was added to the warm solution. The results were not affected by these changes in procedure, and the latter alternative was adopted in the cases of 3-methoxybenzaldehyde and formaldehyde.

The calomel electrode and potassium chloride vessel were placed in the thermostat 30 minutes earlier than the cell, the contents of which were saturated by a slow stream of hydrogen through the inlet tube. Ten minutes later, the tip of the burette was arranged to deliver just above the surface of the liquid in the cell, the hydrogen electrode and its vessel were inserted, and the hydrogen supply was diverted from the inlet tube to the electrode. Twenty minutes later the agar-bridge was inserted, and equilibrium had usually been attained after a further period of 10 minutes.

When the E.M.F. was constant, the titration was begun by the addition of sodium hydroxide solution in portions of 0·1 ml., the new equilibrium being reached within 2 minutes. The contents of the cell were stirred after each addition and between each measurement of potential. Steady values were obtained between p_H 5–6 and 8–10, but occasionally drifts towards the acid side were observed near the neutral point. Since these were observed to the same extent with gelatin alone, it was concluded that they were not due to increased time taken for the aldehyde-gelatin system to reach the new equilibrium. An accuracy of 0·01 p_H unit is probable for the values obtained in the more acid and alkaline regions, but this accuracy is slightly less in the case of values about the neutral point on account of the drifts of potential.

The p_H values were calculated from the observed potential differences by the Nernst expression for the E.M.F. of a concentration cell.

In the titrations of gelatin in presence of small amounts of aromatic acids, a 0·02N solution of the required acid was added to the gelatin solution in the cell until the p_H value had fallen to the same extent as had been observed in titrations of gelatin-aldehyde mixtures where small amounts of the corresponding acid were suspected. The titration of the acid-gelatin mixture was then carried out with 0·02N sodium hydroxide in the usual way. In these experiments 4·2 mg. of 2:5-dimethoxybenzoic acid and 3·6 mg. of 2-methoxybenzoic acid were used.

SUMMARY.

1. A method is described for comparing directly on the same material the spermicidal efficiencies of two substances. This is specially valuable when sparingly soluble compounds are to be examined.

2. This method has been used to arrange a series of mono- and di-methoxybenzaldehydes in the order of their spermicidal efficiencies.

3. Titration curves of gelatin in presence of the same mono- and di-methoxybenzaldehydes are deflected from the gelatin curve towards a more acid reaction over the range p_H 8–10. This deflection is a measure of the extent to which the aldehydes have condensed at equilibrium with the gelatin anion between these p_H values.

4. A series of mono- and di-methoxybenzaldehydes arranged in order of their capacities for condensation with the gelatin anion closely resembles the series of the same aldehydes arranged in order of their spermicidal efficiencies.

5. Titration curves of gelatin in presence of mono- and di-methoxybenzaldehyde are deflected from the gelatin curve towards a more acid reaction between the isoelectric point and p_H 6–7.

6. A method is described for testing the spermicidal efficiencies of acidic substances which disturb the buffer effect of the media in which the sperms are suspended.

XLVIII. AN ULTRACENTRIFUGAL INVESTIGATION OF THE SERUM PROTEINS.

By ARTHUR SPROUL McFARLANE.[1]

From the Institute of Physical Chemistry, The University, Upsala, Sweden.

(*Received December 20th, 1934.*)

The extensive researches into the molecular dimensions of the proteins carried out in recent years by Svedberg and collaborators[2] by means of the ultracentrifuge have hitherto been conducted mainly on dilute protein solutions. This has been necessitated by the fact that the sedimentation velocity in the centrifugal field is independent of the protein concentration only in dilute solution. In addition to this, various practical difficulties arise when it is desired to examine protein solutions, such as serum, which contain more than 1–2 % of protein. For instance, the light absorption in the ultraviolet of such solutions is generally too great to permit the use of the absorption method of following the protein sedimentation. Also, in the case of serum, the absorption over the whole cell would not be due to the proteins alone, as is desirable, but also to the serum pigments.

The refractive index method of Lamm [1928; 1929], which depends on photographic measurements of the light deviation caused by the sedimenting boundary, offers better possibilities of examining strong protein solutions, because in this method light may be used of a wave-length which is outside the absorption region of the proteins or of any non-centrifugible absorbing substances which may be present in the solution. Mutzenbecher has recently used this method extensively in his studies on the serum proteins [1933, 1, 2, 3]. In this method a regular ruled scale is photographed through the centrifuge cell as it rotates, and according to whether the sedimentation boundary is sharp or diffuse the scale must be placed very close to, or at some distance from, the centre of the centrifuge cell. It is at present mechanically impossible to bring the scale closer to the centre of the rotating cell than 3·5 cm.,[3] and at this distance the maximum concentration of serum albumin which can be examined in the thinnest centrifuge cell available is about 4 %, and of globulin about 2 %, owing to its lower diffusion constant. In the course of experiments directed towards the design of a system which might permit satisfactory centrifugal examination of undiluted human serum it was suggested to the writer by Dr Lamm that in place of the actual scale it should be possible to project optically close to, or even inside, the rotating centrifuge cell an image of an actual scale placed at some distance from the centrifuge. This scheme was immediately successful and afforded for the first time excellent photographs of the sedimentation of the proteins in undiluted serum and in some artificial protein mixtures of even higher concentration. It was found, for instance, that with certain undiluted sera scale distances as small as 0·9 cm. were required to give successful photographs. It was also found, however, that there is a definite limit to the concentration of protein which may be examined owing to the appearance at high concentrations of a black band across the scale which completely blots out the lines in the boundary area. This phenomenon, which apparently arises when the deviation of the beam is so great that the light from the mercury lamp fails to reach the camera at all, must depend on a great variety of factors for its appearance, such as the thickness of the cell, the refractive gradient in the solution and the relative positions of lamp, cell, objective lens and camera. The phenomenon is closely related to the "Totalreflexion" described by Gans [1915] in his studies on the propagation of light through inhomogeneous media. On the basis of our experience with the present optical system of the ultracentrifuge we may say that the complication does not in general occur with serum protein concentrations less than 10 % in a 1·5 mm. cell, and that higher concentrations may usually be examined unless there is an abnormally large proportion of globulin or substances of higher molecular weight. With globulin alone, the black band will appear first at a concentration of approximately 6 %.

---

[1] Beit Memorial Research Fellow.

[2] A complete bibliography of this literature will be found in a recent article by Svedberg [1934].

[3] In the new rotors which are in process of construction it will be possible to bring the scale to within 2·5 cm. of the centre of the cell.

The method would appear to open a new field, *viz.* that of very concentrated protein solutions, and promises therefore to throw light on the molecular properties of many proteins in their natural biological state. There will be reported here the results of an investigation into some new phenomena which appear in concentrated mixtures of albumin and globulin, and which affect fundamentally our present ideas of the molecular state of these proteins in untreated serum. Throughout the work the opportunity has been taken to verify experimentally some of Lamm's more fundamental equations relating to the deviation of light by diffusing systems.

GENERAL THEORETICAL CONSIDERATIONS.

(*a*) *The refractive index method of Lamm.* A full account of the theory of the refractive index method will be found in Lamm's original papers. As already stated, a ruled scale is photographed through the centrifuge cell as it rotates and those lines on the scale which are seen through the diffusing boundary area appear in displaced positions. A photograph obtained in a preliminary run at the same speed but with water only in the cell gives a standard undeviated scale in which, of course, the effect of the compression gradient throughout the fluid in the cell is present and may be seen by comparing the average distance between the lines with the same distance on a photograph taken at low speeds. During the subsequent run with the protein solution in the cell photographs are taken at intervals of 10–20 mins. and the position of each scale line on the photograph is then measured with an accuracy of $\pm 1\mu$ in a microscope comparator. In order to find the deviation (Z) of any line in a photograph from its position in the standard undeviated scale it is necessary to have the same comparator zero for all photographs. On each scale photograph there appear also 3 or 4 scale lines which are photographed directly through small apertures in the balancing cell of the centrifuge. Since the absolute positions of these lines in space remain unaltered during the run, one of these is chosen as reference zero and every scale is placed on the microscope stage so that the arbitrary comparator reading for this line is 0.

The photographic displacement of any line (Z) from its position on the undeviated scale is given by

$$Z = G\,a\,b\,\frac{dn}{dx} \qquad \text{......(1)}$$

where G = the photographic enlargement factor;

a = the thickness of the fluid layer in the cell traversed by the beam;

b = the optical distance from the scale to the middle of the cell;

and $\frac{dn}{dx}$ is the gradient of refractive index, along a radial axis, at the displaced line position in the plane of the cell.

The photographic displacement (Z) for each line is plotted against its displaced position in comparator units. In this way a curve is obtained which shows the change of refraction gradient throughout the cell (*cf.* Fig. 2). If we assume that the gradient is zero in those parts of the cell above and below the diffusion region (which is usually experimentally true) then the area enclosed by this curve and the base-line is given by

$$A=\int_{-\infty}^{+\infty}\left(G\,a\,b\,\frac{dn}{dx}\right)dx=G\,a\,b\,(n_1-n_0) \qquad \ldots\ldots(2),$$

where n_0 is the refractive index of the solution of non-sedimenting electrolytes which separates above and n_1 is the refractive index of the protein solution below the sedimenting boundary.

It is to be emphasised that in the derivation of this equation no assumptions are made as to the nature of the forces which give rise to the gradient, and in particular, that the validity of the formula is not dependent on the curve conforming to any particular type.

The area A, obtained by graphical integration, is multiplied by the following factors:

1. $\left(\frac{x}{x_0}\right)^2$ where x and x_0 are the distances of the ideal sedimentation boundary (*i.e.* the theoretical boundary assuming that no diffusion has taken place) and the meniscus respectively from the centre of rotation. This factor [Svedberg and Rinde, 1924] corrects for the sector shape of the cell and the fact that the protein is sedimenting in a centrifugal field the intensity of which varies with the distance from the centre of rotation.

2. A factor (F) which converts the arbitrary comparator and graph units into absolute units (cm.).

3. $\frac{l}{(l+b)\,G}$ where l is the distance of the camera objective lens from the centre of the cell. This factor converts the displaced line positions on the photograph into absolute positions in the plane of the cell.

The equation
$$n_1-n_0=\frac{A}{G\,a\,b}\cdot\left[\frac{x}{x_0}\right]^2\cdot\frac{l}{(l+b)\,G}\cdot F \qquad \ldots\ldots(3)$$

gives, therefore, the protein refraction increment of the solution, but on the condition already stated, *viz.* that the solution which separates above is free from centrifugible matter and that no high molecular protein is thrown to the bottom of the cell before the first photograph is taken. Such an assumption is, of course, only justifiable for approximately monodisperse protein solutions and in particular for protein solutions which are free from protein disintegration products.

(*b*) *The calculation of sedimentation velocity.* The sedimentation constant is given by

$$S=\frac{dx}{dt}\cdot\frac{1}{x_m\omega^2} \qquad \ldots\ldots(4),$$

where the boundary has moved through a cell depth dx in time dt under a mean centrifugal force of $x_m\omega^2$. In every case we have corrected this value to a medium of pure water at 20° by means of the formula

$$S_{\mathrm{W},20}=S_{\mathrm{S},\mathrm{T}}\cdot\left[\frac{\eta_{\mathrm{S},\mathrm{T}}}{\eta_{\mathrm{W},20}}\right]\left[\frac{\left(\frac{1}{V}-\rho_{\mathrm{W},20}\right)}{\left(\frac{1}{V}-\rho_{\mathrm{S},\mathrm{T}}\right)}\right] \qquad \ldots\ldots(5),$$

where $S_{W,20}$ is the sedimentation constant in water at 20°;
$S_{S,T}$ is the sedimentation constant in the salt solution at $T°$;
$\eta_{W,20}$ is the viscosity of water at 20°;
$\eta_{S,T}$ is the viscosity of the salt solution at $T°$;
V is the partial specific volume of the protein (=0·745 for horse serum albumin and globulin [Svedberg and Sjögren, 1928]);
$\rho_{S,T}$ is the density of the salt solution at $T°$;
$\rho_{W,20}$ is the density of water at 20°.

Tiselius [1932] has considered the electroviscous effect which appears when charged particles are caused to move in relation to the surrounding fluid by centrifugal forces and which in certain circumstances may give rise to abnormally small values of S. He gives the approximate formula

$$S^1 = S\,(1 - t_k) \qquad \text{......(6)},$$

where S^1 is the apparent sedimentation constant, S is the true sedimentation constant, and t_k is that fraction of the total conductivity (colloid+all other electrolytes) which is due to the colloidal ions. t_k varies widely with the protein, salt and hydrogen ion concentrations. In spite of the unusually high protein concentrations which we have examined in this work the value of t_k is always small because of the high conductivity of the 1 % sodium chloride or Ringer solution used as dispersion medium for the protein. No electroviscous correction need therefore be applied to the sedimentation constant values.

(c) *The base-line of the sedimentation diagram.* A phenomenon of rather frequent occurrence in the sedimentation graphs consists in a shift of the apparent base-line of the curve, *i.e.* the line joining the two horizontal limbs, so that it lies above or below the true base-line or x-axis. It appears that a displaced base-line is always associated with the use of a large centrifuge cell or a large scale distance or the two together. With water alone in the cell it may be seen from the scale photographs that the light beam passing through the cell is deviated as a whole (in relation to the undeviated beam passing through the apertures in the balancing cell) even at low speeds, and that the angle of deviation changes progressively with changing speed of the rotor. The amount of deviation is too great to be due to the compression gradient in the water. It is possible that the deviation is caused by a lack of true parallelism in the quartz end-plates of the cell. A consideration of the cell as a prismatic deviator of small angle shows that the deviation will increase with an increase of a or b, and this has been observed in practice. It is also possible that changes in the quartz plates under the influence of the high centrifugal forces used may contribute in large part to the deviation.

Pedersen [1934] has found that this deviation is strictly reproducible in the same cell when great care is taken to maintain the speed of the rotor constant to within ± 100 r.p.m. When this and other precautions which we need not mention here are observed it is possible to determine the true base-line, as Pedersen has done in his sedimentation equilibrium experiments with inorganic salts. In a prolonged series of experiments such as we are concerned with here, and in which it is proposed to examine a wide range of concentrations, it is not possible to use the same cell throughout and to observe all the precautions which Pedersen has been able to take. It will be apparent that if an insidious shift of the base-line is allowed to occur, then the area enclosed by the curve and the true base-line, or x-axis, will be abnormal and a serious error will be introduced in the calculations of $n_1 - n_0$ (equation (3)). If instead we measure the area enclosed by the curve and the apparent base-line this will still be accurately related to $n_1 - n_0$ in accordance with the terms of equation (3), provided that by $n_1 - n_0$ we understand the difference in the refractive indices at two levels in the cell just outside the area of the diffusing boundary—one above and one below, and not necessarily as in the original definition, the difference between the refractive indices of the protein solution and of the salt solution in which the protein is dispersed. We have, therefore, throughout this work adopted the convenient and safe procedure of basing all measurements on the apparent base-line. It should, however, be pointed out that in thus abandoning temporarily the true base-line we have no longer an absolute reference point for our optical measurements, and in particular, that it is impossible to make measurements either of absolute refractive index or of absolute refraction gradient in the cell. This means that we cannot compare directly the refractive index of the solution which separates above with that of the inorganic solution in which the protein is dispersed, which we would wish to do in order to verify the absence of so-called non-centrifugible matter. Neither is it possible to compare the refractive index of the solution below the boundary with that of the original protein solution in order to verify the absence of any molecules which might be sedimenting in advance of the protein. In both these cases, however, it is very unlikely that such material would be present in the cell without giving rise to irregularities on the base-line of the curve or without causing it to slope. We have indeed found, especially with globulin solutions, base-line irregularities of this nature, and we have always been able to confirm indirectly the presence of contaminating matter in these cases by comparing the calculated value of $n_1 - n_0$ with the measured value of the total protein refraction increment after dialysis. The difference between the two represents the amount of colloidal matter which is retained in the dialyser and which nevertheless does not appear in the apparent area of the diffusion curve.

The error involved in the sedimentation velocity measurements in using the apparent base-line instead of the true base-line is negligible.

(*d*) *The measurement of refraction increment.* Before each experiment the protein solution is dialysed against 1 % sodium chloride or Ringer solution until ionic equilibrium is reached, and the refractive indices of the solution and its dialysate are then measured. With the high concentrations of protein which we have used, and notwithstanding the relatively high concentration of diffusible electrolytes, considerable inequality in the distribution of diffusible ions is present at equilibrium such as is capable of giving rise to appreciable osmotic pressure effects. Since, however, the refractivity of one molecule of albumin or globulin is so much greater than the corresponding value for sodium chloride (more than 1000 times) the effect on the refraction increment is very small. Adair and Robinson [1930, 1], in a series of experiments on horse serum albumin using concentrations up to 10 g. per 100 ml. of solution in $M/15$ phosphate buffer at p_H 7·4, found the effect of the uneven distribution of diffusible ions to be within the limits of their experimental error, *viz.* 3 %. We have always used higher concentrations of diffusible electrolytes than $M/15$ and p_H values usually less than 7·4, so that the effect in our case must be even smaller. In calculating protein concentrations from these refractometric measurements we have used Adair and Robinson's values for the specific refraction increments of horse serum albumin and globulin, *viz.* 0·00183 and 0·00186 respectively. These are corrected values and we have not endeavoured to apply to our measurements any corrections for Donnan effect or the volume of the protein molecules. Our concentration values may therefore be in error, but by not more than 3 %. For the total protein of horse serum we have assumed a mean value, *viz.* 0·001845.

In the process of sedimentation a protein boundary is set up at which the same uneven distribution of electrolytes must exist, and which, so far as we know, is subject in every way to the same Donnan considerations as the boundary at the collodion bag in the preliminary dialysis [*cf.* Tiselius, 1926]. We are, therefore, strictly justified, subject to certain considerations governing the conditions under which the two measurements are made, in comparing directly the refraction increment from measurements of the refractive indices of the solution and its dialysate with the value obtained from the sedimentation diagram.

With regard to the conditions of measurement it will be seen that the value for $n_1 - n_0$ which is measured with the refractometer is for a wave-length in the region of $590 m\mu$ and at room temperature and atmospheric pressure. From the ultracentrifugal data, on the other hand, we compute $n_1 - n_0$ for the $366 m\mu$ mercury line, at a cell temperature which varies between 30° and 36° and under a hydrostatic pressure of up to 300 atmospheres. The writer has measured the refraction increment of serum albumin over the range 15° to 30° and has found the maximum change to be less than 1 %, so that this factor can be neglected. The pressure factor may be neglected also since the hydrostatic pressure inside the centrifuge cell varies from about 300 atmospheres at the bottom to practically zero at the meniscus, and there is no evidence of the calculated values for $n_1 - n_0$ being significantly different at the bottom of the cell and at the top. It is not possible to neglect the wave-length factor, however. Pedersen and Andersson have recently undertaken an investigation of the variation of the specific refraction increments of various proteins and inorganic salts with the wave-length of the light used, and I am greatly indebted to them for permission to give here some of their preliminary results. They have used a differential prism apparatus arranged for photographic registration of the undeviated and refracted beams. The values in Table I are calculated relative to Adair and Robinson's values for horse serum albumin and globulin. They were obtained in the examination of various preparations of horse serum proteins made by Pedersen and McFarlane according to the technique which will be described later in this paper. Some of the albumin preparations had been electrodialysed and even dried and redissolved, but the agreement between all values for the same wave-length was always within 1 %. The solutions were examined at 20° with the dialysate (water, 1 % sodium chloride or Ringer solution) in the other compartment of the prism. These experiments of Pedersen and Andersson are still in progress and may lead to the publication of new absolute values for α_{albumin} and α_{globulin}, but there is no reason to expect that further investigation will lead to any change in the relative values at different wave-lengths, and in this particular case it is only the relative values which matter. It will be seen that the value for α at $366 m\mu$ is greater than the value at $589 m\mu$ by 0·00015 in the case of albumin, and 0·00016 in the case of globulin. We have,

Table I. *The specific refraction increments* (α) *of horse serum albumin and globulin at different wave-lengths* (*Pedersen and Andersson*).

Wave-length $m\mu$	α_{albumin}	α_{globulin}
366	0·00198	0·00202
436	0·00190	0·00195
546	0·00185	0·00187
579	0·00183	0·00186
589	0·00183	0·00186
656	0·00179	0·00182

therefore, corrected all our values for $n_1 - n_0$ obtained by measurements either with the dipping refractometer, or the Pulfrich refractometer using the sodium D line, to the wave-length 366 mμ by means of the following relationship:

$$n_1 - n_0 \text{ (measured at } 590\,m\mu) = [n_1 - n_0 \text{ (measured at } 366\,m\mu)] \times 1{\cdot}08.$$

This holds with sufficient accuracy both for horse serum albumin and globulin, and we assume it to hold also for the total protein of horse serum.

It would, of course, have been a more direct procedure to use light of the same wave-length for measuring the refractive indices of solution and dialysate and for photographing the scale. Unfortunately, the technique for measuring refractive index in invisible, or poorly visible, regions of the spectrum is not nearly so convenient as with easily visible light, and on the other hand, the line at 366 mμ is much to be preferred for taking centrifuge photographs. It is conveniently present in the mercury arc spectrum in great intensity and almost monochromatic filters are available for its isolation; it is not absorbed to any appreciable degree by most proteins, and it lies in a spectral region in which photographic plates are highly sensitive. While it is possible to use lines in the green or red regions, in general the photographs with these do not show the same degree of contrast as with the mercury line at 366 mμ, and we have, therefore, preferred to use this line throughout and to apply the correction factor given above.

(e) *The measurement of "diffusion" constants.* The diffusion constant may be calculated in various ways from measurements taken from the sedimentation diffusion curve [Lamm, 1928; 1929]. There are, however, a number of factors which reduce materially the accuracy with which diffusion coefficients may be thus obtained from centrifugal data. The exact time at which the diffusion process starts is not known and is almost certainly variable between experiments according to the degree of convectional disturbance at the meniscus during the initial acceleration period. Whereas in an ideal diffusion experiment with proteins extending usually over a number of days it is possible to eliminate the unknown starting time between the equations of two exposures [*e.g.* see Tiselius and Gross, 1934], this cannot be done here with any degree of accuracy because of the very short time during which the diffusion process may proceed and because the diffusing boundary is sedimenting in a cell the walls of which are not parallel. Also, it is not possible to have the temperature of the diffusing solution the same in all experiments. Finally, in the case of protein solutions more concentrated than about 0·5 % the sedimentation velocity is markedly influenced by the protein concentration. This means that as the protein molecules at the boundary diffuse into the supernatant fluid they enter a region of diminished protein concentration in which their sedimentation velocity is increased. The effect of the centrifugal force, therefore, is to cause a "sharpening" of the boundary in opposition to the natural process of diffusion. This sharpening effect will be slightly greater at the bottom of the cell than at the top owing to the increase in sedimentation velocity as we proceed away from the centre of rotation. As will be shown later, it is even possible, with undiluted sera and concentrated globulin solutions, to have the diffusion process so completely counteracted by the differential sedimentation that the boundary sediments to the bottom of the cell with an apparent decrease in the breadth of the diffusion area.

Even a very approximate idea of the extent of "spreading" or "blurring" of the boundary may be of some value, however. Where we are concerned with a mixture of two or more proteins differing so little in molecular weight that a separation of the maxima cannot be obtained with the centrifugal forces available, or with a protein contaminated with numerous molecules slightly larger and slightly smaller than its own (a state of affairs which we have reason to believe exists in certain circumstances), then the only evidence that we are not dealing with a monodisperse protein lies in an abnormal spreading of the boundary. We have therefore endeavoured in this work to calculate a value for this in each case. Now it is clear from the foregoing that we are concerned with a composite effect in which the most that may be said meantime is that the process of diffusion is, in general, a major influence. For this reason, and in the absence of any complete theoretical treatment of the phenomenon, we propose to apply to our concentrated solutions the recognised methods of calculating diffusion coefficients in dilute solutions in the centrifuge cell and to call the resulting figure the spreading coefficient. In doing so we wish it to be understood that spreading coefficients are purely arbitrary measures of the apparent diffusion at a boundary which is sedimenting under non-ideal conditions, and that they may only be compared with each other under strictly comparable conditions of sedimentation. In a private communication Lamm has given the following equation for an ideal diffusion process

$$K.t=\frac{A^2}{Z^2_{\max}}\cdot\frac{1}{4\pi} \qquad \text{......(7)},$$

where K is the diffusion coefficient, t is the time of diffusion, A is the area of the diffusion curve at time t, and $Z_{\text{max.}}$ is the height of the curve. Therefore, for any two exposures, at times t_a and t_b, we have

$$K(t_a-t_b)=\frac{1}{4\pi}\left[\frac{A_a^2}{Z^2_{a\max}}-\frac{A_b^2}{Z^2_{b\max}}\right] \qquad \text{......(8)}.$$

This equation is used throughout to calculate the spreading coefficient. The exposures are chosen as far as possible the second from the beginning and the second from the end of the run. Errors arising in the calculation of individual boundary areas may give rise to large errors in the spreading coefficient because in equation (5) we are concerned with the difference between the squares of the areas. Now the value of each boundary area multiplied by Svedberg and Rinde's factor $(x/x_0)^2$ [1924] is a constant independent of the time at which the exposure was taken. We have, therefore, avoided the above source of error by obtaining firstly an average value for $A\,(x/x_0)^2$ over all exposures and dividing this by $(x_a/x_0)^2$ and $(x_b/x_0)^2$ to obtain the values for A_a and A_b respectively. The x values are usually obtainable with a much higher degree of accuracy than the A values.

GENERAL EXPERIMENTAL TECHNIQUE.

Fig. 1 shows schematically the optical system fitted to the high-speed oil turbine centrifuge which was used throughout this work. The scale and its associated projection lens are mounted together in fixed relationship on a metal base which slides on an optical bench. The position, in relation to a fixed point on the metal base, and the size of the scale image were first determined by photographic means using the mercury line at 366$m\mu$ and allowing for the presence of the quartz windows in the centrifuge housing, but neglecting the effect of the rarified hydrogen atmosphere inside the centrifuge. The optical bench was then graduated in terms of the distance from the scale image to the mid-plane of the rotor (or centre of cell). By means of a fine screw adjustment the scale-lens combination could be set at any position on the bench and the corresponding distance from image to centre of cell read off to 0·1 mm. In addition to enabling much smaller scale distances to be used, this arrangement offers a number of valuable practical advantages over the original method in which the scale was fixed inside a steel tube in the centrifuge housing. For instance, in the course of an experiment using the refraction method the scale-lens combination may be temporarily removed from the optical path and a light-absorption exposure taken in order to measure the concentration distribution of any light-absorbing substance in the cell. Also, since the scale position can be altered during an experiment it is not necessary to know beforehand the value of b which, in association with the boundary gradient to be expected in the cell, will give scale photographs with the requisite degree of definition. The determination of this scale position was formerly a matter requiring some experience. Now it is only necessary to view the scale from the camera by means of a hand lens immediately before the first photograph is to be taken and to judge with the eye which scale position gives the maximum line displacement in the diffusion area consistent with good definition of the displaced lines. Where a mixture of two or more proteins is under examination, one of which is present in much smaller amount than the other, it is also possible, when sedimentation has proceeded long enough to effect a clear separation of the two diffusion boundaries, to photograph the line displacement due to each boundary separately, using the best scale position for each photograph. In this way, where mixtures are concerned, the analytical sensitivity of the method may be increased many times.

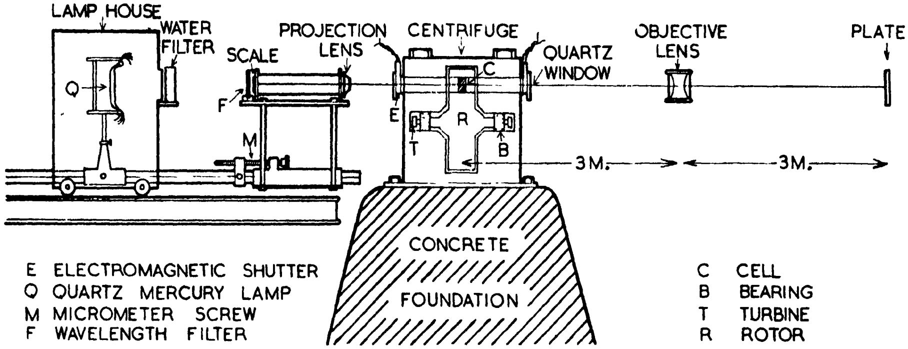

Fig. 1. Showing diagrammatically the new optical system fitted to the high-speed oil turbine centrifuge, which was used throughout this work.

Throughout the work to be described in this and following papers efforts were made to employ as small a number of centrifuge cells as possible and to run the centrifuge at a speed in the neighbourhood of 60,000 r.p.m., which corresponds to a mean force of 255,000 times gravity in the cell. In a preliminary run at 60,000 r.p.m. with each cell filled with water two photographs were obtained for each of a series of scale positions, 3 mm. between each—one just after starting the centrifuge and the other on reaching full speed. The latter served as the standard undeviated scale for that particular scale position and cell, and the former was used to obtain the photographic enlargement factor. The mercury line at $366 m\mu$ was used in all cases and was isolated by means of a nickel oxide glass filter. Imperial Process plates were used in the earlier work but later plates made by G. Cramer and Co., St Louis, Mo., U.S.A., were used, which, although requiring longer exposures, had the advantage of giving better contrast.

According to the concentration of protein, a period of 1–3 hours after reaching 60,000 r.p.m. was required to produce complete sedimentation of albumin and globulin. During this time six to eight photographs were taken at equally spaced intervals and with suitably chosen stops over the objective lens according to the degree of definition of the displaced scale lines. The temperature inside the cell at reaching full speed was usually 28–32° and did not rise by more than 4° during the whole run. The height of the column of solution in the cell was 10–11 mm. and the solution was always covered by a layer of paraffin to prevent evaporation into the rarified hydrogen atmosphere in the centrifuge housing.

The general plan of the investigation was to prepare and centrifuge separately solutions of purified albumin and globulin in various concentrations and then to examine a series of mixtures of the two in various proportions. The preliminary refractive index measurements after dialysis were made at first with the Zeiss dipping refractometer, but subsequently with the Pulfrich refractometer using the "difference" prism and the sodium D line as light source. The two methods of measurement are in essential agreement here but the latter is more convenient in practice, and in later work with highly coloured untreated serum, the use of monochromatic light was found strictly desirable. The hydrogen ion concentrations were measured by means of the glass electrode using a valve potentiometer already described by the writer [1932; 1933, 1, 2]. A few experiments—particularly with dilute solutions –in which the apparent base-line did not run parallel to the x-axis, or the horizontal limbs of the curve differed markedly in height above the x-axis (for reasons probably associated with the establishment of convection gradients in the cell), were discarded and are not reported. But, for the great majority of runs, the apparent base-line was satisfactory and enabled an accurate determination of A and the position of the maximum (corresponding to the position of the "ideal" sedimentation boundary) to be made. In the case of mixtures of two proteins the component curve with the most clearly defined maximum was completed by symmetry first and the other constructed by a process of graphical subtraction from the original.

Methods of preparing serum proteins.

Preparation of horse serum albumin. To fresh horse serum an equal volume of saturated ammonium sulphate was added, and after standing overnight the supernatant fluid was filtered off, treated with $N/10$ sulphuric acid in half-saturated ammonium sulphate to slight permanent cloudiness and given 24 hours to crystallise. The crystals were dissolved in water and recrystallisation induced by half-saturation with ammonium sulphate and careful addition of M acetic acid and M sodium acetate according to the procedure described by Young [1922]. The preparation was recrystallised four times in all and washed between each crystallisation with a solution of approximately the same inorganic composition as the mother-liquor. The final aqueous solution was dialysed and then electrodialysed at 440 v. until the current density was steady at 0·5 ma. per sq. cm. Finally the solution was made quite clear by centrifuging in an ordinary laboratory centrifuge at 2000 r.p.m. and filled into a number of small sterile bottles. The solution had a pale amber colour and was quite odourless.

Preparation of horse serum globulin. The globulin precipitate (above) was dissolved from the filter-paper with water and reprecipitated by half-saturating the solution with ammonium sulphate. The precipitate was washed with half-saturated ammonium sulphate. The precipitation and washing were repeated three times and the final solution dialysed against frequent changes of Ringer solution and under pressure until the product was quite free of sulphate ions and had a concentration of approximately 5 % globulin. This solution was centrifuged clear and stored in the same way as the albumin. The solution was pale blue, faintly opalescent and also quite odourless.

DESCRIPTION AND RESULTS OF A TYPICAL EXPERIMENT.

A solution of horse serum albumin after prolonged dialysis against Ringer had a refractive index of 1·34193, and the dialysate 1·33500. Therefore

$$n_1 - n_0 = 6{\cdot}93 \,.\, 10^{-3},$$

and the concentration of albumin is $\frac{0{\cdot}00693}{0{\cdot}00183}$, or 3·79 g. per 100 ml. solution. The p_H of solution (measured) = 5·26. The solution was placed in a centrifuge cell of thickness (a) 1·5 mm. and with quartz end plates 5 mm. thick. The scale distance was 4·0 cm. Refractive index of crystalline quartz = 1·56.

b (optical distance from scale to centre of cell)

$$= 4{\cdot}0 - \left(0{\cdot}5 + \frac{0{\cdot}15}{2}\right) + \frac{0{\cdot}5}{1{\cdot}56} + \frac{0{\cdot}15}{2 \times 1{\cdot}34} = +3{\cdot}80 \text{ cm.}$$

The centrifuge was started and reached 60,000 r.p.m. in 30 mins. The first exposure was taken 20 mins. later and thereafter five additional exposures were taken at intervals of approximately 10 mins. The scale photograph of each exposure was then measured in the comparator, the line displacements were obtained by subtraction, and the curve showing photographic displacement of each line against its displaced position was plotted. Figs. 2 *a* and 2 *b* show the curves corresponding to the second and fifth exposures. The high degree of symmetry of these curves and the almost complete absence of irregularities of the base-line testify in large measure to the monodispersity of the serum

Table II. *Results of a typical experiment with horse serum albumin.*

Average value (excluding the first) of $(n_1 - n_0)$ $= 6{\cdot}23 \,.\, 10^{-3}$,
Average value (excluding the first) of $S_{W,20}$ $= 3{\cdot}56 \,.\, 10^{-13}$ cm./sec.,
Spreading coeff. (calculated between Exps. 2 and 5) $= 1{\cdot}6 \,.\, 10^{-7}$ cm.^{2}/sec.

* An abnormally large area in the first exposure occurred frequently throughout the present series of experiments. It may be due to optical effects in the neighbourhood of the meniscus, or to the fact that separation from the meniscus was not complete when the photograph was taken. On the other hand, a more probable explanation is that the preparation contains some polydisperse protein molecules which at the beginning of sedimentation give rise to a relatively sharp boundary, but in the later stages the molecules are so separated by the centrifugal field as to give rise to a very diffuse boundary the curve of which merges with the apparent base-line. While it would be of some interest to know in each experiment the maximum area of the sedimentation curve in the early part of the run, we cannot record this because we do not know when to take the photograph, and also very early photographs are often impossible because the gradient at the meniscus is so great. We must, therefore, confine our measurements to those exposures for which the values of the protein refraction increment are constant, and in the process of averaging the refraction increment values for one complete experiment we have accordingly omitted the value for the first exposure where this was clearly abnormal.

albumin preparation. The abscissa of the vertical axis of symmetry of each curve was read off and from it the distance (x) of the boundary from the centre of rotation was calculated. The distance (x_0) of the meniscus from the centre of rotation was similarly calculated and the value of the sedimentation constant obtained by means of equations (4) and (5). Finally, the area of each curve on the graph paper was obtained by counting the equivalent millimetre squares and the value of $n_1 - n_0$ calculated using equation (3). Table II shows the results of this experiment.

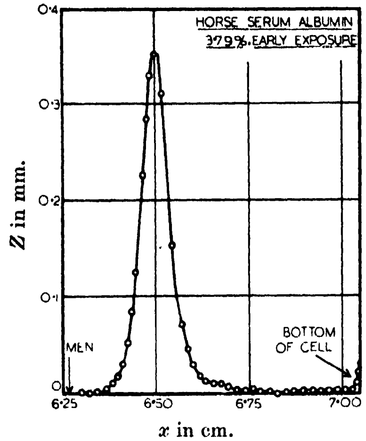

Fig. 2 (a). $a = 1{\cdot}50$ mm.; $b = 3{\cdot}80$ cm. Centrifugal force = 255,000 times gravity. Exposure taken 30 mins. after reaching full speed.

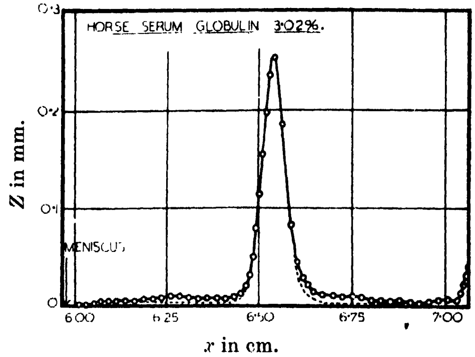

Fig. 2 (c). $a = 2{\cdot}00$ mm.; $b = 2{\cdot}41$ cm. Centrifugal force = 210,000 times gravity. Exposure taken 46 mins. after reaching full speed.

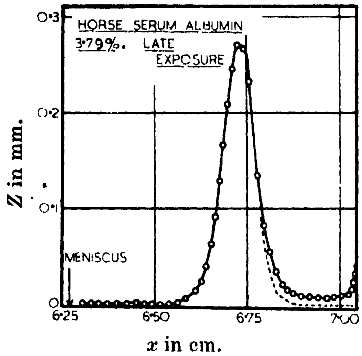

Fig. 2 (b). From same experiment as (a). Exposure taken 60 mins. after reaching full speed.

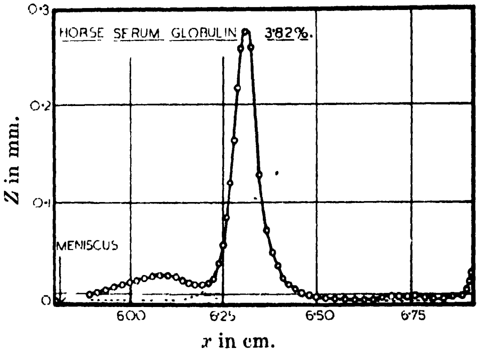

Fig. 2 (d). $a = 2{\cdot}00$ mm.; $b = 2{\cdot}56$ cm. Centrifugal force = 250,000 times gravity. Exposure taken 55 mins. after reaching full speed.

Fig. 2. *Ultracentrifugal sedimentation diagrams obtained by the refraction method.* The abscissae (x) represent distances from the centre of rotation, and the ordinates (Z) represent the scale-line displacements which are proportional to the gradient of refractive index (dn/dx). A comparison of (a) and (b), from the same experiment, shows how the curve moves parallel with the x-axis during the run, and also shows the symmetry and regularity typical of the albumin curves. A comparison of (c) and (d) shows the differences which may be expected in the sedimentation diagrams of different globulin preparations.

DISCUSSIONS OF RESULTS OBTAINED WITH ALBUMIN AND GLOBULIN SOLUTIONS.

In Table III are presented the results obtained from the investigation of various horse serum albumin and globulin solutions. Preparations A2, A3, A4 are all dilutions of the same stock solution of albumin, and the curves all show the same degree of symmetry and absence of base-line irregularities as are shown in Figs. 2 *a* and 2 *b* (from preparation A2). Preparation A1 is also from the same stock solution which, in this case, had been preserved for 6 months in the electrolyte-free state and adjusted to 1 % NaCl just before the experiment. Slight base-line irregularities were present here, suggesting the presence of about 2 % of larger molecules. Also, the value of the sedimentation constant is unexpectedly high. In Fig. 2 *c* is shown one of the curves obtained in the investigation of the globulin preparation G4. The irregularity of the base-line of this curve was also present in the curves of G2, G3, G5 and G6, which are all dilutions of the same stock solution. By constructing the symmetrical curve (shown in dotted lines) it is estimated in this case that the preparation is only 90 % monodisperse, the remaining 10 % consisting of molecules both larger and smaller than the principal molecule. Preparation G1 is from a different stock solution prepared in exactly the same way as the stock solutions of G2, G3 *etc.*, but from a different horse serum. Fig. 2 *d* shows a late exposure from this experiment and it will be seen that the preparation is contaminated with about 20 % of a lighter molecule, presumably albumin. There seems to be no explanation of this other than a possible difference in the constitution of the parent horse serum in the two cases. Data to be presented in a subsequent paper relative to a variety of globulin preparations from human, horse and cow serum will show these preparations to be contaminated to a variable extent with larger or smaller molecules. It does not seem to be possible, merely by a process of repeated precipitation and washing, to obtain a globulin preparation with the degree of monodispersity shown by recrystallised albumin. This observation is one of considerable significance because there has been in the past, and still exists, considerable variation in the physico-chemical properties of serum globulin as recorded by different observers—particularly in regard to solubility, osmotic pressure and isoelectric point. In so far as the methods adopted to measure

these properties are only capable of giving a statistical mean result for all the molecules present, the lack of agreement among different observers may be explained by variations in the composition of different globulin preparations, such as we have found here by ultracentrifugal analysis.

The marked diminution of sedimentation constant with increasing concentration of albumin and globulin will be at once evident. Also at globulin concentrations greater than 3 % practically no active process of spreading at the boundary can be detected.

The column of Table III headed "% diff." expresses the difference between the measured and calculated values of $n_1 - n_0$ as a percentage of the measured values. These values show an average loss of approximately 15 % over all the experiments, and a variation of individual values about the mean "% diff." of never more than ±5 %. This systematic discrepancy of −15 % is difficult to explain. It may be due to basing all our calculations on the apparent instead of the true base-line. If so, it is probable that all our albumin and globulin preparations contain about 15 % of protein which is so completely heterodisperse as not to affect the base-line of the curve. Another source of error, but only in the experiments with the smaller cells, lies in the fact that we cannot measure the thickness of the cell to less than 0·1 mm. because periodical tightening of the assembly rings, which is necessary to prevent leakage, causes small changes in the distance apart of the plates, and also the plates are not absolutely parallel. Changes in the refractive index of the quartz plates under high pressure may be a contributory cause. It is conceivable, also, that the sedimenting assymetrical protein molecules are orientated in a particular plane in relation to the light beam and thus show an abnormal refractivity.

More important, however, than the extent of the discrepancy between measured and calculated $n_1 - n_0$ is the fact that the error appears to be almost entirely systematic and reproducible. It is considered that the agreement of the individual results among themselves, extending, as the experiments do, over a wide range of protein concentration, affords strong support for the validity of Lamm's fundamental equations and demonstrates the practicability of estimating protein concentrations from the scale photographs. When one considers the practical difficulties which beset these measurements of protein refraction increment, using 0·1–0·5 ml. of solution inside an optically imperfect cell and rotating at a speed of 60,000 r.p.m., the whole being observed from a minimum distance of 6 metres, it will be appreciated that the figure of ±5 % for the error in individual experiments is a very satisfactory one. When, further, one considers the possibilities which are presented to estimate the molecular fractions in untreated native protein mixtures and mixtures of non-absorbing substances, even with an error of ±5 %, it will be realised also what considerable satisfaction this substantiation of Lamm's equations gives rise to.

EXPERIMENTS WITH MIXTURES OF ALBUMIN AND GLOBULIN.

The general scheme underlying the preparation and investigation of these mixtures was as follows. A fresh horse serum (undiluted horse serum 1) was examined in the ultracentrifuge without previous treatment of any kind. The curve obtained (Fig. 3 *a*) showed the presence of two molecules corresponding in sedimentation constants approximately to albumin and globulin. The "albumin" component curve is unsymmetrical and represents in its total area 79·1 % of the total protein. The "globulin" curve, representing 20·9 %, is quite sym-

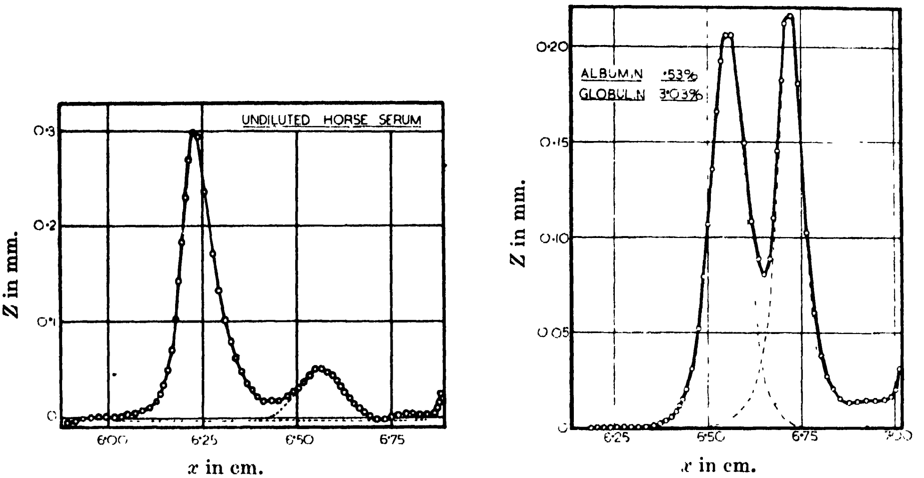

Fig. 3 (*a*). $a = 2{\cdot}00$ mm.; $b = 2{\cdot}14$ cm. Centrifugal force = 235,000 times gravity. Exposure taken 117 mins. after reaching full speed.

Fig. 3 (*c*). $a = 2{\cdot}00$ mm.; $b = 3{\cdot}62$ cm. Centrifugal force = 250,000 times gravity. Exposure taken 57 mins. after reaching full speed.

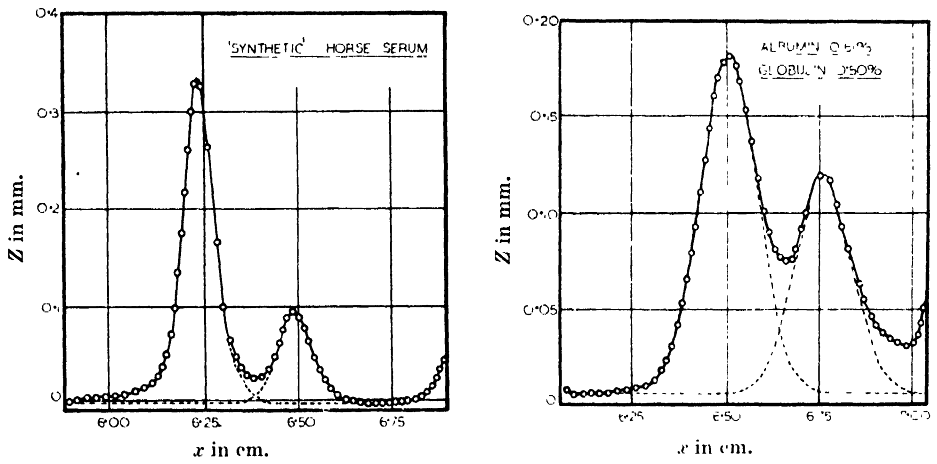

Fig. 3 (*b*). $a = 2{\cdot}00$ mm.; $b = 2{\cdot}26$ cm. Centrifugal force = 250,000 times gravity. Exposure taken 92 mins. after reaching full speed.

Fig. 3 (*d*). $a = 3{\cdot}0$ mm.; $b = 11{\cdot}10$ cm. Centrifugal force = 235,000 times gravity. Exposure taken 60 mins. after reaching full speed.

Fig. 3. *Ultracentrifugal sedimentation diagrams by the refraction method showing the dilution effect in serum and albumin-globulin mixtures.* (*a*) shows the surprisingly small amount of "globulin" present in undiluted horse serum; (*b*) is from an experiment using a mixture of albumin and globulin, both prepared from the serum used in (*a*) and subjected to the usual purification procedures. They were mixed together in the same ratio and approximately the same concentration as in the original serum; (*c*) is from mixture 6, containing 1·53 g. albumin/100 ml. and 3·03 g. globulin/100 ml.; and (*d*) is from mixture 4, containing 0·61 g. albumin/100 ml. and 0·50 g. globulin/100 ml.

metrical, and the base-line is free from irregularities. An analysis of the serum by precipitation with ammonium sulphate gave 51 % albumin and 49 % globulin. The original serum was then used to prepare recrystallised albumin and reprecipitated globulin by methods identical with those already described

(p. 416), and a mixture of the two preparations in the same ratio and of very roughly the same total protein concentration as in the original serum was made up ("synthetic" horse serum 1). Here again the proportion of "albumin" was found to be abnormally high (72·7 %) (*cf.* Fig. 3 *b*). One or two tentative experiments were now tried to suggest a reason for the abnormal albumin/globulin ratio and in one of these the original serum was examined after dilution with 3 volumes of 1 % NaCl. It was noticed that the ratio had now fallen very considerably. Mixtures of albumin and globulin covering a wide range of concentrations were then made up using the same stock albumin and globulin solutions as had been used for A2, A3, A4, and G2, G3, G4, G5 and G6 (Table III) and the behaviour of which on dilution had, therefore, been examined in the ultracentrifuge. The results are shown in Table IV.

Discussion of results.

(*a*) *Sedimentation constants.* The values for $S_{W,20}$ for the "albumin" fraction show a marked concentration effect similar to that shown by pure serum albumin. Also, if we plot the "albumin" values against the calculated value of n_1-n_0 (column D), and show on the same diagram the same values for pure albumin (from Table III) it appears within the rather wide limits of comparability that the sedimentation velocity of the "albumin" fraction in a concentrated mixture is the same as the sedimentation velocity of a pure solution of albumin of the same concentration. In the case of the "globulin" values a marked concentration effect is present, and also the values from the concentrated mixtures as a whole are uniformly smaller than the values for the same concentration of globulin in pure solution. It is impossible to say whether this effect is entirely due to the viscosity and density of the albumin solution in which the globulin molecules are sedimenting, or whether any additional changes in the shape and dimensions of the "globulin" molecule have occurred. It is only at concentrations less than 0·5 % of each that the two proteins in a mixture appear to sediment independently of each other.

(*b*) *Refraction increment.* The figures in the column headed "'% diff.' (total n_1-n_0)" represent the difference between the measured and calculated values of the total protein refraction increment of the mixture, expressed again as a percentage of the former. The average difference is −12·4 %, and the individual figures may be represented by the approximate formula

$$n_1-n_0\ (\text{measured})=n_1-n_0\ (\text{calculated})-(13\ \%\pm 9\ \%).$$

The systematic error agrees well with the value found in the experiments reported in Table III. The range of individual variation in the mixtures is, however, greater than in the case of the pure solutions. This is probably due to the greater difficulty in locating accurately the apparent base-line where, as in the mixtures, only comparatively short horizontal portions of curve can be seen. It is to be noted also that, in spite of the fact that the original globulin of these mixtures is only approximately 90 % monodisperse, the mixtures appear practically free from base-line irregularities (*cf.* Figs. 3 *c* and 3 *d*). No explanation can be offered of this. In view of the agreement between the average "% diff." values of Tables III and IV we conclude that when albumin and globulin are mixed together the total concentration of the added proteins is represented by the sum of the areas of the component curves in the diagram of the mixture. This simple conclusion assumes its full significance when we consider the refractive equivalents of the individual components in the diagram of the mixture.

A = Albumin. G = Globulin.

It is at once apparent in all the more concentrated mixtures that the concentration of the "globulin" component is much less than corresponds to the globulin added, and that the concentration of the "albumin" is correspondingly much greater. In an attempt to express equitably the relative loss of globulin and increase of albumin we have firstly divided the discrepancy between measured and calculated total $n_1 - n_0$ between the two components in the ratio in which they were originally added together and thus we obtain a "theoretically expected" value for the refraction equivalent of the area of each component curve in the diagram (*cf.* column headed "theoretically expected" individual $n_1 - n_0$). The difference between this value and the value calculated for the refraction equivalent of the actual area of the component curve, expressed as a percentage of the former, is shown under "'% diff.' (individual $n_1 - n_0$)". A consideration of the figures in this column leads to the following general conclusions. The "albumin"/"globulin" ratio is always shifted in the direction of increased "albumin". The extent of shift increases markedly with increasing concentration of total protein and is particularly marked with high relative concentrations of globulin (*cf.* mixture 6, Fig. 3 *c*). The phenomenon seems to appear only at concentrations greater than 0·25 % total protein. From a comparison of mixtures 2 and 3 it is deduced that hydrogen ion concentration and the nature of the inorganic ions present seem to have little, if any, effect. The results suffice to demonstrate the existence in mixtures of albumin and globulin of a type of molecular dimensional equilibrium the nature of which is primarily dependent on the concentrations in which the two proteins are present. Before discussing some theoretical aspects of the phenomenon we may consider briefly the boundary spreading coefficients shown also in Table IV.

(*c*) *Boundary spreading coefficients.* In Fig. 4 we have plotted the value of the spreading coefficients of the "albumin" boundaries in each mixture against the calculated values of $n_1 - n_0$ for the same fraction. A mean line has been drawn through the points and its course demonstrates the marked suppression of boundary diffusion which takes place at high protein concentrations and under the roughly standardised sedimentation conditions of our experiments. We have also shown on the same diagram as ringed points the values from Table III for the four albumin solutions, and it will be seen that these points lie tolerably well on the curve. It appears, therefore, that the degree of spreading at the boundary of the "albumin" fraction in a mixture is not significantly greater than the degree of spreading at a sedimenting boundary of pure albumin

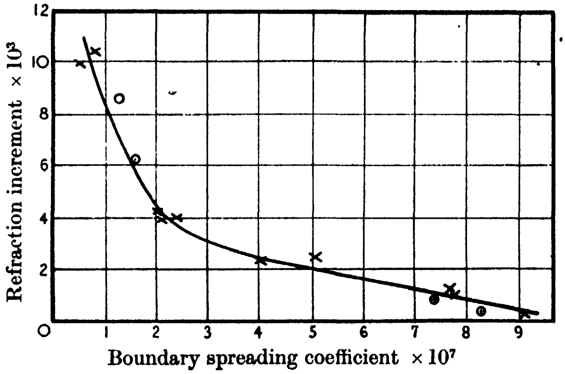

Fig. 4.

of the same concentration. This we consider to be strong contributory evidence in favour of the "albumin" fraction in a mixture being dimensionally homogeneous. We can say nothing with regard to the homogeneity of the globulin fractions because the spreading coefficients cannot be compared with each other owing to the variable effect of the albumin concentration.

GENERAL DISCUSSION.

In the first place we may summarise many of the above data by the statement that only when the total protein concentration is less than 0·25 % does a solution of albumin and globulin behave ideally. At all higher concentrations the diffusion, sedimentation and relative concentration of the component proteins are abnormal.

Throughout this work we have referred consistently, when speaking of the mixtures, to the "albumin" and "globulin" components. This terminology is merely a matter of convenience since the available data are insufficient to define accurately the true nature of either molecular fraction. It can be said from a consideration of the sedimentation constants that the average molecular weight of the lighter fraction corresponds in all mixtures approximately to that of albumin, and from considerations of the degree of boundary spreading, that the fraction is probably homogeneous. On the other hand, in concentrated mixtures it is present in much greater amount than the monodisperse albumin which may be obtained from the same mixture by treatment with ammonium sulphate. With regard to the heavier fraction we can only say that in diluted mixtures it has all the characteristics of salted-out globulin and in concentrated mixtures it may still be the same substance. In the latter case, however, it is present in amount much less than the practically monodisperse globulin which may be obtained by precipitation.

The question has often been asked whether in a solution of two proteins of different isoelectric points mutual neutralisation of the electrical charges on the colloidal particles may not take place, such as occurs with lyophobic colloids of opposite charge and leads to precipitation. Hardy [1905–06] says "The proteids of serum are electrically inactive. Neither the whole nor any fraction moves in a field. It is not possible to detect a trace of 'ionic' protein. Dialysis or dilution disturbs the equilibrium and 'ionic' globulin appears...". For some reason Hardy's views seem to have been largely neglected. Adair and Robinson [1930, 2], however, say that it is possible that Hardy failed to detect any ionic globulin because of the low ratio of the charge to the mass and the effects of the ion atmosphere. Tiselius [1930] using a considerably more accurate cataphoresis technique than Hardy has examined various artificial mixtures of egg albumin, Bence Jones protein, phycocyan, phycoerythrin and also some native mixtures and concludes that oppositely charged proteins can exist together in solution without influencing each other to any great extent. The concentrations of proteins examined by Tiselius were all less than 0·5 % and it is not possible with his method to examine solutions much stronger than this. The possibility of interaction between proteins at higher concentrations, such as we have been examining in the ultracentrifuge, therefore, still remains and indeed becomes more of a probability in view of Hardy's carefully executed, although somewhat crude, electrophoresis experiments. It is indeed difficult to visualise any other method by which albumin and globulin may influence each other, as they do in the above mixtures, than by virtue of their electric charges, and the fact that the p_H of the medium has, if any, a minor effect does not alter the possibility because the force operative in producing the union would be more a function of the difference between the isoelectric points than of the hydrogen ion concentration of the solution.

By whatever means the two molecules influence each other the important fact which is revealed in the above experiments remains, *viz.* that in some manner the interaction involves a reduction in the molecular size of part of the globulin to approximately the size of albumin. It is impossible to determine on the basis of the available data the real mechanism of this. We may say, however, that the work of Svedberg and collaborators in recent years on the structure of the protein molecule and on the p_H stability region of the proteins makes the idea of a reduction in the size of the globulin molecule, under the conditions with which we are dealing here, not at all such an improbability. When the molecules of both albumin and globulin at p_H values below 4 and above 9 disintegrate in a reversible manner into smaller molecular units [Svedberg and Sjögren, 1930] it is clearly a possibility that in circumstances which may cause an electrochemical union of albumin and globulin the same molecular dimensional forces may be operative and ensure that the resulting product has a molecular weight no greater than 68,000.

There are one or two interesting theoretical aspects of the phenomenon which we have described. If there exists in undiluted serum and concentrated mixtures of albumin and globulin a form of equilibrium between a low molecular fraction and a high molecular fraction, then in the process of centrifugal separation of the two a state of unstable equilibrium must exist. Globulin molecules ought to be continually produced in the solution between the two boundaries, and as these sediment more rapidly than the "albumin" molecules among which they originate, the net result ought to be a steady fall in the area of the "albumin" curve. This has never been found. We do not know, however, what order of velocity constant might be associated with the equilibrium reaction or with the process of aggregation by which the globulin is subsequently formed, and it is conceivable that more time than the centrifuge allows is required for an appreciable formation of globulin in the cell.

If we consider the state of affairs at the "globulin" boundary in undiluted serum it is by no means certain that the concentration of albumin is uniform here. It has been shown that when globulin sediments in a medium containing albumin the sedimentation velocity of the globulin is markedly diminished by the viscous effect of the albumin. It is possible, if not probable, that in the same circumstances the rapidly sedimenting globulin molecules exert a viscous traction on the albumin molecules to cause them to sediment more rapidly. If this should be the case more albumin would cross in unit time a unit cross sectional area in the lower ("globulin"+"albumin") part of the cell than in the middle ("albumin" only) part. The net effect would be again a steady diminution in the area of the "albumin" curve analogous to the effect of the increasing centrifugal force on the protein molecules as they sediment away from the centre of rotation.

As already stated, no such abnormal diminution of the area of the "albumin" curve has been recorded. Without some independent evidence of the existence and extent of such a viscous-attractive force it is, of course, impossible to have any exact idea of the concentration disturbance which it might be expected to give rise to. It is also possible that it might give rise to rather low values for the "globulin" areas by superimposing on the positive globulin concentration gradient a negative "albumin" gradient, but it is not conceivable that it could give rise to effects sufficiently great to furnish an explanation of the phenomenon described here. In addition, any apparent dilution of the "globulin" fraction due to an extraneous cause of this type would also represent a loss in the total protein represented in the sedimentation diagram, and this we know to be constant. Also, no concentration disturbance at the "globulin" boundary can explain the abnormally high concentration and apparent homogeneity of the "albumin" fraction. We can find no explanation for all the facts other than the one advanced here, *viz.* that we are concerned with a truly molecular phenomenon governed by some unknown form of interaction between albumin and globulin.

We have thought it wise to postpone to the end of this paper a consideration of the relationship which the results bear to those of Mutzenbecher, who preceded the writer in this field of work at Upsala. The first experiments which we made with the ultracentrifuge were designed to extend some of Mutzenbecher's experiments, and it was during the course of these experiments that we realised that the phenomenon of a shifting base-line, which was a continual source of trouble to Mutzenbecher, was, at least in part, of mechanical origin. Mutzenbecher believed that it was due to the presence in the solution of low-molecular products, and therefore based all his calculations on the true base-line or x-axis without, at the same time, observing all the technical precautions which Pedersen has shown to be necessary if this is done. Also, whereas the conclusions of the present paper are based on determinations of the individual refraction increment of each fraction in a mixture and depend crucially on the preliminary experimental verification of Lamm's relationships, Mutzenbecher, who had no such experimental verification to rely on, has based his conclusions entirely on calculations of the concentration ratio of the fractions. We believe that these, in the main, are the explanations of the different conclusions arrived at because it is clear that the experimental results in the two cases are in essential agreement.

Mutzenbecher has concluded that there exist in normal horse serum two fractions "identisch mit den rein darstellbaren Fraktionen Albumin und Globulin". We prefer to draw the conclusion that there exist in normal horse serum two fractions of very approximately the same molecular dimensional properties as isolated horse serum albumin and globulin, but considerations of the concentrations in which the two fractions are present suggest strongly that at least the lighter fraction cannot be identical from a chemical structural point of view with pure albumin.

SUMMARY.

1. It has been found possible by means of a modification of Lamm's refractive index method of following protein sedimentation in the ultracentrifuge to obtain satisfactory sedimentation photographs using very concentrated protein solutions.

2. It has been shown that recrystallised horse serum albumin in solution exists in a monodisperse state over a wide range of concentration. Reprecipitated horse serum globulin, on the other hand, has not been obtained in a completely monodisperse form, being always associated to a variable extent with molecules both larger and smaller than itself. It is suggested that much of the disagreement in the literature over the characteristic physico-chemical properties of globulin may be attributed to the variable composition of different preparations of globulin. The composition, from a molecular dimensional point of view, of a particular specimen of globulin remains sensibly the same over a wide range of concentration.

3. A sample of native horse serum, quite untreated in any way, has been examined in the ultracentrifuge and shown to contain two molecular fractions. The lighter fraction represents nearly 80 % of the total protein and the heavier fraction 20 %, despite the fact that by ordinary precipitation analysis the albumin/globulin ratio of the serum is approximately 1.

4. It has been found that on simple dilution of this horse serum the ratio of the two fractions obtained by ultracentrifugal analysis approaches the analytical value for the ratio of albumin to globulin.

5. A series of artificial mixtures of albumin and globulin has been investigated in the ultracentrifuge and it has been shown that only at very low concentrations does the mixture behave like an ideal solution. At all concentrations greater than 0·25 % of total protein the sedimentation constants, boundary spreading coefficients, and concentrations of the two fractions are abnormal. With increasing total concentration there is a steady change in the concentrations of the two fractions so that the lighter fraction always increases in amount and the heavier fraction decreases correspondingly—until the state of affairs present in the original serum is reproduced. The phenomenon is primarily a concentration effect and apparently reversible. The hydrogen ion concentration and nature of the salts in the solution appear to have little, if any, effect.

6. A consideration of the sedimentation rate and degree of spreading at the sedimenting boundaries in this series of mixtures indicates that the lighter species in a concentrated mixture has approximately the same molecular weight as albumin and appears to be homogeneous in the centrifugal field. It is only possible to obtain a very rough idea of the average molecular weight and homogeneity of the heavier species, and the most that the results are able to indicate is that this fraction may be identical with pure globulin.

7. The results indicate that it is not possible to regard the lighter molecular fraction in undiluted horse serum as identical with isolated horse serum albumin.

8. Throughout the work the opportunity has been taken to verify experimentally the basic equations of Lamm's refractive index method.

There will be reported in subsequent papers experiments which employ the new method to investigate the structure of the proteins in normal and pathological sera of various types. Throughout the whole of the work I have been greatly indebted to Prof. Svedberg for his inspiring interest and advice and for the innumerable facilities which he has readily placed at my disposal and which have made the research possible. It gives me the greatest pleasure also to express my gratitude to his assistants, in particular to Dr Pedersen and to Dr Lamm, for much kind help and valuable criticism.

The expenses of this investigation have been defrayed by grants from the Andersson Foundation, the Nobel Foundation and the Rockefeller Foundation.

XLIX. UNIMOLECULAR FILMS OF LECITHIN AND RELATED COMPOUNDS.

BY ARTHUR HUGHES.[1]

From the Colloid Science Laboratory, Cambridge.

(*Received December 23rd, 1934.*)

It is a significant fact that organic molecules such as lecithin, cholesterol and protein, which are known to occur in the membrane of a living cell are all molecules capable of forming unimolecular films at an air-liquid interface. The importance in this connection of the established work on unimolecular films of organic compounds has been realised by Leathes [1923; 1925] and Adam *et al.* [1926; 1928; 1929], who have studied films of lecithin and cholesterol on the surface of water. Their results demonstrated the essential difference between the typical loosely packed expanded film of lecithin and the close-packed condensed film of cholesterol and further indicated the power of cholesterol to bring about a closer packing of lecithin in a mixed film of the two substances.

Gorter and Grendel [1925; 1926] approached the problem from a different angle and showed that the amount of lipoid material in a typical living cell is sufficient to form approximately two molecular layers in the cell membrane.

No precise information has been forthcoming as to the orientation and chemical reactivity of these substances when present in the form of unimolecular films. In view of the fresh light that has been thrown on the physical structure and chemical reactions of molecules by the method of surface potentials [Schulman and Rideal, 1931; Fosbinder and Rideal, 1933], this technique has now been applied in conjunction with force/area measurements, to study the physical and chemical properties of the following compounds: tripalmitin, triolein, lecithin, lysolecithin and cholesterol. A preliminary investigation has also been made of composite films of the above substances with protein.

EXPERIMENTAL.

The surface potentiometer employed in the following work was essentially similar to that previously described by Schulman and Rideal [1931]. In Fig. 1 ΔV, the change in air-liquid potential difference due to the presence of the unimolecular film, is plotted against n, the number of molecules per sq. cm. of surface. The main characteristics of the films are given in Table I and refer to dilute NaCl solution at 17–20°. The two values of n, and the corresponding area per molecule (A), are given for the points where a homogeneous film is first formed on compression and where it finally collapses. The values for the resolved vertical component of the electric moment per molecule (μ) are calculated from the equation $\Delta V = 4\pi n \mu$, and are only relative values.

The limiting areas per molecule show good agreement in those cases previously studied by Adam *et al.* [1926; 1929] by force/area measurements. They find for cholesterol 40·8 sq. Å., for lecithin 114 sq. Å. and for triolein 135 sq. Å. (15°).

Tripalmitin, a typical close-packed condensed film, gives a high moment, due to the glyceride group, of $10{\cdot}0 . 10^{-19}$ E.S.U. which is constant during the small compression range of the film. Triolein, an expanded film with a much greater compression range, gives a slightly higher value of μ owing presumably to the presence of the weakly polar double bonds, but on compression the value approximates to that of tripalmitin. For cholesterol μ remains constant at $4{\cdot}2 . 10^{-19}$ E.S.U. during compression over its small range of about 3 sq. Å. The dipole moment is thus considerably smaller than for lecithin which gives an expanded film of the same type as triolein. μ for lecithin decreases on compression to a much greater extent than for lysolecithin probably owing to the absence of the unsaturated hydrocarbon chain from the latter. In comparing lecithin and lysolecithin the most significant feature is the area of surface occupied per hydro carbon chain, which is 58 sq. Å. for lecithin and 108 sq. Å. for lysolecithin, *i.e.* lysolecithin forms a relatively much more distended film than lecithin. Further, μ for lysolecithin is about half that for lecithin, owing possibly to the removal of one ester linkage.

The molecular weights of lecithin and lysolecithin.

The molecular weights of these two compounds assumed in calculating the area per molecule were the formula weights 805 and 540, corresponding to oleyl-stearyl-lecithin and stearyl-lysolecithin respectively. Price and Lewis [1929] give values for the molecular weight of lecithin by the boiling-point method as 797 in ethyl alcohol and 3388 in benzene. A cold solution of freshly prepared lecithin in alcohol or benzene, or of lysolecithin in chloroform, shows a strong Tyndall cone, which decreases in intensity on boiling. At ordinary temperatures it would appear that both substances are highly polymerised. The rapid spreading of these large particles on an aqueous surface, the ease of compression and extension and the fluid nature of the films suggest that such polymerisation is not due to stable chemical linkages but to a physical process of dipole association between the lecithin or lysolecithin molecules, this union being broken down by the strong attraction of the dipoles to the aqueous surface.

Chemical properties of the films.

(i) ***Effect of*** p_H ***of the underlying solution.*** Films of tripalmitin, triolein and cholesterol are unaltered over the p_H range 2–11. Tripalmitin is hydrolysed slowly and triolein about four times more quickly on *N* NaOH. Fig. 2 shows the effect of p_H on the surface potentials of lecithin and lysolecithin films, using dilute HCl and *M*/25 phthalate, phosphate and borate buffers. The curves for myristic acid and triolein are included for reference. Triolein is a non-ionising molecule and shows no change of surface potential with p_H. Myristic acid, with a single acid ionising group, shows a large fall of surface potential on solutions more alkaline than p_H 3 due to soap formation. With lecithin a fall is again noticed at a p_H higher than 3 due presumably to the ionisation of the phosphoric acid group, which appears to be of the same order of strength as the carboxyl group in myristic acid. The fall is not maintained beyond p_H 6 owing to the amphoteric nature of the molecule. In the case of lysolecithin ionisation begins

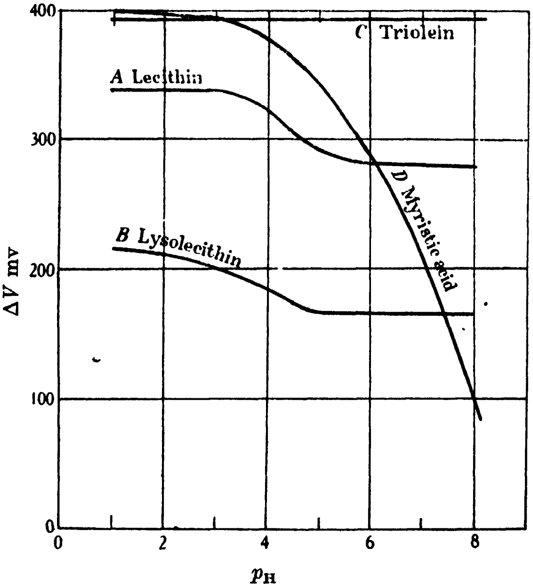

Fig. 2. Effect of p_H on surface potential (ΔV).

A. Lecithin at 100 sq. Å., 20°.
B. Lysolecithin at 100 sq. Å., 20°.
C. Triolein at 95 sq. Å., 20°.
D. Myristic acid at 20 sq. Å., 20°.

at a lower p_H, between 1 and 2, than for lecithin indicating that lysolecithin acts as a stronger acid. An effect peculiar to lecithin films is the change in character on solutions more alkaline than p_H 8, the range of compression becoming much smaller, and implying a much closer packing of the polar head groups (*cf.* Fig. 1).

It is impossible as yet to relate these surface potentials to results of cataphoretic measurements since the latter are not concerned with the total dipole system of the molecule.

(ii) *Oxidation by potassium permanganate.* Fig. 3 shows the change in surface potential with time for films of triolein, lecithin and lysolecithin on 0·1 % $KMnO_4$ in $N/100$ H_2SO_4 at room temperature. Lecithin is attacked rapidly, lysolecithin only very slowly, confirming the absence of an unsaturated hydrocarbon chain from lysolecithin. Triolein is also attacked only very slowly even at the maximum extension of the film to 132 sq. Å. per molecule. The explanation lies in the fact that the area of surface per hydrocarbon chain, 44 sq. Å., is too small to permit the presence of the unsaturated double bonds in the aqueous surface and thus oxidation is inhibited. A similar effect has been observed with oleic acid itself [Hughes and Rideal, 1933].

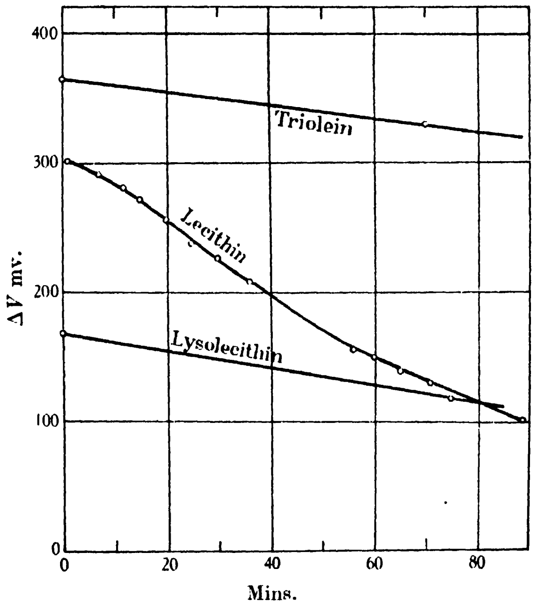

Fig. 3. Rate of oxidation of unimolecular films by 0·1 % $KMnO_4$ in $N/100$ H_2SO_4, 18°.

Mixed films of lecithin and cholesterol.

A series of mixed films of lecithin and cholesterol was examined by the method of surface potentials to ascertain whether any chemical union takes place between the molecules. This would be reflected in a corresponding alteration of the electric moments and hence of the surface potentials. The actual results indicate merely a gradual contracting effect of the cholesterol on the lecithin, except that in the region of equimolecular proportions the film is compressible to values of ΔV higher than the maximum value for lecithin or cholesterol alone, implying a retention of the molecular orientation to higher compressions in these mixtures

(Figs. 4 and 5). Under 20 dynes compression the lecithin in an 80 % cholesterol mixture has an area almost as small as that of cholesterol itself, ca. 40 sq. Å., so that under these conditions the lecithin molecule must be orientated with both hydrocarbon chains nearly vertical, since the minimum area of each chain when vertical is 18·5 sq. Å.

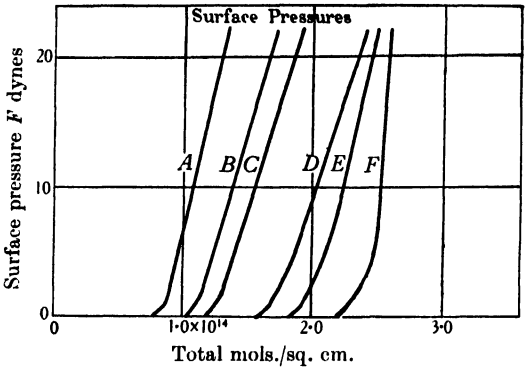

Fig. 4.

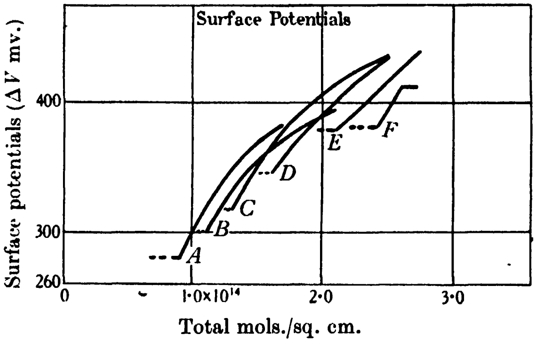

Fig. 5.

Mixed films of protein and fatty molecules.

The possibility of obtaining mixed films of protein and lipoid molecules, and the nature of such films if obtainable, are problems of some importance in connection with current theories of the composition of cell membranes. The work of Mudd and Mudd [1926] on the surface composition of normal and sensitised mammalian blood cells indicates an increased polarity of the cell surface after sensitisation, but there is no information whether the molecules of cholesterol, lecithin and protein can form a composite membrane with properties differing from those of its constituents. With this aim some preliminary experiments have been carried out using a typical protein, egg albumin.

The procedure adopted was first to spread a unimolecular film of the fatty substance on the surface of an aqueous solution and then to inject beneath the film a dilute solution of the protein. It was found that subsequent changes in the physical nature and in the surface potential of the film were affected by the following factors: (i) the p_H of the solution, (ii) the nature of the film-forming molecules, (iii) the surface concentration of the film molecules.

The effect of p_H. On the acid side of the isoelectric point of egg albumin injection of the protein (concentration in trough 0·001 %) causes a rapid rise in the surface potential of a triolein film to a value above that of triolein or of egg albumin. At the same time the liquid film of triolein sets to a rigid gelatinous film similar to that of the protein alone. On the alkaline side of the isoelectric point the rate of gelation of the film becomes progressively slower and is accompanied by a small fall in surface potential. This change, which is complete in 4 minutes at p_H 4·0, takes about 1 hour at p_H 7·0; it cannot be simply a replacement of triolein by protein since the potential of the complex film is always much higher than that of the egg albumin film alone.

Effect of the nature of the film-forming molecule. Films of tripalmitin, hexadecyl alcohol, cholesterol, and lecithin do not appear to be changed by injection of protein at any p_H. Oleic acid behaves in a similar manner to triolein. Lysolecithin is peculiar in that, although gelation of the film takes place very slowly, over a period of hours, an immediate and rapid rise of potential occurs, in 20 minutes at p_H 5. A further study of these complex films is in progress.

SUMMARY.

1. The method of surface potentials has been applied to a study of the physical and chemical properties of unimolecular films of lecithin, lysolecithin, cholesterol, tripalmitin and triolein. The relative electric moments per molecule thus deduced are 8·8, 4·3, 4·2, 10·0, $11{\cdot}3 \times 10^{-19}$ E.S.U. respectively.

2. Lysolecithin forms a liquid expanded film with an upper limiting area of 108 sq. Å., the area per hydrocarbon chain being about twice that for lecithin.

3. Tripalmitin, triolein and cholesterol show no change in properties over a p_H range 2–12. For lecithin a fall in surface potential is noted between p_H 3 and 6, and for lysolecithin between p_H 2 and 5, due to ionisation.

4. On dilute $KMnO_4$ solutions lecithin is oxidised more rapidly than triolein or lysolecithin.

5. Mixed films of protein and fatty molecules have been examined. Homogeneous mixed films are obtainable from egg albumin and triolein.

The lecithin used in these investigations was prepared by Dr Chain by Levene's method through the cadmium chloride compound. It was nearly colourless and gave 3·96 % phosphorus, 1·79 % nitrogen. My sincere thanks are due to Dr Chain for this preparation and to Dr E. J. King for a specimen of pure lysolecithin.

L. THE ACTION OF SNAKE VENOMS ON SURFACE FILMS.

BY ARTHUR HUGHES.[1]

From the Colloid Science Laboratory, Cambridge.

(*Received December 23rd, 1934.*)

THE work of Kyes [1902] and of Kyes and Sachs [1903] showed that the action of snake venom haemolysins is upon the lecithin portion of the cell membrane. Later, Delezenne and Fourneau [1914] found that egg-lecithin undergoes a partial hydrolysis by snake venom, the unsaturated fatty acid residues being specifically removed to form lysolecithin, which contains a single saturated aliphatic hydrocarbon chain. No satisfactory mechanism has been suggested for this specific hydrolysis. A study has been made in the present work of the actions of various snake venoms on unimolecular films of lecithin and other compounds in relation to the processes involved in venom haemolysis.

As opposed to the study of reactions in bulk, the technique of surface films has the advantage that the enzyme substrate can be studied in a definite and reproducible state, that of an oriented monolayer. Chemical reactions occurring therein are observable by the accompanying changes in the surface potential of the film. The surface potentiometer employed has been described elsewhere [Schulman and Rideal, 1931].

Preliminary investigation.

The following venoms were available:

COLUBRIDAE:	Black snake	*Pseudechis porphyriacus.*
	Copperhead	*Denisonia superba.*
	Black tiger	*Notechis scutatus.*
	Cobra	*Naia naia.*
VIPERIDAE:	Daboia	*Vipera elegans.*

A film of lecithin was spread on the surface of dilute NaCl solution in the trough of the surface potentiometer and compressed to a fixed reference area per molecule, usually 100 sq. Å. A dilute solution of venom was then injected under the film from the far side of the movable glass barrier enclosing the film. The solution was well mixed and the change of surface potential was measured. In cases where the change was rapid it was found advisable to mix the venom solution in the trough prior to spreading the film to ensure uniformity of the solution. The lecithin film is spread immediately after cleaning the surface, since protein, which is always present with the venom, accumulates at the free liquid surface in the more concentrated solutions.

With a venom concentration of 0·01 % in the underlying solution a rapid fall in surface potential takes place, *i.e.* in the direction of a conversion of lecithin into lysolecithin (*cf.* Fig. 1), in the case of all the venoms except cobra. This anomaly of cobra venom, ascribable to the different nature and greater proportion of associated protein, will be referred to later. The final values of the surface potential of a lecithin film on the other four venoms depend on the degree to which the associated protein is adsorbed under a lysolecithin film. Thus injection of venom under a lysolecithin film causes a small rise in potential to a value within about 15 mv. of the final value of lecithin on that solution.

---

[1] Beit Memorial Fellow.

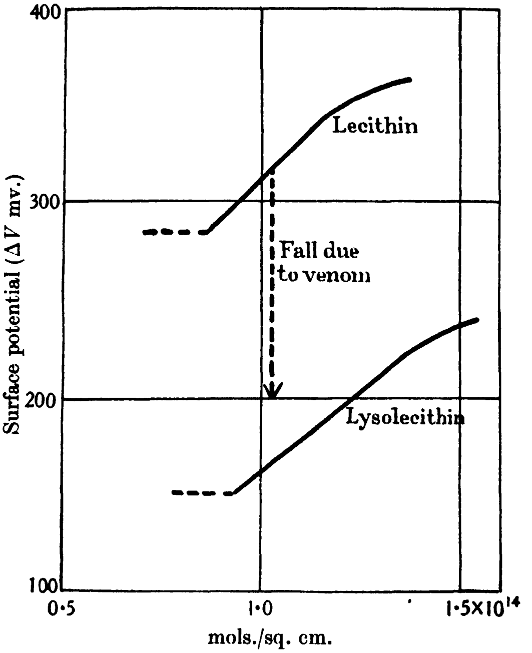

Fig. 1. Surface potentials of lecithin and lysolecithin, 0·9 % NaCl, 18°.

None of the venoms has any effect on a unimolecular film of cholesterol or of protein, and they cause no hydrolysis of tripalmitin, triolein, cerebron or sphingomyelin.

The action of the venom on a lecithin film was found to depend on three main factors:

(i) The p_H of the underlying solution.
(ii) The surface concentration of the lecithin film.
(iii) The venom concentration.

These effects were examined in detail.

(i) *The effect of* p_H. The action of black tiger venom was studied over a p_H range from 4 to 11 using $M/25$ phthalate, phosphate and borate buffers and a fixed venom concentration of 0·001 %. Fig. 2 gives a family of curves showing the change of surface potential (ΔV) with time at various p_H values for a definite initial surface concentration of lecithin ($n = 1{\cdot}0 . 10^{14}$ mols./sq. cm.). There is no reaction on solutions more acid than p_H 4·8, the velocity at p_H 6·0 is about equal to that at p_H 8·0, while at p_H 10·8 the reaction is again strongly inhibited. The optimum is at about p_H 7·3.

The venom itself is stable in fairly strongly acid media but not in alkaline. After keeping for 3 hours in $N/10$ HCl at room temperature and returning to p_H 7·2 the venom solution shows unimpaired activity. Treatment with $N/10$ NaOH for the same period destroys the venom almost completely as regards its action on a lecithin film. The action is not inhibited in the presence of 0·5 % NaF.

(ii) *Effect of surface concentrations of lecithin.* The rate of attack of a lecithin film is considerably diminished as the number of molecules of lecithin per sq. cm. is increased (Fig. 3). The time for complete hydrolysis of the film increases from 7 to 100 minutes for a doubling of the initial surface concentration of lecithin, from 1·04 to 2·07. 10^{14} mols./sq. cm. It is known that the venom specifically removes the unsaturated hydrocarbon chain from lecithin. A triolein film is not hydrolysed even very slowly by venom, the action of which cannot therefore be concerned only with a coupling with the unsaturated group in lecithin. It must also couple with some other point in the lecithin molecule. Compression of the lecithin will alter the spacing of the essential points of attachment, and at the higher compressions the double bonds will be removed from the aqueous surface, as observed in the case of oleic acid [Hughes and Rideal, 1933]. It may thus be suggested that the lecithinase embodies also a spacing of two active groups

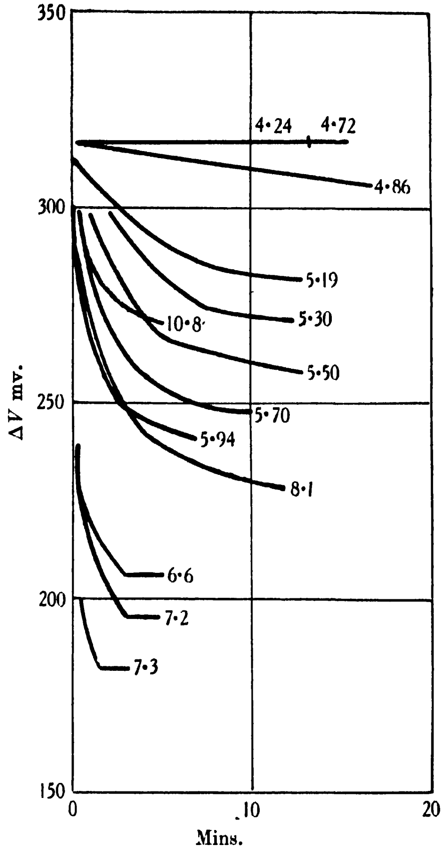

Fig. 2.

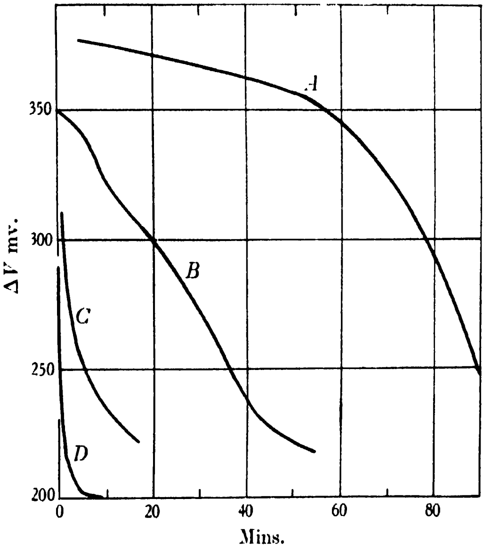

Fig. 3.

Fig. 2. Influence of p_H on attack of lecithin films by black tiger snake venom, 20°.

Fig. 3. Effect of compression of lecithin film on attack by black tiger venom (0·001 %).

$$\left.\begin{array}{ll} A & n=2{\cdot}11.10^{14}\text{ mols./sq. cm.}\\ B & n=1{\cdot}57.10^{14}\text{ mols./sq. cm.}\\ C & n=1{\cdot}27.10^{14}\text{ mols./sq. cm.}\\ D & n=1{\cdot}04.10^{14}\text{ mols./sq. cm.}\end{array}\right\} p_H\ 7{\cdot}2,\ 17^\circ$$

which coincide with a similar spacing of two active groups in the distended lecithin molecule for the maximum probability of reaction.

(iii) *Effect of venom concentration.* Fig. 4 shows the rate of attack of a lecithin film from a fixed initial surface potential of 280 mv. by varying concentrations of copperhead venom, in $M/30$ phosphate buffer at p_H 7·2.

It is seen that at concentrations higher than about 10^{-4} g. venom 100 ml. (1 part in a million), the reaction is of zero order and complete in 5 minutes at 20°. Below this concentration and down to the lowest concentration used, 1 part in 40 millions, the rate of reaction falls off sharply with the venom concentration till at $2{\cdot}5 . 10^{-6}$ % the half life is about 1 hour. It is impossible to give quantitative values for the velocity constants at these low concentrations owing to the varying amounts of protein in the solution and the possible adsorption of the venom on the glass vessel as well as at the surface of the film.

It must be remembered that the values of the venom concentration refer to dry weight of crude venom scale, and that the fraction of this which is pure active principle is unknown.

Attack of lecithin/cholesterol films by venom.

The rate of attack by black tiger venom of a film containing 20 % cholesterol molecules is the same as that for lecithin alone at the same area per molecule. In a 50 % mixture the velocity is not appreciably diminished, but in an 80 % cholesterol film no reaction is observed over a period of hours. It appears that cholesterol has no specific inhibitory power in this reaction other than that due to its causing a general contraction of the lecithin film as the proportion of lecithin is decreased. As shown in Fig. 3, a similar inhibition is observed by mere compression of a pure lecithin film.

Correlation of haemolytic action of venoms with their action on lecithin films.

The following experiments were carried out to ascertain how far the observed changes brought about in a lecithin film by venom were ascribable to the haemolysin of the venom.

Washed guinea-pig cells were used throughout. In Table I a comparison is shown of the effect of black snake venom in haemolysis and on the surface potential of a lecithin film. The venom solution was used (*a*) unboiled, (*b*) boiled 1 hour in saline, (*c*) unboiled but filtered though a Seitz filter.

Table I.

1 ml. 5 % cells, 1 ml. venom solution (1 mg./ml. in saline) at 37°.

	Unboiled unfiltered	Boiled 1 hr. unfiltered	Unboiled filtered
Haemolysis	C.H. 20 mins.	C.H. 20 mins.	N.H. 20 mins. C.H. 40 mins.
Film activity: fall of ΔV in 10 mins.	46 mv.	41 mv.	22 mv.

C.H. = Complete haemolysis. N.H. = No haemolysis.

These figures demonstrate a definite relationship between hydrolysis of a lecithin film and haemolysis, by black snake venom, and further show the remarkable stability of the venom to prolonged boiling in saline, a point which is discussed more fully later.

A more complete set of experiments was carried out using four varieties of venom: copperhead, daboia, cobra and black tiger, while a definite p_H was maintained with isotonic phosphate p_H 7·4. Control experiments on the isotonic buffers employed showed that these had no effect on the fragility of the cells. The system for haemolysis was made up as follows: 1 ml. of venom solution in isotonic saline (1 mg. per ml.), 1 ml. isotonic phosphate buffer and 0·5 ml. of 5 % washed guinea-pig erythrocytes. The venom solution was used (*a*) unboiled, (*b*) boiled 10 minutes, (*c*) boiled 60 minutes, the heating being carried out at p_H 7·4. It was immediately noticed that the cobra venom solution on heating behaved very differently from the other venoms in giving a bulky yellowish white precipitate, whereas the other solutions only showed a slight opalescence even after 1 hour's boiling. This and other anomalies of cobra will be discussed later.

The main results were, in the first place, that ability to hydrolyse a lecithin film does not necessarily imply haemolytic power on red cells of any given species. Thus daboia gave no haemolysis, black tiger only a trace after 16 hours, while copperhead and cobra as well as black snake were strongly haemolytic, showing complete haemolysis in 2 hours with a concentration of 0·2 mg./ml.

Secondly, after 10 minutes' boiling at p_H 7·4 no haemolysis was detectable with any of the solutions. This result in comparison with the results shown in Table I indicates that the heat stability of the venom depends on the p_H of the solution. This question was investigated more closely. It was found for copperhead and cobra that 15 minutes' boiling at p_H 5·9 (phosphate) has no effect on copperhead and only a slight effect on cobra, while apparently complete destruction ensues at p_H 7·0 (phosphate) and at p_H 9·0 (borate) (Table II).

Table II.

1 drop 50 % cells, 1 ml. venom solution (1 mg./ml. in isotonic buffer) incubated at 37°. for 2 hrs. then at room temperature.

p_H	5·9 phosphate	7·0 phosphate	9·0 borate
Cobra			
Unboiled	C.H. 3–3½ hrs.	C.H. 3–3½ hrs.	C.H. 1¾ hrs.
Boiled 15 mins.	P.H. 3–3½ hrs.	N.H.	N.H.
Copperhead			
Unboiled	C.H. 1¾ hrs.	C.H. 1¾ hrs.	P.H. 3–3½ hrs.
Boiled 15 mins.	C.H. 1¾ hrs.	N.H.	N.H.

C.H. = Complete haemolysis. P.H. = Partial haemolysis. N.H. = No haemolysis in 20 hrs.

This sharp effect of p_H on heat stability has not previously been examined and may account for varied reports as to the influence of heat on different venoms [*cf.* Phisalix, 1922].

The experiments with surface films of lecithin revealed further that where complete destruction of the venom is registered with regard to haemolysis, an appreciable quantity of lecithinase may still be present. It has been already mentioned that a concentration of venom as low as $2{\cdot}5.10^{-6}$ % is detectable by means of surface potentials, while a concentration of $1{\cdot}5.10^{-3}$ % venom only produces complete haemolysis in 16 hours (*cf.* Table III and Fig. 4).

Table III. *Effect of venom concentration on haemolysis by copperhead.*

Conditions as in Table II, p_H 7·0 phosphate.

% venom ...	10^{-1}	5.10^{-2}	$2{\cdot}5.10^{-2}$	$1{\cdot}2.10^{-2}$	$6{\cdot}2.10^{-3}$	$3{\cdot}1.10^{-3}$	$1{\cdot}5.10^{-3}$	$7{\cdot}5.10^{-4}$
Time 1¾ hrs.	4	3	3	3	3	1	–	–
3½ hrs.	4	4	4	4	4	4	1	–
16 hrs.	4	4	4	4	4	4	4	3

(4 represents complete haemolysis.)

It is seen that at a concentration of $7{\cdot}5.10^{-4}$ % venom haemolysis is not yet complete even in 16 hours, whereas a lecithin film is completely transformed in 3 minutes by the same venom concentration. The method of surface potentials provides therefore a very much more sensitive check on the presence of a lecithinase haemolysin.

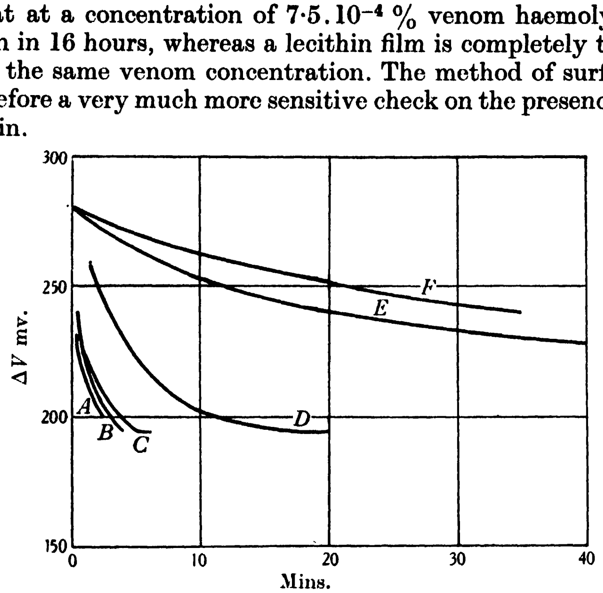

Fig. 4. Attack of lecithin films by copperhead venom, p_H 7·2, 20°.

Venom concentrations: A 5×10^{-4}. B 1×10^{-4}. C 5×10^{-5}. D 1×10^{-5}. E 5×10^{-6}. F $2{\cdot}5\times10^{-6}$. g. %.

The surface activities of venom solutions boiled at various p_H values were compared with the activity of the same venom on progressive dilution and the results are summarised in Table IV. The quantity of undecomposed venom is estimated from the rate of attack on a lecithin film.

Table IV.

Effect of boiling on the lecithinase content of copperhead venom. Initial weight of venom 10^{-3} g.

p_H ...	5·9	6·5	7·2	9·0
Boiled for 15 mins.	10^{-3}	10^{-3}	*ca.* 10^{-5}	nil g. venom remaining
Boiled for 60 mins.	10^{-3}	*ca.* 10^{-4}	*ca.* 10^{-6}	,, ,, ,,

The active principle of the venom is therefore rapidly decomposed on the alkaline side of a sharp p_H limit of 6·5–7·0 and boiling for 15 minutes at p_H 7·2 will inactivate the venom as far as haemolytic experiments can decide, by reducing the venom concentration a hundredfold, although this small quantity, 10^{-5} g., is still readily detected by the method of surface potentials. The complete loss of surface activity as well as haemolytic activity on boiling at p_H 9·0 seems convincing evidence of the close relation of the two effects.

An attempt was made to examine the influence of p_H on the rate of venom haemolysis. It is probably impossible in some cases to separate the effect of p_H from that of the buffering ion. For cobra and copperhead venoms the rate of attack was about the same in two isotonic phosphate buffers at p_H 5·9 and 7·0, but whereas cobra is considerably more active at p_H 9·0 (borate), copperhead is considerably less so (*cf.* Table II). This effect of p_H on copperhead haemolysis supports the results of Holden [1934] that rabbit cells are haemolysed more rapidly at p_H 5·6 than at p_H 8·0.

The anomalies of cobra venom.

Three different specimens of cobra venom were examined, and the behaviour was found to be uniformly different from that of the other venoms studied. At a concentration of 0·01 % and down to 0·0001 % cobra venom gives no detectable hydrolysis of a lecithin film, but on diluting to 0·00005 % (1 part in 2.10^6) a slow reaction takes place as in the case of the other venoms. The inactivity of cobra venom in higher concentration is possibly related to the protective action of excess of this particular venom on the haemolysis of erythrocytes [Kellaway and Williams, 1933]. This inhibition occurs to a negligible extent with the Australian venoms. It is possible that there is a marked preferential adsorption of the protein portion of cobra venom on a lecithin film, and at a concentration sufficient to form a complete layer of protein at the surface the lecithinase is prevented from reaching the lecithin. It is indeed found that the presence of such a quantity of cobra venom will almost completely inhibit the attack of a lecithin film by other normally active venoms such as black tiger or daboia. Again, addition of an equal weight of egg albumin to black tiger venom reduces its rate of attack on a lecithin film tenfold.

Another anomaly of cobra venom has recently been stressed by McFarlane and Barnett [1934], namely its anticoagulant action on plasma, as opposed to the strong coagulant action of Russell's viper (daboia) venom and certain other venoms. It is significant that attempts to separate the toxins from the coagulant principle in these cases have so far failed. There is thus a possibility of a close relation between the coagulant and the lecithinase.

Pre-haemolytic swelling.

In cases of venom haemolysis a large pre-haemolytic swelling of the erythrocytes is usually observed. If the first stage of haemolysis is indeed the liberation of lysolecithin in the lipoidal surface layer of the cell membrane one would anticipate a considerable increase in area since the area per hydrocarbon chain in lysolecithin films is nearly double that obtaining in a lecithin film at the same state of compression. The more expanded nature of the film thus formed would be accompanied by an increased fragility and permeability.

SUMMARY.

1. The physico-chemical properties of snake venom have been examined through its reaction with unimolecular films, particularly lecithin films. Five varieties of venom were studied: black snake, black tiger, copperhead, daboia and cobra.

2. The rate of hydrolysis of a unimolecular film of lecithin to lysolecithin by venom lecithinase is dependent on p_H, surface concentration of lecithin molecules and the venom concentration. The p_H optimum is about 7·3. Compression of the lecithin molecules greatly decreases the rate of hydrolysis. Venom concentrations as low as 1 part in 40 millions are detected by the method of surface potentials.

3. The lecithinase is stable to prolonged boiling at p_H 5·9, but is rapidly destroyed on boiling in solutions more alkaline than p_H 7·0.

4. Haemolysis conducted concurrently with experiments on surface films shows a direct relation between haemolysis and lecithinase content as measured by rate of attack on a lecithin film.

5. Anomalies of cobra venom are discussed.

I wish to acknowledge my indebtedness to Mr E. T. C. Spooner for his invaluable collaboration in the experiments on haemolysis, and further to Dr C. H. Kellaway, whose gifts of snake venom made the work possible. My thanks are also due to Prof. E. K. Rideal for his constant interest and much helpful criticism. I am indebted to Dr Chain for fresh specimens of egg-lecithin used in the above experiments, prepared by Levene's method. The analysis figures were 3·96 % phosphorus, 1·79 % nitrogen.

LI. VARIATIONS IN SERUM-MAGNESIUM AND IN THE PARTITION OF SERUM-CALCIUM IN NORMAL PARTURITION AND IN MILK FEVER.

By WILLIAM GODDEN and JOHN DUCKWORTH.

(*From the Rowett Research Institute, Aberdeen.*)

(*Received December 29th, 1934.*)

The studies presented by Fish [1930] showed that milk fever usually occurred with a serum-Ca average level of 4·1 mg. per 100 ml. of serum, whilst the serum-inorganic P level averaged 2·43 mg. His work confirmed the results of Little and Wright [1925]. Since the work of Fish an increasing amount of attention has been given to the partition of calcium in different pathological conditions including milk fever. Sjollema and Seekles [1930] have reported an average Ca ion value of 0·44 mg. per 100 ml. in the serum of milk fever cows as compared with an average normal value of 1·65 mg. Little and Mattick [1933] reported that the diffusible serum-Ca was never above 3 mg. per 100 ml. in milk fever as compared with the normal value of 5 mg.

Benjamin and Hess [1933] demonstrated that serum-Ca may be divided into four fractions: (1) the Ca ion, (2) an ultrafiltrable Ca complex, adsorbable on barium sulphate, (3) a non-ultrafiltrable Ca complex, adsorbable on barium sulphate, and (4) the so-called "protein-bound" Ca. It was thought that additional information on the changes in blood composition at the time of parturition or during milk fever might be obtained by the application of the technique of Benjamin and Hess. Owing to the fact however that cases of milk fever occurred before a complete study of the most suitable method of ultrafiltration had been made it was possible to make a division into two fractions only, namely the total adsorbable calcium (2+3 of Benjamin and Hess) and protein-bound calcium *plus* Ca ion (1+4 of Benjamin and Hess).

A study of the literature reveals very little definite information as to the changes in serum-Mg consequent upon milk fever. Sjollema and Seekles [1930] give the average value for serum-Mg in normal cows as 1·66 mg. per 100 ml. and in cases of milk fever 2·19 mg. per 100 ml. This latter figure is the average for a number of cows from which the blood sample was taken when the symptoms were acute. As will be shown later, this does not appear to be the time when the magnesium level is at its highest.

EXPERIMENTAL.

For several years a group of non-pedigree Ayrshire cows had been under observation and records of the variation in their blood composition were available as a result of regular sampling at 3-weekly intervals. At the period of the 1934 calvings, it was decided to obtain frequent samples of blood from each cow during the few days immediately before and after calving, one sample being drawn, whenever possible, immediately after parturition. The cows varied in age from 8 to 10 years and as it happened this year there were three typical cases of milk fever, three abnormal cases showing some signs of milk fever, but having other complications, and three normal calvings. We were thus able to make a comparison of the changes occurring in the composition of the blood serum under these three conditions.

Analytical methods.

(1) *Serum-magnesium.* The precipitation method of Denis [1922] was modified as follows. Into a 15 ml. conical centrifuge-tube were measured 1 ml. of concentrated ammonia (sp. gr. 0·880) and then 1 ml. of 5 % ammonium phosphate followed by 3 ml. of the supernatant liquid from the calcium estimation. The precipitate formed when the first two solutions were mixed entirely dissolved on adding the third and then the magnesium ammonium phosphate separated out in a coarsely crystalline form. The precipitate was separated and washed centrifugally, using Holzapfel's washing method [1934], and was then dissolved and the blue colour developed by the method of Fiske and Subbarow [1925], as modified by Stewart [1933], and matched in the usual manner.

(2) *Serum-calcium.* The method of Clark and Collip [1925] was used.

(3) *Adsorbable calcium complexes.* The calcium adsorbable on barium sulphate was determined by the method of Benjamin and Hess [1933]. The difference between this and total serum-calcium represented the "protein-bound" calcium *plus* ionised calcium.

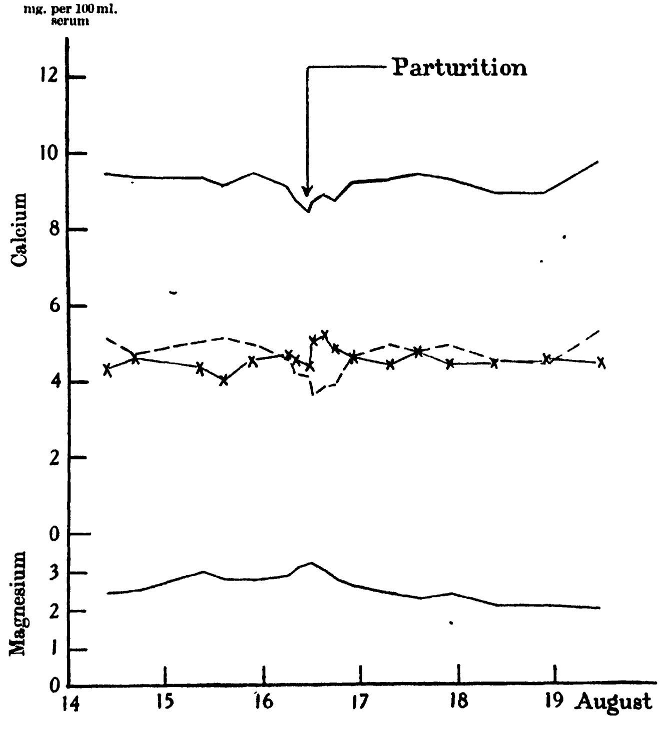

Fig. 1. Cow no. 13. Normal case.

—— Total serum-Ca; x — x non-adsorbable Ca; — — — adsorbable Ca; lower ———— serum-Mg.

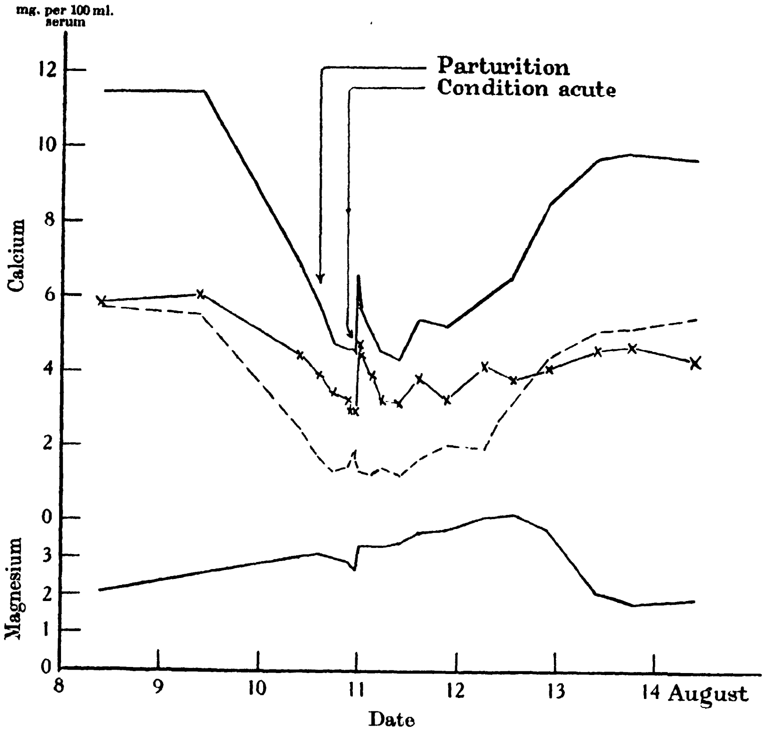

Fig. 2. Cow no. 18. Milk fever case. Description as fig. 1.

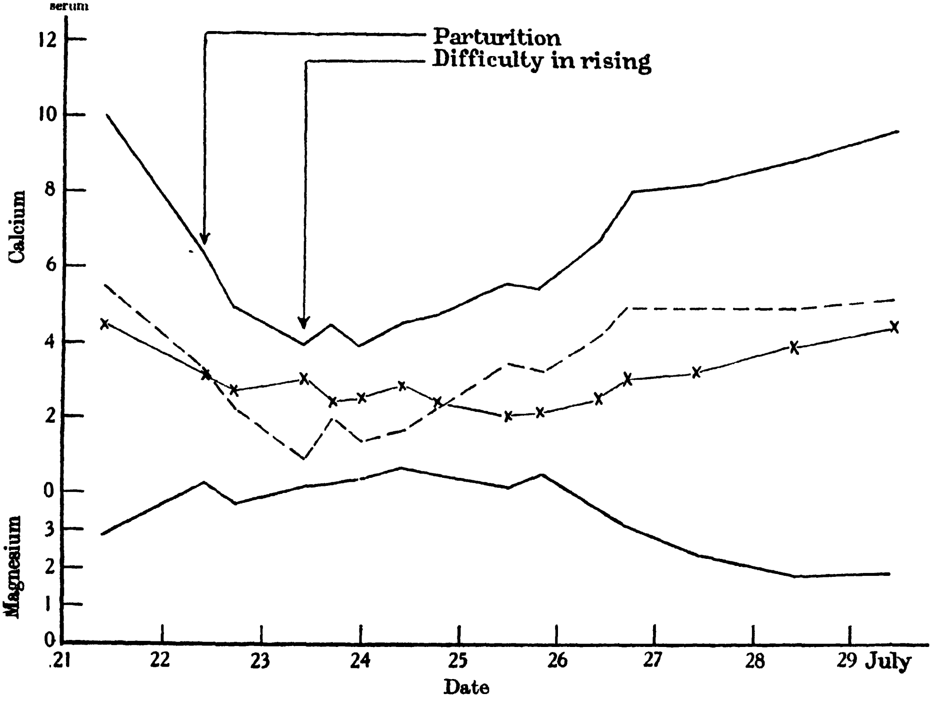

Fig. 3. Cow no. 12. Doubtful case. Description as fig. 1.

Samples of blood were, in all cases, drawn from the jugular vein, employing partial stasis. The serum was separated from the blood clot within 18 hours of drawing the blood.

Typical results illustrating the changes in these four constituents of the serum during normal calvings, milk fever cases and the three doubtful cases are shown in Figs. 1, 2 and 3 respectively. The detailed data for each of the 9 cows are given in Table I and this is followed by the individual case histories. In all cases where calcium gluconate was injected, a 10 % solution (containing 0·91 g. Ca per 100 ml.) was used.

		CASE HISTORIES.
Normal cases.		
(1) Cow no. 13.		
Aug. 16.	11.15 a.m.	Calved with aid. Large calf. Recovery uneventful.
(2) Cow no. 5.		
Aug. 3	12.55 p.m.	Calved normally. Afterbirth retained.
„ 4		Appetite poor.
„ 5		Afterbirth removed. Appetite remained poor for several days, but subsequent recovery was uneventful.
(3) Cow no. 9.		
Oct. 15	2.00 p.m.	Calved normally. No subsequent complications.
Milk fever cases.		
(4) Cow no. 18.		
Aug. 10	1.50 p.m.	Calved normally.
	5.00 p.m.	Unwilling to rise but not staggering.
	8.50 p.m.	Fell at sampling. Unwilling to rise.
	9.55 p.m.	Condition worse. Refused to rise.
	10.45 p.m.	Condition acute. Animal comatose.
	10.55–11.03 p.m.	250 ml. of calcium gluconate injected intravenously.
	11.15 p.m.	Blood sample taken from opposite side of neck.
Aug. 11	12.15 a.m.	Improvement.
	3.00 a.m.	Refused to rise until 7·30 a.m.
	7.30 a.m.	Tried to rise.
	10.00 a.m.	Milk fever again. 325 ml. calcium gluconate given intravenously.
	2.30 p.m.	Improvement.
Aug. 12	12.15 p.m.	Able to rise if assisted.
„ 13	10.00 a.m.	Able to rise if assisted.
„ 14	10.00 a.m.	Normal.
(5) Cow no. 7.		
July 12	1.30 p.m.	Calved normally.
„ 13	10.00 a.m.	Slight staggers.
	7.30 p.m.	Condition worse.
	10.35 p.m.	Condition acute. Injected with 250 ml. calcium gluconate.
„ 14	1.00 a.m.	Improvement.
	5.30 a.m.	Walking fairly steadily.
„ 15	5.30 a.m.	Normal.
(6) Cow no. 15.		
July 19	10.00 a.m.	Fell when bled. Difficulty in rising.
	1.30 p.m.	Normal calving.
	7.45 p.m.	Fell when bled. Difficulty in rising. Staggering.
	11.30 p.m.	Unable to rise. Not known to have risen. Hourly examinations. Condition unchanged until.
„ 20	4.00 a.m.	Condition much worse.
	5.15 a.m.	Symptoms acute.
	5.40 a.m.	400 ml. calcium gluconate injected subcutaneously.
	8.45 a.m.	Marked improvement.
	4.45 p.m.	Able to rise and stand.
	9.45 p.m.	Able to walk but unsteady.
„ 21	10.00 a.m.	Gait almost normal.
	11.00 a.m.	Afterbirth removed. Subsequent recovery normal.
Doubtful cases.		
(7) Cow no. 12.		
July 22	8.45 a.m.	Calved normally.
„ 23	10.00 a.m.	Difficulty in rising but not staggering. No faeces passed since calving. Appetite poor.
„ 24		Given 1·5 pints linseed oil.
„ 25		Very little faeces passed. Given 1 pint linseed oil. Ate a little grass.
„ 26		Appetite still only fair, but improving.

Table I (*cont.*).

(8) Cow no. 11. *Post partum* paralysis.		
July 26	6.00 p.m.	Calved normally. Unable to rise afterwards.
	10.30 p.m.	No evidence of milk fever, but unable to rise. Inversion of uterus. Afterbirth removed, uterus irrigated and returned. Vulva stitched.
	11.30 p.m.	1 oz. chloral hydrate administered. Tongue flaccid. Possibility of milk fever. 250 ml. of calcium gluconate injected subcutaneously.
„ 27	3.15 a.m.	Marked improvement in carriage of head.
	5.30 a.m.	Uterus inverted between stitches in vulva, returned. Still unable to rise.
Aug. 7		Still unable to rise. Animal slaughtered.
9) Cow no. 19.		
Sept. 21	8.15 p.m.	Calved normally.
„ 22	5.00 p.m.	Fell when bled. Afterbirth removed.
	10.00 p.m.	Steadier.
„ 23	2.30 a.m.	Almost normal.
„ 24		Normal.

RESULTS.

Serum-magnesium.

Normal cases. Of the three animals which calved normally, two (Cows nos. 9 and 13) showed a rise in serum-Mg at or about the time of calving similar to that recorded by Allcroft and Godden [1934], whilst in the third case there was no marked rise.

Milk fever cases. The three animals which showed definite symptoms of milk fever all gave a rise in serum-Mg at the time of calving, of the order generally found in normal cases. In two of the cases there was then a slight fall in the serum-Mg which was followed by a very definite rise persisting throughout the period of milk fever. In the third case the fall was not noted but the rise continued until the clinical symptoms abated. It is interesting to note that this rise, which persisted after the injection of calcium gluconate, is not in keeping with the results usually found with rising serum-Ca. In general a rise in serum-Ca is accompanied by a fall in serum-Mg and this holds for cases of normal parturition and for the milk fever cases until the condition becomes acute. Following the injection of calcium gluconate in these latter cases however the consequent rise in serum-Ca is not accompanied at first by a fall in serum-Mg, the latter only occurring when the condition of the animal has almost returned to normal.

Doubtful cases. In these three cases there was found the usual rise in serum-Mg at calving. In the two cases in which the animals received no subsequent treatment there was a further rise similar to that occurring in the milk fever cases. The results for the third case (no. 11) are of doubtful value owing to the varied treatment which the animal received (*vide* case history).

Total serum-calcium.

In all cases, whether milk fever occurred or no, the changes in total serum-Ca were in general accord with those already recorded in the literature. An examination of the total serum-Ca figures for the period around parturition shows however that, in all the cases where milk fever subsequently occurred and in the doubtful cases, the fall in serum-Ca just before and at calving was very much steeper than in the case of the normal animals. It appears that this steep fall is probably a beginning of the syndrome of milk fever, but the development of the latter into an acute condition is dependent upon the simultaneous low values for both adsorbable calcium complexes and non-adsorbable calcium, as discussed below.

Calcium complexes adsorbable on barium sulphate.

Normal cases. The values were at their lowest about the time of calving, the lowest value being 3·5 mg. per 100 ml., and they quickly rose again to normal, except in the case of Cow no. 5, where there were the complications of loss of appetite and retained afterbirth.

Milk fever cases. The fall in the complexes accounts for the major part of the fall in total serum-Ca in cases of milk fever. With a pre-parturient level of about 5·5 mg. per 100 ml., minima as low as 0·5 mg. were found. These animals showed a much steeper fall in adsorbable calcium complexes just before calving than did normal animals. The values remained uniformly low during milk fever, persisting at this level until definite improvement occurred.

Doubtful cases. In these three cases the complexes showed similar diminutions to those of the milk fever cases. In the case of Cow no. 11 the onset of paralysis made it difficult to determine whether or no she was going to develop milk fever. In the case of Cow no. 12 the difficulty in rising coincided with the minimum value of 0·9 mg. per 100 ml. and in the case of Cow no. 19 the value of 0·5 mg. per 100 ml. coincided with the animal falling at blood sampling.

Non-adsorbable calcium ("protein-bound" Ca and Ca ion).

Normal cases. In two cases the non-adsorbable Ca was lower at calving than before, while in the third case there was a slight rise.

Milk fever cases. The non-adsorbable Ca in milk fever cases showed greater depression than in normal cases. In Cow no. 7 the acute symptoms did not coincide with the period of greatest depression of the non-adsorbable calcium, but only occurred when this fraction underwent a second depression, which corresponded with the minimum value, namely 0·5–0·6 mg. per 100 ml. of the adsorbable complexes. In Cow no. 15 the acute symptoms occurred when the non-adsorbable calcium reached a minimum, and the adsorbable complexes were at a low level. In Cow no. 18 there were two periods when the symptoms became acute and each of these occurred when both the adsorbable and the non-adsorbable fractions were simultaneously at low levels.

Doubtful cases. In one case, Cow no. 19, the unsteady gait and difficulty in rising, usually associated with milk fever occurred at a higher level of non-adsorbable calcium, *i.e.* 4·3 mg. per 100 ml., than might have been expected. In the case of Cow no. 12, the period of depression of this fraction was associated with loss of appetite and constipation. Cow no. 11 showed a low value, but her condition made accurate diagnosis impossible.

DISCUSSION.

The striking diminution in adsorbable calcium complexes which was found to occur in milk fever should be considered in the light of the results of Benjamin and Hess [1933]. They found that in low phosphorus type rickets the adsorbable complexes were below normal and that this was coincident with low serum-inorganic phosphorus. Later work by Benjamin [1933] showed that the ultrafiltrable calcium complex contained Ca^{++}, $PO_4^{\equiv}$ and HCO_3^- ions. Since this is so, any decrease in the amount of the ultrafiltrable calcium complex would result in a corresponding decrease in the inorganic P, unless more phosphorus were secreted into the blood stream to make good this deficit. While normally the inorganic P of the blood varies inversely with the total Ca of the serum, at parturition both values fall simultaneously. The low inorganic P values found in milk fever by Fish [1930] and other workers can be interpreted therefore as being caused by the tremendous reduction in the $Ca_x(PO_4)_y.(HCO_3)_z$ complex.

The parturient cow has considerable demands for calcium owing to the sudden onset of lactation which must be met by mobilisation of calcium from the bone reserves. Benjamin [1933] has shown that the ultrafiltrable calcium complex is removed from normal serum by calcifying cartilage and thus it is of interest to note that the failure of the parturient cow to mobilise her calcium reserves in milk fever should be associated with a decrease in the calcium complexes, of which the ultrafiltrable complex forms the greater part. Further work in progress has shown that the ultrafiltrable portion constitutes about 80 % of the total adsorbable complexes.

The connection between the parathyroids and low serum-calcium has led some workers to believe that these glands are intimately connected with milk fever. The main objection to this theory has been the low serum-inorganic P of milk fever cows. It appears that the failure to mobilise calcium, whether directly dependent on the parathyroids or no, is indirectly responsible for the failure to mobilise phosphorus.

The fluctuations in non-adsorbable calcium are in agreement with the results of Seekles *et al.* [1932] and Sjollema and Seekles [1930]. They found that the decrease in the Ca ion in milk fever to an average level of 0·44 mg. per 100 ml. ran closely parallel with the increase in severity of the symptoms. The decrease which we have found in total non-adsorbable calcium is, however, more than sufficient to account for the drop in Ca ion. From the work of Stewart and Percival [1928] the Ca ion seems to be mobilised from the "protein-bound" calcium although to what extent the organism is capable of performing this is unknown. If this process takes place, as apparently it does, during milk fever, it seems that the newly formed Ca ion disappears from the blood as fast as it is formed.

It appears that the symptoms of true milk fever only become acute when the values for both the adsorbable calcium complexes and the non-adsorbable calcium are simultaneously at low levels and near to their minima. A reference to Table I will show that in some cases the value of the non-adsorbable fraction had begun to rise slightly before the adsorbable fraction had reached its minimum and *vice versa*, and that only when the low values coincided did the condition become acute. The adsorbable calcium complexes fell to a level, in one case, of 10 % of their original value. The fall in non-adsorbable Ca was much less, the lowest value obtained being about 40 % of its original value. In the doubtful cases (Cows nos. 12 and 19) the adsorbable complexes were at their minima at the time when the non-adsorbable calcium showed maximum values and only the preliminary symptoms of milk fever appeared.

A point of interest in connection with the injection of calcium gluconate may best be illustrated by reference to the results for Cow no. 18. 12 minutes after the completion of the injection of 250 ml. of calcium gluconate at 10.55–11.03 p.m. on August 10th the total serum-Ca had risen from 4·5 to 6·6 mg. per 100 ml., the non-adsorbable calcium had risen from 2·9 to 4·7 mg., whereas the adsorbable complexes had only risen from 1·6 to 1·9 mg. Similar but less marked results were obtained on August 11th. A rough calculation based on the amount of calcium gluconate injected and the rise in total serum-calcium on August 10th shows that only about 15 % of the calcium injected could be found in the serum 12 minutes after injection.

The serum-Mg values are of particular interest and especially those maxima which occurred several hours after the crisis of the milk fever condition. As pointed out on page 452, the serum-Mg, subsequent to calcium gluconate injection, rose at the same time as the serum-Ca rose and this rise persisted until the milk fever conditions subsided. It does not appear that this parallel rise is necessarily consequent upon the injection since in two of the doubtful cases (Cows nos. 12 and 19) it also occurred without any injection of calcium gluconate. At the moment we are unable to offer any explanation of these changes in the level of serum-Mg in milk fever cases. The possible relationship between these results and those recorded by Bell and Morris [1934], indicating the persistence of an oxytocic substance in the blood of cows suffering from milk fever, has been considered, but the two sets of data run by no means parallel.

SUMMARY.

1. Values are recorded for serum-Mg, serum-Ca and calcium partition in the blood of dairy cows at parturition and in milk fever.

2. The acute symptoms of milk fever are preceded by a much steeper fall than usual in the total serum-Ca before and at calving and arise when there is a simultaneous fall in both the adsorbable calcium complexes and the non-adsorbable calcium ("protein-bound" Ca *plus* Ca ion).

3. The fall in adsorbable Ca complexes accounts for the major part of the fall in total serum-Ca in cases of milk fever.

4. During the recovery stage of milk fever serum-Mg and serum-Ca rise together.

5. A possible explanation is offered of the low values for serum-inorganic P in milk fever.

We wish to acknowledge our indebtedness to Mr W. Thomson for his care of the animals and for assistance in the blood sampling.

LII. A STUDY OF THE UNSAPONIFIABLE FRACTION OF WHEAT GERM OIL WITH SPECIAL REFERENCE TO VITAMIN E.

By JACK CECIL DRUMMOND, ELEANOR SINGER
and ROY JAMES MACWALTER.

From the Department of Biochemistry, University College, London.

(*Received January 1st, 1935.*)

Previous chemical studies of vitamin E have shown it to be a substance which can readily be concentrated in the unsaponifiable fraction of certain oils. The properties of these concentrated preparations indicate that the active substance possesses a relatively high degree of stability. The original investigations of Evans and Burr [1927, 1] showed that the vitamin is not readily destroyed by aeration at 100°, treatment with 20 % hydrochloric acid, subjection to temperatures up to 250° or hydrogenation with palladium at 75°. Exposure to strong ultra-violet radiation seemed to cause slight inactivation after 20 minutes, whereas after 45 minutes much activity was lost. Treatment with alcoholic hydrochloric acid or bromination in glacial acetic acid caused inactivation and, more surprisingly, evidence that acetylation was also destructive was obtained.

Little had been added to this knowledge of the chemical behaviour of vitamin E concentrates until Olcott and Mattill recently began to report the results of their investigations [1934; Olcott, 1934, 1, 2].

In the main the observations of Evans and Burr were confirmed. A striking exception was a failure to bring about inactivation by acetylation and an important addition was successful reactivation of chlorinated and brominated material by boiling with zinc dust and hydrochloric acid in methyl alcoholic solution. Destruction by ozone, perbenzoic acid, potassamide and, somewhat unexpectedly, potassium ethoxide was recorded.

Investigators are agreed that the vitamin is volatile. Evans and Burr found on refractionating that activity was associated with material collected in the narrow range 225–30°/0·01 mm., but Olcott and Mattill recorded a much greater volatility (190–220°/0·1 mm.).

An important question concerns the absorption bands shown by concentrates of vitamin E. Evans and Burr remarked "these measurements did not point to any definite curves for vitamin A or E which would help in following the concentration of the substance". Broad but diffuse bands, becoming much sharper at the temperature of liquid air, were however detected by Bowden and Moore [1933, 1] and additional maxima were recorded by Morton and Edisbury [1933]. Correlation of these data with biological activity was first attempted by Bowden and Moore [1933, 2] who pointed out that some part of the absorption in the range 320–285 $m\mu$ might be related to vitamin E.

Edisbury [1933] also reported a detailed consideration of the spectroscopic data obtained from the examination of vitamin E concentrates, with the object of tracing a correlation with the chemical behaviour of the vitamin.[1] He also reached the conclusion that the bands in the region indicated by Bowden and Moore should be further studied and drew attention to the three maxima, 291, 271, and 256·5 $m\mu$. The work of Olcott and Mattill [1934] tended however to weaken the belief that the vitamin might be a substance showing marked selective absorption in the ultra-violet, because their highly concentrated fractions showed only general absorption. Recently, however, a preliminary communication by Martin *et al.* [1934] announced that a well-defined absorption band was exhibited by a vitamin E concentrate. The band in question had a maximum at 294 $m\mu$; the strongest absorption recorded being $E^{1\%}_{1\,cm} = 27$. This material gave a positive biological test on one female rat when a single dose of 16 mg. was administered.

---

[1] We are greatly indebted to Dr R. A. Morton for his kindness in bringing this report of Dr Edisbury's work to our attention and for putting unreservedly at our disposal the results of his own spectrographic examinations of vitamin E concentrates.

Olcott [1934, 2] has also recorded this band in the examination of concentrates from wheat germ oil and cottonseed oil. Whereas Martin and his colleagues are undecided whether the band can be ascribed to the vitamin or to accompanying substances, Olcott concludes tentatively that it is not related directly to the vitamin because certain treatments ($AgNO_3$, acetylation) change or obliterate the band but do not destroy biological activity.

Chemical analyses of biologically active fractions have been made but the results have been put forward with reservations regarding the homogeneity of the material. These figures will be referred to later.

EXPERIMENTAL.

The raw material employed for the investigation now being recorded was the unsaponifiable fraction of wheat germ oil. The oil was prepared by cold extraction of a commercial wheat germ preparation (Bemax) with purified trichloroethylene. Ordinary commercial wheat germ is seldom a good raw material because it usually contains a large proportion of bran and other milling products and, moreover, may often be badly rancid. These facts are often ignored. On the one hand, some recorded estimations of the vitamin B content of wheat germ are low because of the unsuspected presence of bran; on the other, it is reasonable to attribute the low vitamin E activity of some preparations of wheat germ oil to the post-milling changes which rapidly occur in the crushed embryo. In this connection the work of Evans and Burr [1927, 2] on the influence of rancidity on vitamin E is of interest. The preparation (Bemax) chosen for this experiment is practically pure germ, has a negligible degree of free acidity and no trace of other products associated with rancidity.

The germ yielded 7·2 % of oil possessing the following characteristics:

Sap. value	182
Iodine value	131
Refract. index (20°)	1·4773
Unsap.	5·76 %
Iodine value of unsap.	97·6

The oil was found to be biologically active in daily doses of 23 mg. In our experience extraction with ether may sometimes cause inactivation. One sample prepared from the same bulk of germ failed to protect 5 rats from resorptions when given in daily doses of 46 mg. Preparation of the unsaponifiable fraction was made by treatment with boiling alcoholic KOH. Two saponifications of 30 minutes' duration were found to serve best. In the light of our experience it is surprising to learn that Olcott [1934, 2] has found inactivation after treatment with potassium ethoxide.

The unsaponifiable fraction thus obtained was, at room temperature, a hard yellow wax. It was found to be active in doses of 2·5 mg. It usually contained about 60 % of sterols precipitable by digitonin.

The bulk of the sterols was removed by cooling a saturated solution in methyl alcohol to $-25°$ by the direct addition of powdered CO_2. This treatment effectively removed between 80 and 90 % of the sterols present. The mother-liquor from the crystallisation of the sterols yielded on removal of the methyl alcohol a red-orange coloured, soft wax.

Crude sterol fraction.

As was suspected from reference to the observations of Anderson and Nabenhauer [1924, 1], the greater part of the crude sterol mixture was found to consist of sitosterol and dihydrositosterol. Using their method of separation [1924, 2; Anderson *et al.* 1926–27], a preparation of the saturated constituent was obtained possessing the following characteristics: M.P. 143–5°; $[\alpha]_D^{18}+21{\cdot}9°$; acetate, M.P. 141°; $[\alpha]_D^{18}+13{\cdot}29°$. All the sterol fractions showed absorption bands at 261 $m\mu$ and usually well-marked bands at 254 and 244 $m\mu$ in addition to the triple system characteristic of ergosterol. Similar findings have been reported by Morton and Edisbury [1933] and by Edisbury [1933]. It is probable that certain of these bands are related to ergosterol D, but unidentified sterols may also be concerned.

Fractional adsorption experiments.

Preliminary experiments having shown that more promising fractionation of the unsaponifiable material after removal of the greater part of the sterols was effected by adsorption on aluminium oxide than by distillation in high vacua or by partition between solvents, the former method was adopted. A typical experiment is described. 33 g. of the viscous red-orange oil obtained after removal of the crude sterols were dissolved in 500 ml. light petroleum. A small amount of dark brownish red material remained undissolved and was filtered off. More of this dark red material separated from the petroleum solution on standing overnight. The combined weight of the two insoluble fractions was 0·67 g. It proved to be slightly impure lutein (xanthophyll). Recrystallisation from methyl alcohol gave typical crystals, M.P. 194·5°.

The material soluble in light petroleum was passed slowly through a column of "Aluminium oxydatum anhydricum, nach Brockmann" (Merck), long-continued washing with the solvent being maintained. Two fractions of unadsorbed material were separated. The first represented that which passed through the column without any delay (fraction *A*). The second corresponded with a pale yellow coloured zone which slowly passed down the column as the washing proceeded. Eventually this pigmented substance passed out into the receiving flask completely, the washings once again becoming colourless (fraction *B*).

At this stage the experiment was usually discontinued and the column of adsorbent was broken up into four sections. The uppermost layer containing the most strongly adsorbed substance was of a deep brownish yellow tint (fraction *F*). Next came a paler, sandy coloured zone (fraction *E*), below which was another coloured region but definitely darker in tint (fraction *D*). At the bottom of the column came a deep zone showing in general little colour but marked by more than one indefinite band of slightly more pronounced yellow or sandy colour (fraction *C*).

It must be emphasised that this description refers only to one experiment. In every case the behaviour was similar so far as the separation of fractions *A* and *B* was concerned but the appearance of the column itself at the end of the experiment was not always the same.

To what causes these differences, not always of a minor character, are to be ascribed we do not know, but with experience it was found possible to recognise and separate the important sections of the column. The fractions of oxide were separately eluted with 80/20 methyl alcohol-ether.

The amount and characteristics of the fractions obtained in the actual experiment we have described are given below in Table I.

Table I.

Fraction	Appearance	Wt. (g.)	Iodine value	Biological activity	Spectroscopic examination max. at $m\mu$
A	Clear, pale lemon-yellow oil	6·23	64	—	388, 362, 337, 323, 289
B	Orange oil	3·97	235	—	485, 453, 362, 320, 289
C	Rich orange oil	6·97	200	Active 1 mg., slightly active 0·2 mg.	492, 303, 295
D	Soft red wax	6·16	216	Active 2 mg., slightly active 1 mg.	475, 445, 295
E	Dark brown-red crystalline mass	4·60	101	Slight activity 2·5 mg.	344, 327, 303, 297, 284, 273
F	Dark red, thick oil containing crystals	3·34	105	—	475, 445, 416, 347, 335, 320, 297, 284, 273

Fraction A. Superficial examination of this mixture suggested that it consisted for the greater part of hydrocarbons. It contained material precipitated by digitonin, the amount usually being about 3·5 %. This was removed before further fractionation was attempted by passing again through aluminium oxide. The latter treatment removed by adsorption a small amount of material with a high iodine value (see fraction *B*) and gave clear, pale yellow oils with iodine values in the range 40–50. This material seeming to be suitable for purification by distillation the latter was carried out (*a*) by the usual procedure at a pressure of 0·05 mm. and (*b*) by use of the Burch [1929] molecular still.[1] Even at the higher pressure (*a*) the material distilled readily. A typical distillation gave the following fractions:

(*a*) 2·1 g. distilled at 0·05 mm.

Temp. range	Wt. of fraction g.	Iodine value	Refractive index 18°	C %	H %
122–148°	0·861	39·4	1·5002	86·49	12·35
148–165°	0·779	37·7	1·5062	86·78	12·42
165–200°	0·359	46·7	1·5088	86·09	12·05
above 200°	0·079	69·0	—	—	—

(*b*) A fractionation of 4·35 g. in the molecular still (pressure *ca.* 0·00001 mm.).

Temp. range	Wt. of fraction g.	Iodine value	Refractive index 18°	C %	H %
55–69°	1·75	43·7	1·5009	86·64	12·16
69–120°	1·25	73·0	1·5059	86·06	12·44
above 120°	0·70	71·0	—	—	—

---

[1] We are much indebted to Dr F. H. Carr and Mr Jewell of B.D.H. Ltd. for carrying out this and a number of other fractionations in the molecular still. We greatly appreciate their valuable and ready help.

Inspection of these figures suggests a relatively low-boiling hydrocarbon contaminated with a less volatile oxygen-containing impurity possessing a higher degree of unsaturation and a higher refractive index. We have succeeded in obtaining after more than one distillation preparations of the former which gave satisfactory analysis.

The best material had the following properties:

B.P.	120–140° (0·05 mm.)	
Iodine value	42	
C %	87·02, 87·05	
H %	12·82, 12·96	
Mol. wt. (camphor)	258, 249	
Refract. index 18°	1·5009	
Absorption bands	336 $m\mu$	medium intensity
	326·5 ,,	very narrow
	301 ,,	inflection
	288 282 277 ,,	very weak and narrow
	257 ,,	broad and strong

The analyses would agree with a formula such as $C_{18}H_{32}$ (C, 87·09; H, 12·91 %).

Some or all of the members of this group of absorption bands appear to be always shown by these hydrocarbon fractions and it is of interest to note that they were also exhibited by a similar fraction obtained from olive oil by Thorbjarnarson and Drummond [1934]. It is possible that those with maxima at 336, 326·5 and 301 $m\mu$ may be associated with dihydroergosterol, although these bands do not correspond closely with the published figures.

Enough of this liquid hydrocarbon has not yet been available to enable us to examine its properties more fully.

In view of the discovery in fraction *B* of a highly unsaturated hydrocarbon of the squalene type it was thought at one time that the iodine value of preparations from fraction *A* might be due to contamination with this substance. An effort was made to separate the suspected contaminant by bromination and by treatment with HCl (see fraction *B*), but without appreciable success. Only very minute amounts of solid derivatives separated and on removing the halogens from the residues the iodine values remained in the neighbourhood of 35–40.

It would be inadvisable to comment further on this compound until larger quantities have been prepared and examined. The fraction was inactive as a source of vitamin E.

Fraction B. The constituents of this fraction passed slowly through the adsorbing column, visibly as a pale yellow zone, during the washing with light petroleum. The pigment was characterised by absorption bands in the visible spectrum at 453 and 485 $m\mu$. The position of these bands and the behaviour during adsorption suggest that the colour is due to kryptoxanthin[1] [Kuhn and Grundmann, 1933]. Absorption in the ultra-violet zone was indicated by maxima at 362, 325 and 289 $m\mu$. The intensities were usually of approximately the same order as that obtained in the examination of fraction *A*. The significance of these bands is as yet unknown.

This fraction was characterised by high iodine values, the range encountered in different experiments being 215–266. This fact, together with the low adsorbability of the fraction, suggested the presence of a highly unsaturated hydrocarbon. Attempts were made therefore to prepare halogenated derivatives. Bromination in dry ether at 0° gave a moderately good yield of a white micro-crystalline bromide resembling the bromides of the squalene type of hydrocarbon. This derivative darkened at 165° and showed definite signs of decomposing at 180°. It contained 69·2 % of bromine. Treatment with dry HCl gas in acetone at $-10°$ gave crystalline derivatives, the form of which usually recalled the prismatic plates of squalene hydrochloride. In a few cases however the typical plates did not appear and the form was that of bunches of very small fine needle-shaped crystals, more like the hydrochloride of the hydrocarbon isolated by Channon and Marrian [1926] from pig liver fat. Sometimes both types of crystals have appeared. Preparations of the hydrochloride recrystallised from acetone showed melting-points within the range 107–116°, but insufficient was available to enable an adequate fractionation to be carried out. Recent evidence [Thorbjarnarson and Drummond, 1934] supports the belief of earlier investigators that several isomeric squalene hydrochlorides with different melting-points exist.

---

[1] In a preliminary report of this work the pigment was described as β-carotene, the absorption bands of which correspond closely with those of kryptoxanthin [Drummond *et al.*, 1934].

The analytical figures for the hydrochlorides are also unsatisfactory. Squalene hydrochloride, $C_{30}H_{50}.6HCl$, has 33·9 % Cl; the hydrochloride of the liver hydrocarbon is probably $C_{45}H_{78}$, 8 HCl containing 31·2 % Cl [Channon *et al.*, 1934]. Various preparations of our hydrochloride gave 31·34, 31·39, 31·99, 32·08, 32·24, 32·79, 33·34 % Cl.

Until material is available for a more thorough study it is unwise to draw conclusions from these figures but they suggest the possibility that more than one hydrocarbon of the squalene type is present. It is not unreasonable to think that the liver hydrocarbon might be present in plant materials, particularly since squalene has recently been identified as an important constituent of olive oil.

Analysis of the crude fraction *B* having shown that considerable amounts of oxygen-containing substances were also present, even after removal of all material precipitable by digitonin, efforts were made to separate them from the hydrocarbon by the use of solvents and by fractional distillation. Neither was successful. Fractions were obtained with higher iodine values, the highest being 306 (squalene has I.V. 371), but analyses and the yields of hydrochloride and bromide showed that no effective concentration had been achieved.

Since it appeared that at least one of the oxygen-containing substances was highly unsaturated attempts were made to separate it on the assumption that it was alcoholic in character by acetylation and benzoylation. Evidence that reaction occurred was obtained, but no real success in separation was attained; once again our efforts being limited by the small scale on which we were obliged to work. Fraction *B* was found to be biologically inactive as a source of vitamin E.

Fraction C. The material yielded by elution of the lower zone of the adsorption column was in all experiments a deep orange-yellow viscous oil. The amount was usually of the order of one-fifth of the original material submitted to adsorption. When sterols had not been completely removed before the adsorption was performed as much as 15 % of material precipitated by digitonin was found in this zone. In such cases it was quantitatively removed before further fractionation was attempted. The sterol-free material behaved on general examination as if it were composed to a large extent of unsaturated alcohols of high molecular weight. The degree of unsaturation was indicated by iodine values ranging from 170 to 200. This fraction invariably showed a well-marked absorption band with a maximum at 294 $m\mu$ (Curve *A*, Fig. 2), to which we are inclined to attach importance. Related to this maximum is a minimum displayed at 267·5 $m\mu$, but in the examination of some preparations, particularly in the early stages of fractionation, this may be masked by general absorption. For a typical preparation of sterol-free material the measurements gave $E^{1\%}_{1\,\mathrm{cm}}$ 294 $m\mu = 27{\cdot}8$;

$267{\cdot}5\ m\mu = 17{\cdot}3$. Definite biological activity is found in this fraction, a daily dose of 0·2 mg. producing satisfactory litters. Since 1 mg. of the material before adsorption exerted about the same biological activity this indicates satisfactory concentration without significant loss.

Adsorption having proved so helpful and other methods of fractionation having given such disappointing results it was decided to carry the concentration as far as possible by use of aluminium oxide. Fraction *C* was therefore readsorbed from light petroleum solution, on appropriately smaller columns of the oxide. One unexpected observation was made. Whereas in the initial adsorption the biological activity was associated with the fractions more lightly adsorbed, in subsequent readsorptions it was usually found in fractions located higher up the column. After a third readsorption it appeared to be almost wholly concentrated in the top zone of the oxide and held there in spite of prolonged washing with solvent (see Fig. 1). Without doubt the position taken up by any substance in these adsorption columns is much influenced by the presence of other substances. In our experience it was the removal of the highly unsaturated substance described as being found in fraction *B* which rendered the vitamin more readily adsorbed by the oxide.

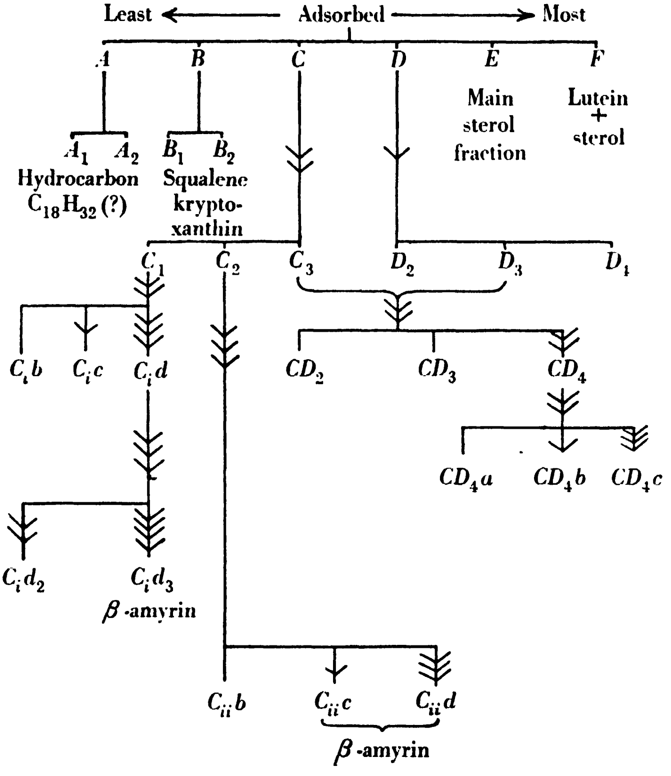

Fig. 1. General scheme of fractionation of wheat germ oil unsaponifiable. The "arrow-heads" indicate the fractions which contained the substance responsible for the 294 $m\mu$ band. An attempt to indicate the quantitative distribution has been made by using one to four "arrow-heads". In general the distribution of the vitamin is similar.

Biological activity having also been detected in fraction *D* (see later) and refractionation of this material being decided upon, it became necessary to combine certain fractions from the main fractions *C* and *D*. The scheme of separation is shown in Fig. 1.

From Fig. 1 it will be seen how curiously the active material changes in its behaviour from being adsorbed at the bottom of the column to being readily held up by the uppermost layers of the oxide.

At the stage of fractionation represented by the fractions 75 $C_i d$ and 75 $C_{ii} d$, the biological activity was found to be represented by the minimum daily dose of 0·1 mg. This corresponds satisfactorily with the factor of concentration represented by the material yields. Further attempts at concentration were disappointing. Fractions 75 $C_i d_2$ and 75 $C_i d_3$ were not found active in 0·1 mg. but a hydrogenated preparation of the former was found active in doses of 0·2 mg.; unfortunately, this material was not tested in smaller doses.

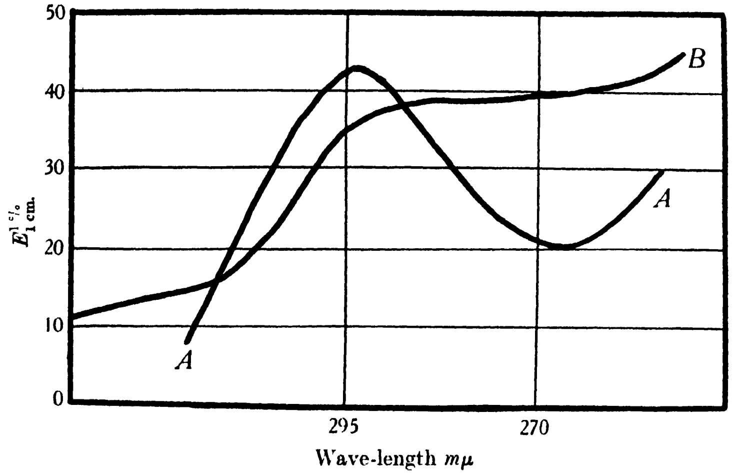

Fig. 2. Influence of 12 hours' short range irradiation by a mercury vapour lamp on the absorption band of an active vitamin E concentrate. Little change in the absorption at the maximum at 294 *mμ* but a great decrease of the "persistence" are regarded as evidence of considerable reduction in the concentration of the substance responsible for the band (see p. 465). (*A*) Original material. (*B*) Irradiated material.

A general parallel was noted between biological activity and the intensity of absorption in the ultra-violet region at 294 *mμ*, particularly when this was measured in relation to the minimum at 267·5 *mμ*.

In attempting to find a correlation between the biological activities of our concentrates and their absorption measurements we found it important to consider this relation rather than the individual values for $E^{1\%}_{1\,\mathrm{cm.}}$. In general, the substance responsible for the selective absorption at 294 *mμ* will be contaminated by other absorbing materials. Removal of these latter often causes a decrease in the measured maximum of absorption, but also causes a decrease (to a proportionately greater extent) in the absorption at the minimum of the band.

We have therefore been concerned with two criteria in considering the effect of concentration of the substance responsible for the band: (i) increase in absorption at the maximum and (ii) "persistence", which we describe as the ratio of maximum to minimum absorption. We are inclined to consider that this ratio provides a better estimate of the effect than the difference between maximum and minimum absorption.

Certain data for four of the more powerfully absorbing fractions obtained are set out in Table II.

Table II.

Fraction	Iodine value	Absorption $E^{1\%}_{1\,\text{cm.}}$ 294 $m\mu$	Absorption $E^{1\%}_{1\,\text{cm.}}$ 267·5 $m\mu$	Ratio 294/267·5	Optical rotation approx. 1·5 % in benzene $[\alpha]^{18°}_{D}$
75 $C_{ii}d$	167	42·6	20·0	2·13	+20·0°
75 $C_{i}d_{3}$	177	39·6	20·4	1·96	+16·2
75 $C_{i}d_{3b}$	164	40·9	12·8	3·18	+22·6
75 $C_{i}d_{3c}$	141	45·0	17·6	2·56	+18·0

Investigation of the nature of these active fractions led in due course to acetylation which immediately revealed that they were not homogeneous. Variable amounts of a beautifully crystalline acetate were obtained, some of the higher yields being as much as 15 %. The acetate was slightly soluble in methyl and ethyl alcohol, more readily in ether and chloroform. Recrystallised from acetone or ethyl alcohol it melted sharply at 236°. (Found: C, 81·59, 81·24; H, 11·10, 11·26 %; mol. wt. 442, 455; $[\alpha]^{18°}_{D}+97·3°$.) Determination of acetyl value showed the presence of one acetyl group. The parent alcohol crystallised in fine needles from ethyl alcohol, M.P. 190°. (Found: C, 84·57, 84·52; H, 11·66, 11·70 %; mol. wt. 427, 430; $[\alpha]^{18°}_{D}+97·7°$.) It appeared certain from this data that the substance was β-amyrin, $C_{30}H_{50}O$.[1] Mixed melting-point determination with pure specimens of the parent substance and the acetate showed no depression. Spectroscopic examination showed that β-amyrin exhibits only very slight absorption in the vicinity of 284 $m\mu$ ($E^{1\%}_{1\,\text{cm.}}=1·0$) so that this substance is not responsible for the selective absorption shown by the active fraction. The acetate is no more transparent. It was also without biological activity in doses of 0·1 mg. daily. It is as yet too early to dismiss the possibility that β-amyrin is related to the vitamin E activity but animal tests on this substance itself have given negative results.

Acetylation of our active fraction also threw light on another interesting matter concerning the vitamin. It will be recalled that other investigators are not in agreement regarding the effect of this treatment. Olcott did not confirm Evans and Burr's observation that destruction of biological activity followed treatment with acetic anhydride. He noted, however, that it caused a change of the absorption in that the maximum moved from 294 to 281 $m\mu$. He does not mention the relative intensities but he is inclined to use these observations as support for concluding that the former band is not connected with the vitamin content.

We have found that selective absorption disappears on acetylation and reappears on hydrolysis but biological activity is unaffected. We have as yet insufficient data to give us confidence, but we are inclined to believe that immediately after hydrolysis the 294 $m\mu$ band may reappear with an intensity greater than that shown by the material before acetylation. The position of the band and its intensity are not incompatible with the substance being a polycyclic ketone. Apart from this question the disappearance and regeneration of the band suggest that the responsible structure may be one capable of undergoing tautomeric change.

---

[1] Mr F. A. Askew has very kindly examined this compound by the surface film technique and is satisfied that it behaves in a manner similar to what would be expected from a very slightly impure β-amyrin [Askew, 1935].

Susceptibility to ultra-violet radiation. If the absorption band at 294 $m\mu$ is a property of the vitamin, it would be expected that radiation at the appropriate frequency would result in photochemical change, and that changes occurring in the absorption spectrum would be accompanied by corresponding changes in vitamin activity. Evans and Burr [1927, 1] found signs of loss of biological activity after short range exposure to ultra-violet radiation for 20 minutes at 0° and definite destruction after 45 minutes at ordinary temperature. Our preliminary experiments with a relatively crude preparation (55 F) indicated an even greater degree of stability. This preparation before radiation was biologically active in doses of 0·2 mg. daily. 0·33 g. of the preparation contained in a quartz flask and sealed under nitrogen was exposed to the direct rays of a mercury arc lamp (atmospheric type) at a distance of 3 inches for 13·75 hours. The activity was not completely destroyed, since 5 out of 6 rats produced litters on a daily dose of 1 mg. A dose of 0·4 mg. was inactive.

A definite change in absorption spectrum was observable. The intensity of the original material at 294 $m\mu$ was $E^{1\%}_{1\,\text{cm}} = 48{\cdot}2$ and the persistence (see p. 463) 1·74. After irradiation the intensity maximum remained constant ($E^{1\%}_{1\,\text{cm}} = 47{\cdot}8$) but the persistence had decreased to 1·33.

A more highly refined preparation (75 $C_{ii}d$), originally active in 0·1 mg. dose, lost at least half its activity after direct exposure under similar conditions for 12 hours. In this experiment the change in absorption spectrum was considerable (see Fig. 2), the band having disappeared almost completely after irradiation.

Influence of hydrogenation on vitamin E activity. Evans and Burr [1927, 1] found that wheat germ oil and extracts prepared therefrom retained their vitamin E activity after hydrogenation with palladium at 75°. Olcott [1934, 1, 2] found that active fractions withstood drastic catalytic hydrogenation at 200° and 200 atmospheres but were still unsaturated, as indicated by an iodine value of 70.

Our own experience confirms the survival of biological activity after catalytic hydrogenation but we found no difficulty in obtaining a more satisfactory uptake of hydrogen. One of our most active fractions (75 $C_{ii}d$) was reduced with palladium at atmospheric temperature and pressure, the concentrate being dissolved in absolute alcohol. In one experiment 138 mg. of this golden yellow viscous oil took up hydrogen readily under these conditions, the iodine value falling from 166 to 26 in about 5 hours with one renewal of the catalyst. Difficulty was encountered in carrying the hydrogenation further and it is possible that the residual iodine value represented an unsaturated impurity resistant to reduction. The amounts of material available did not enable us further to investigate this matter. The hydrogenated material was a soft white wax with an indefinite melting-point about 35°. The biological activity was unaffected by the reduction, good litters being obtained with a dose of 0·2 mg. The examination of the material before and after reduction showed that the absorption band had been but slightly changed, apart from a very slight shift towards the more refrangible region, the maximum and minimum being now at 296·5 and 271 $m\mu$ respectively (Table III).

Table III.

Condition	Iodine value	Absorption $E^{1\%}_{1\,\text{cm.}}$		Ratio	Positive rat dose
Original	166	294	42·6	2·13	0·2 mg.
		267	20·0		
Partly reduced	70	296	40·2	2·58	—
		268·5	15·6		
Maximum reduction achieved	26	296·5	37·8	2·52	0·2 mg.
		271	11·0		

Unfortunately, we have not had sufficient reduced material to make it possible seriously to attempt chemical fractionation but a few preliminary trials have given encouraging results.

Chemical composition of the active fractions. We have thought it worth while to make a few analyses of our most active fraction although we are fully aware that they may have been far from homogeneous. These materials are yellow and somewhat viscous oils. The analytical data are given below:

	C %	H %	Mol. wt. (camphor)	Iodine value
	80·77	11·44	460	164
	81·12	11·66	430	179
	81·16	11·56	420	166
	80·62	11·61	445	162
	80·82	11·64	—	167
Mean	80·89	11·58	439	167

The material acetylates with the introduction of one acetyl group. It will be remembered that we found that the band at 294 $m\mu$ disappeared as a result of this change and was again exhibited by the material after hydrolysis. Analyses of the acetylated product gave:

	C %	H %	Mol. wt. (camphor)	Iodine value
	78·33	10·70	480	160
	78·55	10·85	440	156
	78·36	10·41	476	—
Mean	78·41	10·65	465	158

Determination of acetyl groups.[1]

(*a*) 0·1197 g. contains 0·223 milliequiv. acid.
(*b*) 0·113 g. „ 0·230 „

On the assumption that our material is homogeneous these analytical figures would agree reasonably well with a polycyclic structure related to the sterol or amyrin class.

	C %	H %	Mol. wt.	Iodine value (3 double bonds)
$C_{28}H_{48}O_2$	80·76	11·53	416	183
$C_{30}H_{50}O_2$	81·44	11·31	442	172

It will be recalled that the analyses of the distilled fraction of Evans and Burr [1927, 1] fitted the formula $C_{36}H_{64}O_2$. Regarding the degree of unsaturation it may be noted that the volume of hydrogen absorbed was of the order required to saturate three double bonds. Again assuming homogeneity, the formulae indicate the presence of two oxygen atoms in the molecule. On the spectroscopic evidence one of these might represent a ketonic grouping capable of tautomerising and yielding an acetylated derivative on treatment with acetic anhydride. If so, the second oxygen is present either as a relatively stable ketonic group or in another form not reacting to acetylation.

Again with reservations regarding purity the view that a polycyclic ketone may be concerned is not at variance with the evidence derived from a study of surface films which is presented by Askew [1935]. His data suggest that if the substance contains two polar groups they are probably close together in the molecule.

---

[1] We are greatly indebted to Dr A. H. Palmer for making these determinations.

In order to test for the presence of ketonic substances in the active concentrates two methods of fractionation were investigated. One has been devised by Girard [1933] but as the nature of his reagent has not yet been fully revealed this could not be investigated without his assistance. Dr Girard was kind enough to carry out for us an extraction depending upon the use of his "Reagent T". He informs us that under the conditions of his reaction all ketones except the "aromatic nuclear ketones" are converted into water-soluble derivatives which can be readily separated from impurities soluble in ether and other fat solvents. When ketones are thus abstracted in water-soluble form the solutions give a precipitate with mercuric iodide; the reaction being so sensitive that it will detect 1 or 2 γ per ml. of oestrone. Approximately 1 g. of sterol-free wheat germ concentrate was sent to Dr Girard for treatment. He reported that the extraction and separation of the ketonic fraction did not proceed altogether smoothly. From the behaviour with HgI_2 he was inclined to think that only small amounts of ketonic substances were present. "If the molecular weight of the ketones present is about the same as that of oestrone I would consider the total amount of the ketones as not greater than 10 to 15 mg." Actually, the extracted material, a pale yellow, soft wax, weighed 10 mg. (1·0 %).

This material gave disappointing results on spectroscopic examination for no evidence of significant concentration of the substance responsible for the 294 $m\mu$ band was obtained.

Material before treatment	Inflection 294 $m\mu$ $E^{1\%}_{1\,\text{cm.}}=46$
"Ketonic" fraction	,, 294 $m\mu$ $E^{1\%}_{1\,\text{cm}}=45$
Residue after removal of "ketonic" fraction	,, 294 $m\mu$ $E^{1\%}_{1\,\text{cm}}=30{\cdot}8$

The extracted material has not yet been tested biologically.

Another attempt was made to separate ketones by the method fully described by Beall and Marrian [1934]. This was applied to two active fractions:

(*a*) a sample of the sterol-free unsaponifiable fraction similar to that which had been treated by Dr A. Girard;

(*b*) a more highly concentrated preparation (75 $C_{,,}d$).

In both cases the yield of ketonic substances was small, whilst the spectroscopic examination gave no evidence of effective concentration (Table IV):

Table IV.

	Material	Wt. g.	$E^{1\%}_{1\,\text{cm}}$ 294 $m\mu$	$E^{1\%}_{1\,\text{cm}}$ 268 $m\mu$	Remarks
a	Before treatment	2·268	46·9	32·7	Persistence (ratio) 1·4
	"Ketonic" fraction	0·206	21·6	—	Inflection slightly better defined than in "non-ketonic" fraction
	"Non-ketonic" residue	1·997	26·8	--	Very weak inflection
b	Before treatment	0·098	42·6	20	Persistence (ratio) 2·13
	"Ketonic" fraction	0·0035	43	—	Inflection only
	"Non-ketonic" residue	0·086	35	—	Bands of low persistence

Whether these "ketonic" extracts contain a high concentration of the vitamin has not yet been ascertained, but it is difficult to reconcile the relevant spectroscopic data with the view that the active substance is a polycyclic ketone normally showing a broad strong absorption band at 294 $m\mu$.

The pigment responsible for the yellow colour of fraction *C* was not satisfactorily identified. The band at 492 $m\mu$ (alcohol) indicates a lipochrome; probably a trace of γ-carotene or rubixanthin.

The substance responsible for the maximum at 303 $m\mu$ was not traced.

Fraction D. Spectroscopic examination of this soft red wax showed the presence of a lipochrome pigment resembling lutein. The only other important absorption was at 295 $m\mu$ in the ultra-violet. Since this fraction showed biological activity its investigation proceeded in the main side by side with that of fraction *C* (see Fig. 1). It contained about 33 % of the familiar sterol mixture in all cases in which this material had not been removed before adsorption. In the examination of this fraction some evidence of the presence of phytol was obtained by the preparation of phthalates but the amounts of silver derivatives isolated were too small to purify and analyse.

Fraction E. In all cases in which sterols were not completely removed by digitonin before adsorption this fraction contained the highest proportion of these substances. The appearance of the material in such cases clearly indicated its composition, as it usually resembled a crude preparation of phytosterol coloured with a brownish yellow pigment. The latter was identified as lutein. Quantitative estimations showed from 80 to 89 % of sterol precipitable by digitonin.

By recrystallisation from methyl alcohol or light petroleum clean preparations of crystalline sterol mixtures (phytosterol) were readily made. Spectroscopic examination of this material revealed bands at 342, 328, 294, 283, 272 and 262 $m\mu$; that at 283 being strong. Edisbury [1933] has recorded rather feeble maxima at 312, 323 and 343 $m\mu$ in sterol fractions and thought they might be attributed to dehydroergosterol. Only one of these is recorded in our measurements. Other maxima are probably attributable to ergosterol. Fractional crystallisation of the sterol from methyl alcohol gave crystalline preparations from the more soluble fractions which showed clearly the ergosterol group of bands and the other triplet believed to be due to ergosterol D (254, 243 and 235 $m\mu$). In the less soluble fractions, as in the original material, general absorption tended to mask selective absorption in the shorter wave-length range.

Fraction F. This material, the most firmly adsorbed, was but superficially examined as it did not possess vitamin E activity. The pigment was almost certainly lutein. Considerable amounts of sterol (35 %) and the associated absorbing substances were also present.

Behaviour of the active fractions on distillation.

Some of the later stages of fractional adsorption having given disappointing results efforts were made to carry the concentration a step further by distillation in high vacuum. Unfortunately, the quantities of material available were so small that satisfactory fractionation could not be expected. The following results refer to the distillation of 1·35 g. of fraction 75 $C_i d_3$ which was believed to be biologically active in doses of 0·1 mg. daily. Dr Carr and Mr Jewell, who very kindly carried out the fractionation of this material in a Burch molecular still, reported that "no sign of a constant-boiling fraction could be observed".

The fractions were examined with the following results (Table V).

On the assumption that the persistence of the 294 $m\mu$ is a measure of vitamin activity fraction 2 from the distillation should have been the most potent material we have possessed. Unfortunately, the biological tests were inconclusive owing to a large proportion of the animals showing infertile matings. Two

Table V.

				$E^{1\%}_{1\ \text{cm.}}$		Ratio
Fraction	Temp.	Wt. g.	Iodine value	294	267	294/267
1	76–103°	0·3	169	13·5	8·16	1·65
2	96–127°	0·45	164	40·9	12·8	3·18
3	123–180°	0·45	151	45·0	17·6	2·56
4	>180°	0·1	—	—	—	—

typical resorptions on a daily dose of 0·1 mg. of fraction 2 make us fear, however, that the material was not as potent as our interpretation of the spectroscopic data had led us to expect.

Discussion.

Most of the work reported in this paper must be regarded as of a preliminary nature and at this stage it is impossible to consider the results from the standpoint of the chemical identity of vitamin E. If we were certain that the intensity of selective absorption at 294 $m\mu$ were a measure of vitamin E potency the problem would be greatly facilitated, but unfortunately at the moment there are discrepancies which make us hesitate to conclude that such is the case. In general we have found that biological potency and absorption at 294 $m\mu$ run parallel during the fractionation, and the results with irradiation and hydrogenation can be reconciled with the view that the vitamin is a substance showing selective absorption at this region of the ultra-violet.

There are, however, other observations, such, for example, as the apparently low biological activity of a distilled fraction showing relatively high intensity of absorption, which make us cautious. The difficulties are in many respects similar to those which were encountered in the early days of the investigation of vitamin A and the most serious one is the absence of any criteria of purity. The information we have obtained does not enable us to say whether our most highly active fractions represent nearly pure vitamin E or whether they are composed of a biologically inert substance in a state of comparative purity contaminated with a small amount of highly active vitamin.

We are inclined to think that our most potent fractions consist to a large extent of one substance. It is true that the evidence from fractional distillation experiments does not support this view, but the amounts subjected to fractionation by this method were so small that too much weight must not be attached to the results.

The analytical data recorded for this active fraction must also be accepted with reserve, until more definite information is forthcoming to show whether or not the material is reasonably homogeneous.

Our studies provide further confirmation of the relative stability of vitamin E. Of its chemical nature we can say little beyond expressing an opinion that it may prove to possess a polycyclic nucleus. We are inclined to dismiss the suggestion put forward by Euler *et al.* [1933] that it may be related to xanthophyll. The vitamin is probably a colourless substance or one showing very slight absorption in the visual spectrum.

Summary.

1. An examination of the unsaponifiable fraction of wheat germ oil has been made with the object of throwing light on the chemical nature of vitamin E.

2. The following substances have been isolated from or detected in this material: sitosterol, dihydrositosterol, ergosterol, dihydroergosterol, lutein, kryptoxanthin, β-amyrin, squalene, a second hydrocarbon of the squalene type,

possibly identical with that found by Channon and Marrian in mammalian livers, a new liquid hydrocarbon which may have the composition $C_{18}H_{32}$ and a lipochrome which may be γ-carotene or rubixanthin. None of these substances appears to be related directly to the vitamin activity.

3. Fractional adsorption on aluminium oxide was found to effect a considerable concentration of vitamin E. The most potent fraction obtained was physiologically active in rat tests in doses of 0·1 mg. daily.

4. The most active fractions were pale yellow and somewhat viscous oils. In the absence of any criteria of purity it is worth recording that analyses of several such fractions show reasonably good agreement, the analytical data indicating a polycyclic structure possibly related to the sterols or amyrins. Two oxygen atoms are present in a molecule of mol. wt. about 440. One of these forms an acetyl derivative but the spectroscopic evidence suggests that the reacting grouping may be keto-enol. If so, the second oxygen is present in a form which does not react with acetic anhydride. The reactions with iodine and hydrogen suggest that three reacting double bonds are present. Whether these observations concern the vitamin itself or another substance which forms the greater part of the active fractions is as yet unknown.

5. The active fractions show a well-marked absorption band with a maximum at 294 $m\mu$ and a minimum at 267 $m\mu$. So far as this investigation has progressed it has shown that the vitamin activity tends to run parallel with the intensity of this band or, more particularly, with its "persistence". It is not yet finally determined whether the band is a characteristic of the vitamin or of an associated substance, but it is significant that with ultra-violet irradiation the reduction in "persistence" is accompanied by loss of biological activity, whereas treatment with hydrogen and palladium, which effects almost complete saturation of the material of the active fraction, does not appreciably lower either the "persistence" of the band or the value as a source of vitamin E.

6. The absorption band at 294 $m\mu$ disappears on acetylation but is shown again by the hydrolysed acetate. As other investigators have noted, biological activity is unaffected by acetylation. The position of the absorption band and its disappearance on acetylation are compatible with the substance containing a ketonic grouping capable of exhibiting tautomeric change.

7. Attempts were made to separate the ketonic substances present in the active fractions in the form of water-soluble mercury complexes. Small yields of "ketonic" material were obtained. These showed no concentration of the substance responsible for the 294 $m\mu$ band.

The authors wish gratefully to acknowledge a grant from the Medical Research Council from which the greater part of the cost of this investigation was defrayed. Messrs Imperial Chemical Industries are also thanked for a personal grant to one of us (E. S.). Valuable assistance was also given by Messrs Vitamins, Ltd., who provided a considerable supply of appropriate wheat germ (Bemax) as well as a contribution towards the general expenses.

It is desired, furthermore, to record appreciation of the help of Mr L. B. Holt, who extracted for us considerable quantities of wheat germ oil and prepared the unsaponifiable fraction.

LIII. SURFACE FILMS OF VITAMIN E CONCENTRATES.

By FREDERIC ANDERTON ASKEW.

From the Sir William Ramsay Laboratories of Inorganic and Physical Chemistry, University College, London.

(*Received December 31st, 1934.*)

CERTAIN preparations described in the preceding paper [Drummond *et al.*, 1935] were examined by the method of surface films, with the object of obtaining information about their molecular structure. The substances examined included an oil concentrate rich in vitamin E, and the crystalline substance M.P. 190° (from acetate M.P. 236°, from E-active fractions 3 and 4).

The substances were spread on the surface of $N/50$ HCl and the surface pressures were measured by the method of Adam and Jessop [1926; Adam, 1930] and the surface potentials by the method of Adam and Harding [1933].

Vitamin E-active oil.

This substance, spread from benzene solution, gave the curve shown in Fig. 1, in which surface pressures are plotted as ordinates and values of area/molecule in sq. Å. as abscissae. The latter were calculated on the assumption that the solute spread consisted of a substance with mol. wt. = 390. Fig. 1 also shows the relation between surface potentials and area, and values of μ calculated from the equation

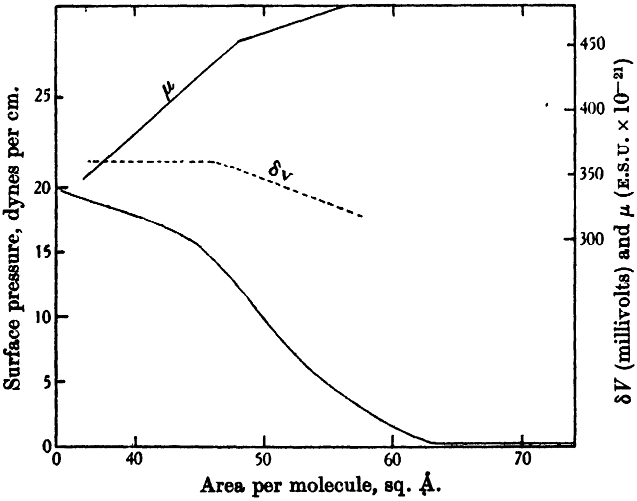

Fig. 1.

$$\delta V = 4\pi n\mu,$$

n being the number of molecules per sq. cm. μ measures the effective vertical component of the dipole moment of the molecule at the corresponding compression.

The surface pressure-area curves are consistent with the view that the substance is polycyclic, with a water-attracting group at or near one end of the molecule. The relatively high compressibility of the film and the limiting area of 63 sq. Å. are similar to those of ketones of the sterol series (*cf.* cholestenone [Rosenheim and Adam, 1929]). If more than one polar group is present in the molecule, it is unlikely that they are far apart in the molecule. If this were so, one would expect the molecule to lie flat on the surface and give a film of the gaseous type (*cf.* pregnandiol, pregnandione, oestrone derivatives [Danielli *et al.*, 1933]).

The films of this substance collapsed when the surface pressure was greater than about 15 dynes/cm.; this collapse was reversible and examination of the films under the ultra-microscope by the method of Zocher and Stiebel [1930] showed the appearance of numbers of fine droplets at about this pressure. The films were unusual in that the reversible collapse was accompanied by a rise in surface pressure; this might be due to the presence of a less readily collapsing impurity. The possibility that the upper flattened portion of the curve was due to a transition between liquid expanded and condensed states was further excluded by measuring the surface pressure at a low temperature (1·5°), which resulted in a curve similar to the one obtained at room temperature (15°).

The moderate changes of surface potential and μ over the unimolecular portion of the film (below 15 dynes/cm.) indicate that only small alterations in the tilt of the molecule and the adhesion of the polar groups to the water took place on compression; beyond this point, where collapse occurred, μ appeared to fall more rapidly, but this was probably due to the area assumed in calculating μ being too small, owing to collapse.

Crystalline substance; M.P. 190°.

This substance on the surface of $N/50$ HCl gave the rather compressible solid film shown in Fig. 2, curve I. Extrapolation to zero pressure gave a limiting area of 47·6 sq. Å. On first compression the film contracted, but above 3 dynes/cm. pressure it formed a stable solid film. The values of surface potential and μ are also shown in Fig. 2.

The data suggest a polycyclic structure with the water-attracting group near one end of the molecule. The limiting area is much in excess of that required for long-chain compounds or terminal groups such as phenol or hexahydrophenol; on the other hand reduced polycyclic structures such as sterols give curves showing limiting areas ranging from 38 sq. Å. upwards, according to the position of the water-attracting group. Among compounds of this type, cholestane-6-ol shows an area of 48 sq. Å. and its surface pressure curve is similar to that of the crystalline substance obtained from vitamin E preparations. The surface potential is somewhat lower.

The empirical formula ($C_{30}H_{50}O$) for the crystalline substance is the same as that of the amyrin series of compounds. These substances are known to be polycyclic, probably containing five rings, and have a hydroxyl group in a position not yet definitely ascertained [Ruzicka *et al.*, 1929; Spring, 1933]. As has been shown in the preceding paper [Drummond *et al.*, 1935] the melting-points of the crystalline vitamin E derivative and its acetate closely correspond with those of β-amyrin. Accordingly, the surface properties of a specimen of β-amyrin were investigated. The results are shown in Fig. 2. On first compression the film showed marked contraction; this effect was similar to that observed with the crystalline substance itself, but occurred to a much greater extent. The initial course which the curve tended to follow is shown as curve III A in Fig. 2. The film rapidly rearranged to give a stable solid film (curve III), rising fairly steeply and tending to a limiting area at zero compression of 47 sq. Å. This initial contraction and rearrangement to give a solid film is common to several substances of the amyrin group (Askew; unpublished measurements).

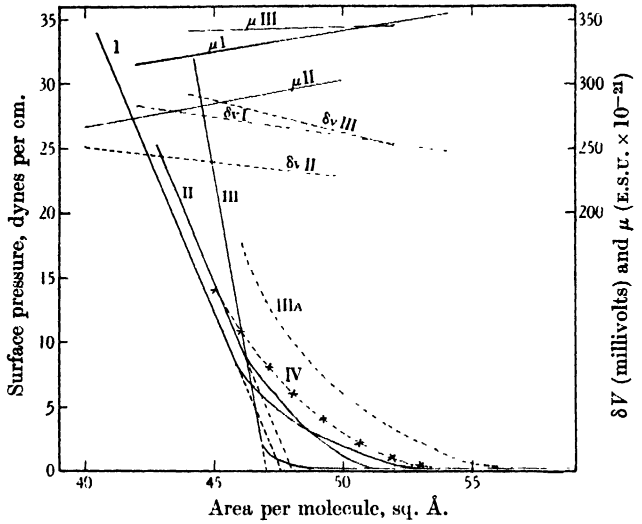

Fig. 2. I. Crystalline substance. II. Cholestane-6-ol. III. β-Amyrin (contracted film). III A. β-Amyrin (initial film). IV. Combined curve, 80 % β-amyrin, 20 % vit. E oil.

The surface pressures of the two substances, although they approach approximately the same limiting areas, differ in two respects: (a) that of β-amyrin is much steeper, (b) it shows the rearrangement phenomena to a much more marked extent. In view of the similarity of the other properties of these two substances and the similarity of their limiting areas, experiments were performed to see whether these differences could be accounted for by impurities in the specimen of the crystalline substance. A mixture of 80 molecules % of β-amyrin and 20 molecules % of the vitamin E-rich oil was spread on the same surface. The resulting curve is shown as curve IV, Fig. 2. The tendency to form a contracting film was greatly diminished, and the slope of the curve approximated to that of the crystalline substance. Hence it appears that the properties of these substances may be greatly modified by the presence of impurities, and a more complete check on the identity of the crystalline substance with β-amyrin awaits the preparation of larger quantities of purified material. At present it can be stated that the substance almost certainly has a polycyclic structure, akin to that of the sterols, with a polar group, most probably a hydroxyl group, near one end of the molecule; that it closely resembles in some of its surface properties substances of the amyrin type, and that the surface data are consistent with the view that the substance is β-amyrin. The surface potentials of the crystalline substance and β-amyrin were of the same order of magnitude, but that of the latter appeared to rise more steeply; this is however uncertain, owing to the tendency of the film to rearrange in the initial stages of compression. The rearrangement was not accompanied by large changes in surface potential.

SUMMARY.

A concentrate rich in vitamin E and a crystalline substance derived from vitamin E preparations have been examined by the method of surface films.

Both substances appear to have condensed polycyclic structures.

The possibility that the crystalline substance is identical with β-amyrin is discussed in the light of surface film data.

The author wishes to express his thanks to Prof. J. C. Drummond for specimens of the substances investigated, to Dr N. K. Adam for much helpful advice and to the Medical Research Council for a maintenance grant.

LIV. COPPER METABOLISM IN MAN.

By TUNG-PI CHOU and WILLIAM H. ADOLPH.

From the Department of Chemistry, Yenching University, Peiping, China.

(*Received December 17th, 1934.*)

Recent experiments have shown the importance of copper in haemoglobin formation in the animal body, and the wide distribution of copper in plant and animal material has been repeatedly confirmed. There is a lack of quantitative data however on copper metabolism. We have conducted balance experiments with the object of estimating the copper requirement of man, and in addition we have undertaken copper analyses of human cadavers for the purpose of estimating the total copper content of the human body.

Copper metabolism in normal subjects.

Copper balance experiments were carried out during the late spring and early summer on three different subjects, all Chinese, who consumed simple diets of measured copper content. The copper content of Chinese food materials has been reported elsewhere by Adolph and Chou [1933]. White flour (steamed bread) and milk with a small quantity of vegetables were employed for the low copper diet. An increased copper intake was arranged by replacing the milk with increasing amounts of spinach and pork. Copper was determined in food, urine and faeces by the Biazzo method as modified by Elvehjem and Lindow [1928].

Series 1, in which the copper balance was determined on a subject daily for four successive days, was carried out for the purpose of determining how rapidly the body adjusted itself to altered copper intake. Results are shown in Table I. As a result of this preliminary experiment, it was proposed to employ 2- and 3-day metabolism periods in the series following.

In Series 2, three subjects consumed prescribed diets of increasing copper content over four periods. Each period consisted of 4–6 days, the four periods following each other without interval. The metabolism measurements involving the collection of urine and faeces were confined to the last 3 days and in some cases to the last 2 days of each period. Faeces markers were used and the usual precautions in conducting metabolism balance experiments were observed. The iron intake was not controlled.

The urine and faeces were collected directly in glass or porcelain receptacles. The faeces for each collection period were dried over sulphuric acid and ground in a porcelain mortar. For the analyses, 400 ml. samples of urine were evaporated to a volume of 30–40 ml. and then digested with 40 ml. of sulphuric acid in a Kjeldahl flask till colourless. The dried faecal material was treated in a similar manner. The resultant digest was then transferred to a volumetric flask and diluted so that the acid concentration was about 1 %. In carrying out the analyses the copper was separated from iron by precipitation with hydrogen sulphide, with subsequent determination of the copper in the precipitate as outlined by Elvehjem and Lindow [1928]. All analyses were carried out in duplicate.

Table I. *Copper metabolism in man; intake and output averaged in mg. Cu per day.*

Series 1.

Subject	Sex	Age	Weight kg.	Period	No. of experimental days	Cu intake mg.	Cu output (mg.) Urine	Faeces	Total	Balance
A	F	36	45·5	I	1	0·66	0·27	2·08	2·35	-1·69
				II	1	0·51	0·16	2·43	2·59	-2·05
				III	1	1·72	0·23	1·92	2·15	-0·43
				IV	1	2·17	0·27	1·22	1·49	+0·68
Series 2.										
A	F	37	46·5	I	3	0·67	0·21	1·19	1·40	-0·73
				II	3	2·07	0·23	1·67	1·90	+0·17
				III	2	3·40	0·33	4·49	4·80	-1·42
B	M	17	30·2	I	2	1·11	0·20	1·72	1·92	-0·81
				II	3	1·28	0·18	1·81	1·99	-0·71
				III	3	2·63	0·27	1·84	2·11	+0·52
				IV	2	3·69	0·31	6·41	6·72	-3·03
C	F	62	41·2	I	3	1·09	0·15	1·58	1·73	-0·64
				II	3	2·38	0·27	2·14	2·41	-0·03
				III	2	2·85	0·36	2·37	2·73	+0·12
				IV	2	3·39	0·30	2·43	2·73	+0·66

The results, shown in Table I, indicate that equilibrium was reached when the copper intake was about 2 mg. per day.

Copper content of the human body.

Material from five cadavers, all Chinese, two being adults, was obtained from the Department of Pathology of the Peiping Union Medical College, and analyses made of muscle, liver, heart *etc.* In preparing the material for analysis, the tissues were first washed free from blood and the weighed samples then dried in an electric oven at 60° and ashed in an electric furnace at as low a temperature as possible, and the estimation of copper was carried out by the Biazzo method as for food materials. The results are shown in Table II. In Table III, using the data from the two adult cadavers, figures are calculated for the copper content of each tissue, and also for the total copper content of the body. The copper content of blood is estimated at 5 mg. for the entire body.

Table II. *Distribution of copper in tissues of the human body (amounts expressed in mg. per kg. of dry material).*

DISCUSSION.

The copper balance experiments indicate that equilibrium was reached when the copper intake was approximately 2 mg. per day, and we suggest that this figure represents the daily copper requirement in man. A consideration of the copper content of common foodstuffs, which ranges from 2 to 25 mg. per kg. of dry material, indicates that the average mixed diet readily supplies this amount of copper, particularly if it contains a liberal amount of spinach and similar leafy vegetables.

Inasmuch as copper appears to be associated with iron in haemoglobin formation, it is interesting to compare this figure for copper requirement, 2 mg. per day, with the accepted requirement for iron in man, 15 mg. per day [Sherman, 1932], iron and copper standing in the ratio 7 : 1. Iron and copper requirements per day for the white rat have been accurately determined on the basis of haemoglobin recovery experiments by Hart *et al.* [1928] and Waddell *et al.* [1928], who give the figures 0·5 mg. and 0·06 mg. respectively for iron and copper; these represent an iron-copper ratio of 8 : 1. This ratio is almost identical with that above, and suggests that the outstanding rôle of iron and copper in the human body is expressed in the haemopoietic function.

From the copper balance experiments it is evident that in man copper is mainly excreted through the faeces. This was shown by Filehne [1896] to be the case with dogs and cats, and by Flinn and Inouye [1928] and Lindow *et al.* [1929] to hold also for rats. It is important to note that in spite of changes in the copper intake, our figure for urinary copper remains fairly constant, varying between the limits 0·15 and 0·36 mg. (average 0·25 mg.) per day. Rabinowitch [1933] has recently reported values ranging between traces and 0·7 mg. per day for urinary copper in normal man. The excretion of faecal copper is more irregular, and with two of our subjects a further increase in copper intake was accompanied by a pronounced negative balance and by an apparent breakdown in the storage supply.

Our calculated figure, 115·9 mg., for the copper content of the adult body can be regarded only as a rough estimate. If brain, skin, and other tissues are included this figure should be increased, and it is probable that the total copper content is between 100 and 150 mg. The copper stored in the body is found mainly in the liver, muscles and bones. Our results for copper determinations in adult tissues are slightly higher than those reported by Cunningham [1931].

The higher percentage copper content of certain of the tissues of the two infant cadavers studied is rather marked. A reserve supply of copper in the livers of the newborn has been reported by a number of observers, and discussed by Morrison and Nash [1930], Nitzescu [1931], and Cunningham [1931]. It appears that in certain mammals, including human beings, a reserve storage of both iron and copper is provided to the newborn to insure adequate haemoglobin formation. Cadaver 2, a case of anaemia, exhibits a much smaller amount of copper in the liver. A similar observation is recorded by Morrison and Nash [1930].

SUMMARY.

From copper balance experiments on three adult subjects fed with copper-containing foods, it is shown that the copper requirement in man is approximately 2 mg. per day.

The copper excretion in the urine of the normal individual does not vary appreciably with varied copper intake and averages 0·25 mg. per day.

From analyses of tissues, it is estimated that the adult body contains between 100 and 150 mg. of copper.

We wish to thank Dr C. H. Hu of the Department of Pathology of the Peiping Union Medical College for material used for analysis, and also the Department of Biochemistry of the same institution for laboratory facilities during part of the work.

LV. THE COPPER AND "INORGANIC" IRON CONTENTS OF HUMAN TISSUES.

By SIDNEY LIONEL TOMPSETT.

From the Biochemical Laboratory of the Institute of Pathology of the Royal Infirmary and University of Glasgow.

(*Received December 27th, 1934.*)

The present paper is concerned with the concentration of copper and "inorganic" iron in various tissues and bones of the human body and also with suitable methods for their determination.

COPPER.

Several writers have determined the distribution of copper in human tissues. Herkel [1930] obtained values of 2·88–12·9 mg. Cu per kg. fresh liver and ranged in descending order of concentration his results may be summarised as follows: liver, kidney, spleen, pancreas and bone. Cunningham [1931] found that the average concentration of copper in three human livers was 24·9 mg. per kg. of dry tissue and ranged in descending order of concentration his results may be summarised as follows: liver, kidney, brain, pancreas and spleen. Others have published analyses of single organs, especially the liver, which agree more or less with the analyses of the above two writers [Schönheimer and Oshima, 1929; Kleinmann and Klinke, 1930; Cherbuliez and Ansbacher, 1930; Gordon and Rabinowitch, 1933].

The majority of distribution studies such as these must almost necessarily be done with pathological subjects. In certain pathological conditions of the liver in the adult, there appears to be a very marked increase in the concentration of copper. This occurs often in both pigmented and non-pigmented cirrhosis of the liver [Schönheimer and Oshima, 1929; Cherbuliez and Ansbacher, 1930; Kleinmann and Klinke, 1930; Herkel, 1930]. Gordon and Rabinowitch [1933] in one case of yellow atrophy of the liver obtained the extraordinarily high value of 179·3 mg. copper per kg. fresh tissue. Herkel [1930] states that in haemochromatosis the concentration of copper is increased in all the organs, with the exception of the kidney and bone. The copper content of foetal organs appears also to be higher than in adults [Kleinmann and Klinke, 1930; Cunningham, 1931; Sheldon and Ramage, 1931]. Sheldon and Ramage [1931] report that five foetal livers examined by them contained 5–7 times the concentration of copper present in adult organs. In a survey such as is intended here, it will be necessary then to exclude foetal organs and organs from cases of liver disease.

The question of bone seems to have been neglected. Of the above-mentioned writers only Herkel [1930] and Sheldon and Ramage [1931] appear to have examined this material. The former, as a result of two analyses, obtained values of 3·7 and 4·03 mg. per kg. fresh material. Sheldon and Ramage state that bone contains only a trace of copper.

The various colorimetric methods for the determination of copper in biological material have been discussed elsewhere [Tompsett, 1934, 2]. With the exception of Sheldon and Ramage, who used a spectrographic method, the abovementioned analyses were obtained by modifications of the Biazzo method. The writer has found the method of Callan and Henderson [1929] as modified by

McFarlane [1932] to be the most sensitive and accurate. In this method sodium diethyldithiocarbamate is added to the solution under test, a yellow complex with copper is formed and this is extracted by shaking with amyl alcohol. The extract is compared in a colorimeter with a standard prepared similarly. This reaction, although independent of p_H, is carried out in alkaline solution in the presence of pyrophosphate to prevent interference by iron.

Methods.

Tissues. The following method is based on that used for blood and reported previously [Tompsett, 1934, 2].

A porcelain pestle and mortar and some broken glass were treated several times with hot dilute hydrochloric acid to render them copper-free. The tissue to be examined was cut up into small pieces and 10 g. ground up with the broken glass. About 40 ml. of 10 % trichloroacetic acid were added and the grinding continued. The supernatant fluid was filtered through an acid-washed filter-paper and the residue washed with 10 % trichloroacetic acid until the requisite volume of filtrate was obtained. Extracts of liver tissue were made up to 100 ml., while extracts of other organs were made up to 50 ml. The final estimation was made directly, using 20 ml. of extract with a standard containing 0·01 mg. copper as described for blood.

The results obtained by this method were compared with those obtained after ashing either with sulphuric and perchloric acids or by ignition in a silica basin. For the ignition method the tissues (10–20 g.) were mixed with 5 g. of copper-free sodium phosphate for reasons that have been stated in a previous paper in connection with the analyses of samples of diet [Tompsett, 1934, 4].

From the figures shown in Table I it will be seen that the copper contents of tissues as determined by the two methods are the same within the limits of experimental error, that is copper may be extracted completely from tissues by trichloroacetic acid and reacts directly with sodium diethyldithiocarbamate.

Table I. *Copper content of fresh tissue.*

(mg. Cu per 1000 g.)

Tissue		A Determined directly in trichloroacetic acid extract	B Determined after ashing tissue
Liver	1	22·24	22·80

	16	1·96	2·06
	17	2·22	2·20

Bone. Bone offers special difficulties in the determination of copper, owing to its high content of calcium phosphate. Since the final determination is carried out at alkaline reaction, precipitation of calcium phosphate would be so great as to interfere with the result. The same difficulties are met with in milk, owing to its relatively high concentration of calcium phosphate and low concentration of copper. In the case of faeces, urine and samples of diet, materials containing relatively much lower concentrations of calcium phosphate, copper may be determined directly in solutions of their ash by addition of sodium citrate to prevent precipitation of the phosphates [Tompsett, 1934, 4]. With bone or milk, however, there is no alternative but to make a preliminary separation of copper.

Many authors have separated copper as the sulphide but this is time-consuming and liable to lead to difficulties. The following method has been found to give accurate and rapid separations of copper.

The sample of bone (30–40 g.) was ashed in a silica basin. The final traces of carbon were destroyed by the addition of 10 ml. concentrated nitric acid and further heating. The ash was dissolved in distilled water containing 15 ml. of concentrated hydrochloric acid filtered through an acid-washed filter-paper and diluted to 250 ml. A sample of 50 ml. was measured into a 750 ml. separating funnel and diluted to about 400 ml. with distilled water. To the solution 100 ml. of 20 % sodium citrate were added and the whole made slightly alkaline to litmus by the addition of ammonia. After the addition of 5 ml. of 2 % aqueous sodium diethyldithiocarbamate, the yellow copper complex which was formed was extracted with ether. 25 ml. of ether were added and the whole vigorously shaken. A further 25 ml. of ether were added and the vigorous shaking repeated. The ether layer containing the copper complex separated very quickly. The aqueous layer was run off and the ether washed twice with about 50 ml. of distilled water. The ether extract was then run off into a 300 ml. Kjeldahl flask and the separating funnel rinsed with 25 ml. of ether which was transferred to the Kjeldahl flask. The aqueous layer and washings were re-extracted with 25 ml. ether which was washed and added to the other ether extracts. The ether was evaporated off on a steam-bath and the organic matter destroyed by heating with 1 ml. concentrated sulphuric acid and 1 ml. of perchloric acid. The contents of the flask were diluted to 25 ml. with distilled water and the copper content determined in an aliquot (about 5 ml.) using 0·01 mg. Cu as standard.

From the results shown in Table II it will be seen that copper added to solutions of bone ash could be recovered quantitatively by this technique.

Table II. *The recovery of copper added to an acid solution of bone ash.*

6	0·064	0·100	0·157	0·093

Table III gives the copper content of cows' milk as determined by the above procedure. No special precautions were taken in the collection of this milk which was unpasteurised and delivered in iron cans. These figures agree very closely with those obtained in America by Lindow *et al.* [1929] who obtained an average value of 0·15 mg. Cu per litre.

"INORGANIC" IRON.

No figures for the "inorganic" iron content of human tissues appear to be available. Copper may be extracted from biological materials with trichloroacetic acid but "inorganic" iron is extracted either partially or not at all [Tompsett, 1934, 1, 3].

It has been shown that the whole of the iron of egg yolk is in the "inorganic" form, which confirms the earlier work of Hill [1931]. When a suspension of egg yolk was treated with trichloroacetic acid, no iron could be detected in the filtrate, but if, prior to the precipitation of the proteins, thiolacetic acid, sodium hydrosulphite or sodium pyrophosphate were added, the whole of the iron was present in the filtrate. This work was extended further when it was shown that this phenomenon observed with egg yolk was due to the presence of indiffusible phosphorus compounds, *e.g.* phospholipins and phosphoproteins. When solutions of iron salts were added to a suspension of lecithin or solutions of caseinogen or to milk and the protein or phospholipin precipitated with trichloroacetic acid, no iron could be detected in the filtrate, but if thiolacetic acid, sodium hydrosulphite or sodium pyrophosphate were added prior to the addition of trichloroacetic acid, the iron could be estimated quantitatively in the filtrates. On the other hand, when mixtures of ferric salts and either egg white or solutions of edestin were treated with trichloroacetic acid, the iron could be estimated quantitatively in the filtrates. It has been suggested that ferric but not ferrous iron forms complexes with these indiffusible phosphorus compounds, and that upon reduction of the ferric iron by sodium hydrosulphite or thiolacetic acid these complexes are destroyed. The complex also appears to be unstable in the presence of sodium pyrophosphate which is probably due to the property of iron of forming non-ionised compounds with pyrophosphates.

The iron was detected and determined with thiolacetic acid, which gives a purple colour with iron salts on the addition of ammonia. The reaction is very delicate, is quantitative and is not affected by the presence of organic substances such as may be present in filtrates like the above. Both ferric and ferrous salts give the reaction since the former are reduced to the ferrous state by thiolacetic acid.

In his investigations Hill [1931] used $\alpha\alpha'$-dipyridyl. This substance gives a red colour with ferrous salts and no reaction with ferric salts. He found that when egg yolk was suspended in an acid acetate buffer and $\alpha\alpha'$-dipyridyl added, no colour developed, whereas when a reducing substance such as sodium hydrosulphite was added, a red colour developed. When this colour was compared with standards, he noted that it accounted for all the iron of the yolk.

McFarlane [1934] has studied the iron of the rat's liver. He found that trichloroacetic acid extracts gave only faint reactions for iron with the thiocyanate reagent, whereas the "inorganic" iron as determined by Hill's $\alpha\alpha'$-dipyridyl method was very much higher.

Method.

For the complete extraction of "inorganic" iron by trichloroacetic acid, the complexes must be broken down first. For this type of extraction it was considered that sodium pyrophosphate would answer this purpose better than a reducing agent such as thiolacetic acid or sodium hydrosulphite. The extraction and estimation were carried out as follows:

Some broken glass and 10 g. of finely cut tissue were ground up in a porcelain mortar. 20 ml. of 4 % sodium pyrophosphate were added and the grinding continued. The mixture was allowed to stand 15 minutes after which 20 ml. of 20 % trichloroacetic acid were added and the mixture ground. After a further 15 minutes the mixture was filtered through an acid-washed filter-paper and the residue washed with 10 % trichloroacetic acid until the volume of the extract was either 100 ml. (liver and spleen) or 50 ml. (other tissues). An aliquot portion of the filtrate, containing no more than 0·03 mg. Fe, was diluted to 5 ml. with distilled water and 6 drops of thiolacetic acid were added, followed by 1 ml. of ammonia (sp. gr. 0·88). This was compared in a colorimeter with a standard similarly prepared and containing 0·005, 0·010 or 0·020 mg. Fe.

If copper is being estimated in the same tissue as "inorganic" iron, it may be determined in the extract prepared for the determination of "inorganic" iron, so that only one extraction is necessary.

Table IV.

A. *Copper.*

The figures are expressed in mg. Cu per kg. fresh tissue (1) and in mg. Cu per organ (2).

THE COPPER AND "INORGANIC" IRON CONTENTS OF TISSUES.

In Table IV are shown the concentrations of copper and "inorganic" iron in the tissues of 12 cases. These cases had no organic disease of the liver. The bones examined were the rib and the vertebra. Figures are given for the iron content of these bones. These were determined in the solutions of their ashes by the thiolacetic acid method as used for the tissue extracts. Although these figures cannot be classed as "inorganic" iron yet it is more than likely that the greater part of the iron in bones is in the inorganic form. A precipitate of calcium phosphate always appears during the estimation of iron in bone but this may be removed by centrifuging without interfering with the results.

DISCUSSION.

In a previous paper [1934, 2] the writer has reported that when the proteins of blood are precipitated with trichloroacetic acid, the whole of the copper is present in the filtrate and reacts directly with sodium diethyldithiocarbamate. It has been shown in this paper that the copper of tissues such as liver, kidney, brain, pancreas and spleen may be completely extracted with trichloroacetic acid and the copper may be determined directly in the extracts with sodium diethyldithiocarbamate in the same way as blood. During the progress of this work McFarlane [1934] published a paper on similar lines. He extracted rat livers with trichloroacetic acid, found that these extracts gave a direct reaction for copper with sodium diethyldithiocarbamate and that direct estimations using these extracts agreed with those obtained after ashing.

A method has been described for the extraction of copper from solutions of bone and milk ash by means of sodium diethyldithiocarbamate and ether. This extraction is independent of p_H so that it is as efficient in acid as in alkaline solution. It is carried out in alkaline solution in the presence of pyrophosphate to prevent the extraction of iron. If the extraction be carried out as soon as the solution of the ash is obtained it is not necessary to add pyrophosphate since sufficient of this substance is formed during the ignition process. Since the reagent itself is insoluble in ether, the ethereal extracts contain only minimum amounts of organic material. Chloroform was tried as a solvent but it was found that the solubility of the copper complex in this solvent is very poor, nor does chloroform separate very easily.

The values obtained for the copper content of various tissues with the exception of bone agree with those obtained by other workers. Vertebra contains a very low concentration of copper which is fairly constant throughout the series. Rib on the other hand appears to contain very varied amounts of copper, exceeding that in the liver in many cases even when differences of water concentration are taken into consideration. It appears possible that the bones may act as stores for copper as well as the liver.

As would be expected, liver and spleen contain the highest concentrations of "inorganic" iron. Tissues such as brain, kidney or pancreas contain on an average less than a tenth of the concentration of "inorganic" iron of the liver or spleen. The values obtained for the spleen are more constant than those for the liver but from the size of the latter organ it must be the principal store of "inorganic" iron. Vertebra and rib contain fairly high concentrations of iron and, in contrast to copper, the concentrations are almost identical in the two types of bone.

The term "inorganic" iron is probably incorrect since this iron will be in some form of organic combination. It may be justified since ferric salts added to egg yolk *etc.* react in the same way and require the same methods for their separation.

All tissues such as have been examined contain considerable amounts of haematin iron. It would appear, however, that the whole or almost the whole of the iron present in plasma is in the "inorganic" form. The writer [1934, 1] has estimated the "inorganic" iron content of normal sera and obtained values of 0·12–0·22 mg. per 100 ml. Fowweather [1934] in a recent paper has estimated the total iron of plasma, obtaining values of 0·06–0·18 mg. per 100 ml. He noted that precipitation of the proteins with trichloroacetic acid removed a considerable portion of the iron.

SUMMARY.

1. Copper may be determined directly with sodium diethyldithiocarbamate in trichloroacetic extracts of liver, kidney, spleen, brain and pancreas.
2. A method has been described for the determination of copper in bone and milk.
3. The copper and "inorganic" iron contents of a series of tissues including bone have been determined.
4. The values obtained for the copper contents of liver, spleen, kidney, pancreas and brain agree with those obtained by other writers. Vertebra contains very low concentrations of copper while the concentrations in rib are extremely variable.
5. Liver and spleen contain high concentrations of "inorganic" iron whereas kidney, brain and pancreas contain very low concentrations.

In conclusion I wish to thank Dr A. B. Anderson for his helpful criticism and advice and the Medical Research Council for a grant towards expenses.

LVI. THE REDUCTION OF DINITROPHENOLS BY REDOX INDICATORS AND ENZYMES.

BY GUY DRUMMOND GREVILLE[1] AND KURT GUENTER STERN.

From the Courtauld Institute of Biochemistry, Middlesex Hospital, London.

(*Received January 1st, 1935.*)

Two types of reagent are known to cause an increase in the respiration of surviving tissues and yeasts when added to the medium in which these cells are respiring: firstly certain organic dyestuffs which form reversible and electro-active systems with their readily autoxidisable leuco-forms [Barron, 1930; Chang and Gerard, 1931; Gerard, 1932; Friedheim, 1932; 1934; Fleischmann and Kann, 1933; Dickens, 1934]; and secondly the dinitrophenols [Dodds and Greville, 1933; 1934; Ehrenfest and Ronzoni, 1933; Field *et al.*, 1933; 1934].

As in many ways there is a striking resemblance between the actions of the two types of agent, which even extends to their effects on the anaerobic glycolysis of frog muscle [Gerard, 1931; Ehrenfest and Ronzoni, 1933], it seemed of interest to inquire whether the dinitrophenols can be found in any way to form a reversible system under physiological conditions. A nitrophenol might conceivably form an oxidation-reduction system in two ways: it might be the oxidant of a system the reductant of which is formed by reduction of a nitro-group, or it might be the reductant of a system the oxidant of which is formed by oxidation of the phenolic hydroxyl group. From the data of Fieser [1930, 1, 2] it would appear that the oxidation of a nitrophenol would require an oxidation intensity far in excess of that possessed by living cells or by any system so far isolated from them (about 1 v.). Hence for the present problem the second alternative may be neglected. On the other hand it is known that dinitrophenol is reduced by the living animal to nitroaminophenols [Guerbet and Mayer, 1932]. We have therefore concentrated on the reduction of nitrophenols by various agents. An attempt was made to see whether this would lead to the formation of a reversible system, and whether the reduction could be performed by enzymes extractable from living cells.

EXPERIMENTAL.

Tests for reversibility.

Potentiometric experiments. We tested for reversibility at p_H 7 by the methods commonly employed in potentiometric analysis, namely the methods of reductive and oxidative titration and the method of mixtures.

Titration of $10^{-3} M$ 4:6-dinitro-*o*-cresol with hydrosulphite did not yield typically S-shaped curves. The potentials measured on the two electrodes employed were not stable and differed widely. Flattening of the curves in different experiments occurred in different E_h ranges. The colour changes observed during the course of the titration were: lemon-yellow (before addition of the titrant) → orange → red → colourless.

The same sequence of colour changes could be observed on reduction with hydrogen in the presence of colloidal palladium. Since reversibility of the system was the more likely to be found the less extensive the reduction, the dinitrocresol was reduced by palladium-hydrogen under photo-electric control to maximum red colour production, presumably to the nitroaminocresol stage. The hydrogen was then replaced by nitrogen and the system was titrated back with ferricyanide. Each addition of a small amount of the titrant caused an initial rise of the potential followed by a drifting back to approximately the original value, until finally a point was reached where the potential suddenly rose into the potential range of the ferricyanide system and remained there. During the titration the colour changed from dark red to dark brown.

---

[1] Halley-Stewart Research Fellow.

Finally the method of mixtures was tried. An equimolar amount of 4-nitro-2-aminophenol was added to a de-aerated buffered solution of 2:4-dinitrophenol. No steady potential was reached within 40 mins. and the two electrodes disagreed. A small quantity of methylene blue was added without any stabilising effect being observed. In order to see whether the presence of living cells would cause the system to attain a stable potential, a small quantity of washed baker's yeast was added to an equimolar mixture of dinitrophenol and nitroaminophenol. This caused the potential to become somewhat more negative. When methylene blue was added to the system, a slow potential decrease was observed with a flattening of the time-potential curve as the poising range of the indicator was approached. It follows that the presence of the nitrophenols did not alter the course of events which normally occurs with de-aerated suspensions of yeast cells in the presence of methylene blue [Cannan *et al.*, 1926].

Experiments with mammalian erythrocytes.

It has been found that reversible oxidation-reduction systems, the normal potentials of which may vary within very wide limits, cause an increase in the oxygen uptake of non-nucleated red cells, the respiration of which is normally very low [Harrop and Barron, 1928; Michaelis and Salomon, 1931; De Meio *et al.*, 1934]. Hence if nitrophenols were found to increase catalytically the oxygen uptake of such cells, this would provide evidence for their conversion into a reversible system when in contact with living matter. Experiments with human and rabbit erythrocytes, however, failed to demonstrate any such effect. The results of a typical experiment are given below.

Material: Washed rabbit erythrocytes made up to blood volume with phosphate-saline mixture, containing 0·25 % lithium *d*-lactate, p_H 7·3.

Each Warburg vessel contained 2 ml. of this suspension, oxygen capacity 142 μl.

Temperature: 38°. Observation time: 60 mins.

Added agent	O_2 uptake in μl.
None	2·5
$10^{-4}M$ methylene blue	112
$10^{-4}M$ thionine	115
$3.10^{-6}M$ thionine	35
$10^{-3}M$ dinitro-*o*-cresol	2
$10^{-4}M$ dinitro-*o*-cresol	3
$10^{-5}M$ dinitro-*o*-cresol	1
$3.10^{-6}M$ dinitro-*o*-cresol	3·5
$10^{-6}M$ dinitro-*o*-cresol	0

In contrast to these findings the respiration of avian (nucleated) erythrocytes, which normally is already considerable, is greatly increased by dinitrophenol [De Meio and Barron, 1934]. Dinitrophenols have so far been shown to exert their effect only on those cells which already possess a complete respiratory system.

REDUCTION EXPERIMENTS.

*Reaction of dinitro-*o*-cresol with redox indicators.*

We first sought to determine the level of reduction intensity at which, in the absence of bio-catalysts, the rate of reduction of the nitro-groups in dinitro-*o*-cresol becomes appreciable. A scale of reduction intensities is provided by a series of partially reduced redox indicators. The method employed was that of "potentiometric indicators" [Conant and Lutz, 1923], which consists in determining electrometrically the rate of change of potential following the addition of the substance under investigation to equilibrated mixtures of redox indicators and their leuco forms. For discussion of the theory of the method the reader is referred to Fieser [1930, 2].

Seven indicator systems were employed, covering the E_h range between +0·040 and −0·270 v. All experiments were carried out at p_H 7·3 and at a temperature of 30°. The apparatus used is described below. 40 ml. of a buffered solution of the selected indicator were titrated with chromous acetate to a definite potential well inside the poising range. In most cases a value near the normal potential (E_0') of the indicator was selected. When the electrode potential had become perfectly steady, an equimolar amount of dinitro-*o*-cresol dissolved in 1 ml. of carefully de-aerated buffer was added. The total concentration of the indicator was $10^{-4} M$. In addition one experiment with gallophenin was carried out with a five times higher concentration of dyestuff and dinitrocresol. The results are shown in Table I, and some curves are given in Fig. 1.

Indigodisulphonate

Anthraquinone-β-sulphonate

Fig. 1.

It is obvious that the rate of reduction of dinitrocresol is not determined solely by the potential of the indicator system, which finding is in agreement with the observations of Conant and Lutz [1923]. It may, however, be said that the rate of reduction is negligible above −0·05 v., small between −0·05 and −0·20 v., and considerable below −0·25 v. It is clear that this statement holds only for the experimental conditions chosen.

Reduction of dinitrophenols by enzyme systems.

It is now known that the activation of different substrates, *e.g.* formate or lactate, by the appropriate dehydrogenase systems gives rise to different levels of reduction intensity. Certain dehydrogenases (succinic, lactic and xanthine dehydrogenases) indeed are found to set up with the oxidised and reduced forms of their substrates reversible systems whose potentials have been measured by indirect methods [for literature see Stern, 1934, 2]. We have studied the reduction of dinitrophenols by four different dehydrogenase-substrate systems whose reduction intensities cover a wide range.

(1) *Formic dehydrogenase.* Though its reversibility has not yet been established, the formic dehydrogenase-formate system reduces very negative indicators so easily that a very high reduction intensity is indicated. One might therefore expect that dinitro-*o*-cresol would be easily reduced by this system. It was nevertheless found that formic dehydrogenase in the presence of formate caused no visible reduction of dinitro-*o*-cresol in the Thunberg tube. If, however, a small quantity of benzyl viologen (E_0' −0·359 v.) was added, a brown colour rapidly appeared. The protocol of a typical experiment is given below.

Formic dehydrogenase prepared by tryptic digestion of a washed suspension of *Bact. coli commune* Escherich according to the method of Stickland [1929]. 0·1 ml. of this preparation reduced 1 ml. of 1/5000 methylene blue in the presence of formate in 3 mins. at 21°. In the absence of substrate the reduction time exceeded 16 hours.

Benzyl viologen was prepared by the method of Michaelis and Hill [1933].

The experiment was carried out in vacuum tubes at 38° in the manner described below.

Solutions: phosphate buffer, 0·1 M, p_H 7·3; dinitro-*o*-cresol, 10^{-2} M; benzyl viologen, 4 . 10^{-3} M; sodium formate, 0·2 M.

After 45 mins.:	No change	No change	Red-brown	No change

* Heated to 100°.

Passing oxygen through the solution in tube 3 at the end of the experiment for 30 mins. resulted in no change of colour.

Experiments with 2:4-dinitrophenol led to similar results. The coloured reaction product was identified in this case as 4-nitro-2-aminophenol by following the procedures described by Guerbet [1932], who has worked out methods for the separation and detection of small quantities of the reduction products of 2:4-dinitrophenol. 30 ml. of reaction mixture were incubated at 30° for 5·5 hours in a stream of pure nitrogen. At the end of the experiment diaminophenol was tested for with dichromate with a negative result. This test was found to be sensitive to 1/50,000 diaminophenol added to the reaction mixture. 4-Nitro-2-aminophenol was separated in aqueous solution from the remainder of the reaction mixture by Guerbet's procedure and identified by Derrien's reaction (diazotisation and coupling with β-naphthol). The characteristic two-banded spectrum was observed after the addition of zinc acetate in methyl alcohol to the ethereal solution of the azo-β-naphthol. The amount of 4-nitro-2-aminophenol formed was roughly estimated by comparison in Nessler glasses with a standard solution of this compound (solvent: 5 % ammonia). From this comparison the degree of conversion was seen to be at least 45 %. 2-Nitro-4-aminophenol could not be detected.

In order to obtain insight into the mechanism of the coupled reaction observed in the Thunberg tube experiments, the system was subjected to potentiometric and photometric analysis in the apparatus described below. The phenomena observed in these experiments are represented in the composite diagrams of Fig. 2. In the first experiment (upper diagram), after the formic dehydrogenase-formate system had been allowed to reduce the benzyl viologen, the addition of a relatively large amount of dinitro-o-cresol caused a sudden rise in potential to a level which was maintained for over 3 hours. The violet colour of the reduced indicator was discharged immediately after addition of the dinitrocresol, and during the subsequent observation time the solution became

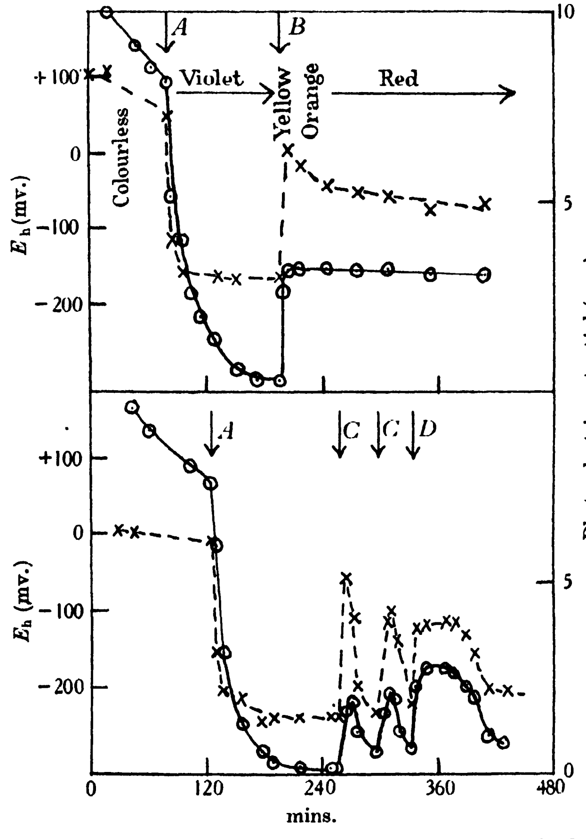

Fig. 2. Formic dehydrogenase and benzyl viologen. *A*, Formate added. *B*, 1 ml. dinitrocresol added. *C*, 0·1 ml. dinitrocresol added. *D*, 0·3 ml. dinitrocresol added. ——— Electrode potentials. - - - - Photo-electric potentials.

increasingly red. At the steady potential level attained no appreciable quantities of the reduced viologen indicator could exist. It was concluded therefore that the enzyme-formate system reduces the viologen, and the reduced form of the indicator reacts with the dinitrocresol (when the latter is in excess) as fast as it is formed. This view was confirmed by the experiment shown in the lower part of Fig. 2, in which successive small quantities of dinitro-*o*-cresol were added. Here the potential fell and the purple colour of reduced viologen appeared each time that the whole of the dinitrocresol present had been used up.

In addition to benzyl viologen the following indicators were found to bring about the coupled reduction of dinitro-*o*-cresol: brilliant cresyl blue ($E_0' + 0{\cdot}045$ v. (p_H 7)), Nile blue ($E_0' - 0{\cdot}116$ v. (p_H 7)), Janus green ($E_0' - 0{\cdot}256$ (p_H 7)). In order to judge the degree of reduction of the dinitrocresol at the end of the experiments the dyestuffs were removed after admission of air by shaking with kieselguhr and filtering.

(2) *Xanthine oxidase.* The redox potential of the hypoxanthine-enzyme-uric acid system is $-0{\cdot}44$ v. at p_H 7 [Filitti, 1933]. It was found that this system, in contrast to the formic system, was able to reduce dinitrocresol in the absence of any indicator. The rate of reduction, however, was increased by the addition of benzyl viologen.

Enzyme: whey preparation of Dixon and Kodama [1926]. 1 ml. of the solution used reduced 1 ml. of 1/5000 methylene blue in the presence of 0·2 mg. of hypoxanthine in 1 min. 50 secs. at 37°.

Solutions: phosphate buffer, $0{\cdot}1\,M$, p_H 7·3; hypoxanthine, 1 mg. per ml.; benzyl viologen, $2.10^{-3}M$; dinitro-*o*-cresol, $10^{-2}M$.

Temperature: 37°.

Tube	1	2	3	4

After 1 hour:	No change	Orange	Brown	Purple

2:4-, 2:5-, and 2:6-dinitrophenols are also reduced by this enzyme system. An attempt to identify the brown reduction product of 2:4-dinitrophenol failed.

Since the xanthine oxidase system showed such an interesting difference from the formate system in that no extraneous carrier was required for the reduction of dinitrocresol, we subjected this reduction process to potentiometric and photo-electric analysis (Fig. 3). Whilst reduction of the dinitrocresol was proceeding in the absence of benzyl viologen, as seen from the light transmission curve, the potential remained fairly steady at a comparatively positive level. Addition of benzyl viologen caused the potential to fall. Another experiment conducted in a manner similar to that of the second experiment with formic dehydrogenase (Fig. 2, lower part) gave results similar to that experiment; in both the reduction of dinitrocresol proceeded at approximately the same potential level.

(3) *Lactic dehydrogenase.* The normal potential of the lactate-enzyme-pyruvate system has been found by various workers to be near $-0{\cdot}200$ v. at p_H 7 [see Stern, 1934, 2]. It was found that yeast lactic dehydrogenase in the presence of lactate would not reduce dinitrocresol to a brown compound, but in the

presence of the following indicators it was capable of doing so: pyocyanin (E_0' −0·034 v. (p_{H} 7)), toxoflavin (E_0' −0·049 v. (p_{H} 7); [Stern, 1935], β-anthraquinonesulphonate (E_0' −0·250 v. (p_{H} 7)).

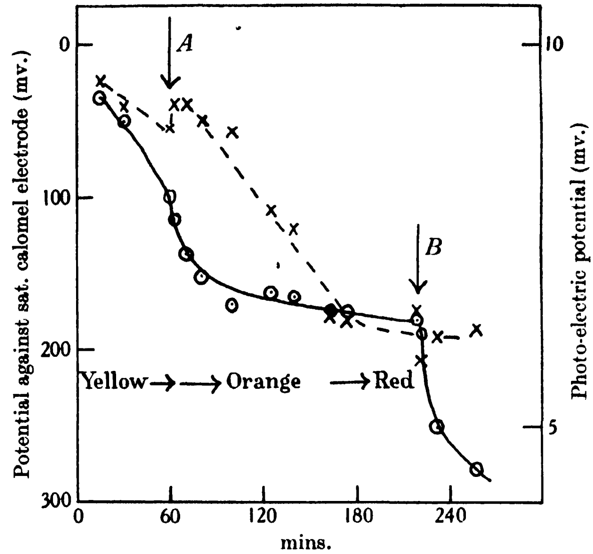

Fig. 3. Xanthine oxidase + dinitro-*o*-cresol, p_{H} 7·3, 30°. *A*. Hypoxanthine added. *B*. Benzyl viologen added. ——— Electrode potentials. – – – – Photo-electric potentials.

Enzyme: extracted from acetone-yeast by the method of Bernheim [1928]. The extract was dialysed against 0·15 *M* phosphate buffer p_{H} 7·3 to minimise volume increase. 0·5 ml. enzyme solution reduced 1 ml. 1/5000 methylene blue in presence of lactate in 14 mins. at 38°.

Solutions: phosphate buffer, p_{H} 7·3, containing enzyme; dinitro-*o*-cresol, $2.10^{-2}M$; lithium *d*-lactate, *M*; pyocyanin (from *Ps. pyocyanea*), $2.10^{-3}M$; toxoflavin (from *Bact. bongkrek*), $2.10^{-3}M$.

Temperature: 38°.

Tube	1	2	3	4	5
	ml.	ml.	ml.	ml.	ml.
Enzyme	2·0	2·0	2·0	2·0	2·0
Substrate	0·5	0·5	0·5	0·5	0·5
Dinitrocresol	0·2	—	0·2	—	0·2
Pyocyanin	—	0·3	0·3	—	—
Toxoflavin	—	—	—	0·5	0·5
Water	0·3	0·2	—	1·0	0·8
At beginning:	Lemon-yellow	Blue	Green	Yellow	Yellow
After 1 hour:	No change	Colourless	Orange	Colourless	Yellow
After 3 hours:	No change	Colourless	Brown-orange	Colourless	Orange

The reaction product in the case of toxoflavin as indicator gave a positive reaction for a 4-nitro-2-aminophenol.

We have found that yeast lactic dehydrogenase + lactate will not take up oxygen in the presence of varying concentrations of dinitro-*o*-cresol in the Warburg apparatus. De Meio and Barron [1934] have just reported similar results with the α-hydroxy-oxidase of gonococci. This is readily explained by the fact that nitrophenols cannot be reduced by the lactate system in the absence of carriers, apart from any considerations of reversibility.

(4) *Succinic dehydrogenase.* The normal potential of the succinate-enzyme-fumarate system has been found to be near 0 v. at p_H 7 [Lehmann, 1929; Borsook and Schott, 1931]. It could hardly be expected that such a relatively positive system would be able to reduce nitrophenols readily even in presence of indicators. It was indeed found that a strongly active succinic dehydrogenase solution prepared according to Lehmann's directions, 0·5 ml. of which decolorised 0·3 ml. 1/2000 methylene blue in 15 mins. at 38°, failed to reduce dinitro-*o*-cresol either alone or in presence of the dyestuffs brilliant cresyl blue or thionine, although these dyes were completely decolorised.

As with the lactic dehydrogenase system, we tested the capability of dinitrocresol to provoke an oxygen uptake in the succinic dehydrogenase-succinate system. Washed chopped guinea-pig muscle, in the presence of cyanide to inhibit the normal oxygen utilisation, failed to take up oxygen in the presence of succinate when concentrations of dinitro-*o*-cresol varying between $2 \cdot 10^{-3}$ and $5 . 10^{-7} M$ were added (Fig. 4).

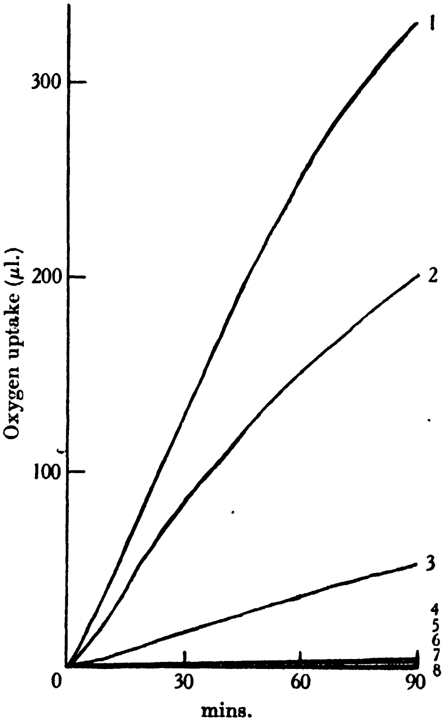

Fig. 4. Washed chopped guinea-pig muscle.

2. Succinate $+ 5 \times 10^{-3} M$ KCN $+ 2 \times 10^{-3} M$ methylene blue.
3. Succinate $+ 5 \times 10^{-3} M$ KCN $+ 2 \times 10^{-4} M$ methylene blue
4. Succinate $+ 5 \times 10^{-3} M$ KCN $+ 10^{-4} M$ dinitrocresol.
5. Succinate $+ 5 \times 10^{-3} M$ KCN $+ 10^{-5} M$ dinitrocresol.
6. Succinate $+ 5 \times 10^{-3} M$ KCN.
7. Succinate $+ 5 \times 10^{-3} M$ KCN $+ 2 \times 10^{-3} M$ dinitrocresol.
8. Succinate $+ 5 \times 10^{-3} M$ KCN $+ 5 \times 10^{-7} M$ dinitrocresol.

(5) *Reduction by muscle.* Unwashed chopped rat muscle contains systems which reduce benzyl viologen. Dinitro-*o*-cresol is likewise reduced, and the rate

of reduction is increased in the presence of benzyl viologen. Washing the muscle decreases its capability of reducing dinitrocresol, but the rate of reduction is still increased by the addition of benzyl viologen. We have not yet ascertained what systems are responsible for these reductions.

TECHNIQUE.

Experiments with Thunberg tubes. The vacuum tubes used in these experiments were mostly of the type shown in Fig. 5. They incorporate Keilin's hollow stopper, and in addition they are provided with glass collars which, together with the side arms, are filled with liquid paraffin. Fig. 5 also shows the arrangement used for alternately evacuating and refilling the tubes with nitrogen from a cylinder. The three-way tap T is first turned so that the Thunberg tube is connected with the water pump. When the liquid in the tube is boiling, the valve of the nitrogen cylinder is opened and the tap T is so turned that nitrogen passes into the Thunberg tube. The capillary constriction C prevents the rushing in of water from the safety device S. Evacuation and refilling with nitrogen are then repeated, and the tube is finally evacuated by leaving it in connection with the pump for 1 or 2 minutes.

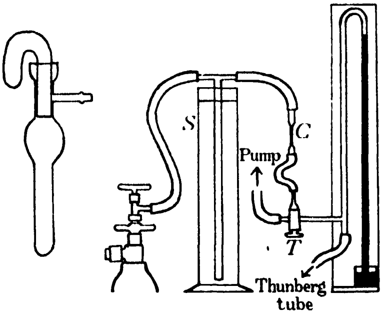

Fig. 5.

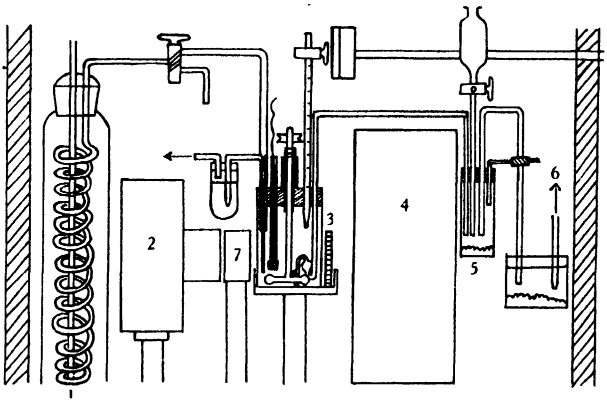

Fig. 6. 1. Pre-heating tower. 2. Photo-electric cell. 3. Light filters. 4. Light source. 5. Siphon system. 6. Calomel cell. 7. Diaphragm.

Potentiometric and photometric measurements. The apparatus illustrated in Fig. 6 allows simultaneous measurements of potential changes and of changes in light transmission to be made. The electrode vessel was fitted up in the manner described by Clark and Cohen [1923]. Two electrodes were used, one being of blank platinum foil and the other of the Westhaver type (platinum film on glass). Connection with the saturated calomel electrode was made by means of a syphon system [*cf*. Elema, 1931]. Before entering the titration vessel the gases passed through the pre-heating tower. Gas purification, temperature control and potential measurements were carried out as previously described [Stern, 1934, 1]. The electrode vessel was of square section with polished surfaces, the breadth being 4 cm. It was mounted on an optical bench between a 100-watt opal metal filament lamp and a photo-electric cell of the selenium type (Weston Photronic Cell). The light was filtered by means of a suitable combination of Schott coloured glass filters before it entered the titration vessel. The three filters used, each 1 mm. thick, were BG 17, 13, and 10. The photo-electric potentials, which varied between 1 and 14 mv., were measured with the same potentiometer and galvanometer as were used for the electrode potential measurements, the higher sensitivity range of the potentiometer being selected. The light source was switched on about 20 secs. before each reading. Stray light was eliminated by suitable housings for light source and photo-cells and by the provision of diaphragms.

DISCUSSION.

It is proposed first to discuss the question of the reversibility of the reduction of dinitrophenols. The reason for taking nitroaminophenol as the reductant in our potentiometric experiments was that the orange-red colour due to this compound begins to appear right from the beginning of reductive titrations. We have controlled this point by cautious titration of dinitrocresol with leucobenzyl viologen. The brownish colour appeared at once. Furthermore nitroaminophenol has been isolated as a product of the reduction of dinitrophenol by mild agents. Attainment of this stage, however, involves six hydrogen equivalents. No reversible system is known to be concerned with the exchange of more than two hydrogen equivalents in a single step. Since no typical reduction curves could be traced with dinitrocresol, no conclusions can be drawn from their slope as to the number of hydrogen equivalents involved.

Very probably all so-called irreversible systems possess a reversible phase in their oxidation or reduction as the case may be. The possibility of its detection is dependent upon the life time of the primary reaction product, which may usually be depicted as a radical liable to decomposition or secondary condensation. The refinement of methods in recent years has led to the demonstration of such reversible phases in systems hitherto regarded as irreversible. The rate of the disappearance of the radical determines the method to be chosen. Though the simple methods applied by us have failed, it may well be that by the application of such methods as the flow method [Ball *et al.*, 1933] or the method of discontinuous titration [Fieser, 1930, 1] a reversible stage may still be demonstrated in the reduction of dinitrophenols. From our data the possibility that dinitrophenol together with nitroaminophenol forms a sluggishly reversible system, comparable with the haemoglobin-methaemoglobin system, would appear to be ruled out.

For the time being Fieser [1930, 2] has recommended the method of potentiometric indicators for systems in which reversibility cannot yet be demonstrated. The critical oxidation potential introduced by this author is a unique function of the normal potential, by analogy with systems where both constants could be measured. Our experiments with potentiometric indicators suggest that the critical reduction potential of dinitrocresol is in the neighbourhood of −0·1 v. If it be assumed that there exists a reversible phase in the reduction of dinitrocresol involving two hydrogen equivalents, then following the deductions of Fieser one would arrive at a normal potential near −0·2 v., which would be in the region of the so-called anaerobic reduction potential of cells as determined by various methods (for literature see Stern [1934, 2]).

The experiments with the enzyme systems tried show that dinitrophenols can be reduced by enzyme systems which cover a wide range of reduction intensity provided a suitable carrier be present. It is not impossible that the cell contains such a carrier [see however Green, Stickland and Tarr, 1934]. With xanthine oxidase no extraneous carrier was necessary. We do not know whether this system contains already an appropriate carrier or whether it does not need one [*cf.* Green and Dixon, 1934]. The reduction of dinitrophenols in this respect parallels that of nitrate which is reduced by xanthine oxidase in the absence of a carrier, whereas its reduction by Stickland's preparation demands the presence of an added indicator [Green, Stickland and Tarr, 1934].

Our experiments show that dinitrophenols are not available to the dehydrogenases tried, with the exception of the xanthine oxidase system. An apparent inconsistency in our results concerning the coupled reduction of dinitrocresol demands comment. This compound is reduced in the presence of formic dehydrogenase-formate by an indicator, brilliant cresyl blue, which even in the 99 % reduced state does not possess a potential level low enough to cause an appreciable rate of reduction, as judged from our potentiometric indicator results. We would remark, however, that (1) the conditions in the potentiometric indicator and in the Thunberg tube experiments are not entirely comparable; (2) the potential of a fully reduced indicator is theoretically $-\infty$; (3) a leuco-dye formed by reduction on an enzyme surface is possibly in an "activated" state which may be very different from that of a dye reduced by non-enzymic agents.

We would emphasise the importance of arriving at an explanation of the action of nitrophenols on the living cell. In the stimulation which they produce, there is an overcoming of the processes which normally limit the respiration, and in some cases the glycolysis, of normal and tumour tissues. If the effect of the nitrophenols could be referred to their behaving as reversible redox systems, their action would be brought into line with that of reversible dyestuffs such as methylene blue, pyocyanin and thionine. If, on the other hand, the mechanism of their action were quite different, the possibility would arise that the reversible dyestuffs which stimulate the metabolism of tissue do so in virtue of some property not necessarily dependent on the reversibility of their reduction or the autoxidisability of their leuco-forms.

Whilst the work described in this paper was being completed, two communications appeared which give hypotheses for the mode of action of nitrophenols. De Meio and Barron [1934] state: "...the increase in respiration produced by dinitrophenol is not due to direct oxidation of the oxidisable substrates. It is suggested that dinitrophenol acts by combining with some of the substances acting as agents for the control of the speed of cellular oxidations, thus increasing the activity of the oxidising enzymes". On the other hand, according to Krahl and Clowes [1934], it is likely that dinitrocresol "stimulates cellular respiration by accelerating the oxidation by cytochrome of some substrate previously or simultaneously acted upon by the anaerobic dehydrases of the cell. It is too early to say whether DNC acts as a diffusible oxygen carrier between cytochrome and the substances normally oxidised or as an artificial substitute for a co-enzyme in the activation of substrates which do not normally play an important rôle in respiration".

We do not propose to comment upon these views, save to remark that De Meio and Barron's most weighty evidence for their views, namely that dinitrophenol is without effect when the respiration of cells and tissues has been inhibited by cyanide or carbon monoxide, does not exclude the possibility that the nitrophenols are converted into reversible systems in the presence of actively functioning oxidases or other cyanide-sensitive systems of the cell.

This paper does not attempt to explain the mechanism of nitrophenol action. It can, however, be said that, if the action of the nitrophenols depends on their reduction, a way in which such reduction may occur in the cell has been indicated.

SUMMARY.

1. The reduction of nitrophenols by enzymic and non-enzymic means has been studied, in the hope of obtaining an insight into the action of these compounds on the cell.

2. No evidence has been obtained that the reduction of dinitrophenols by agents such as hydrosulphite or palladium-hydrogen is reversible. The possibility of detecting a reversibility by more refined means than those employed is discussed.

3. The approximate potential level at which the reduction of dinitro-*o*-cresol becomes apparent has been determined by the method of potentiometric indicators.

4. Dinitrophenols are reduced by xanthine oxidase, formic dehydrogenase and lactic dehydrogenase in the presence of the appropriate substrates. With the last two enzymes, a small quantity of a reversible redox system must be added before reduction occurs. The product of reduction of 2:4-dinitrophenol by formic dehydrogenase-formate is 4-nitro-2-aminophenol.

5. No theory for the action of nitrophenols on cellular respiration is advanced; but the significance of the results is discussed.

It is a pleasure to acknowledge the interest that Prof. E. C. Dodds has taken in these experiments. We wish to thank him and the Council of the Middlesex Hospital Medical School for the hospitality afforded. To Dr Paul Fildes and to Dr G. P. Gladstone we are indebted for bacteriological assistance and advice.

LVII. OXIDATION-REDUCTION POTENTIALS OF TOXOFLAVIN.

By KURT GUENTER STERN.

From the Courtauld Institute of Biochemistry, Middlesex Hospital, London.

(*Received December 21st, 1934.*)

Toxoflavin is the name given by van Veen and Mertens [1934] to the prosthetic group of the yellow pigment which is formed in cultures of *Bacterium bongkrek* under aerobic conditions. The native pigment complex together with a colourless compound is thought by these authors to be responsible for the occurrence of a number of cases of foodstuff poisoning among the natives of Java. Whereas the native pigment is highly toxic when administered perorally or intraperitoneally to monkeys, pigeons and rats, toxoflavin in crystallised state has only retained its toxicity for rats when injected intraperitoneally, 5–25γ representing the lethal dose. The decrease in toxicity is ascribed by the authors to the detachment of the prosthetic group from some colloidal carrier substance in the course of purification.

The empirical formula assigned to toxoflavin is $C_6H_6O_2N_4$. The constitutional formula is unknown. Of the chemical properties reported in van Veen and Mertens's publication only the following may be mentioned here in view of their bearing on the present work. The compound (M.P. 171°) is readily soluble in water and alcohol, less soluble in ethyl acetate and chloroform, hardly soluble or insoluble in ether, benzene, and light petroleum. In water the yellow colour is only stable between p_H 3 and 7. Slow decoloration takes place at p_H 1 and 9. Addition of mineral acids or strong alkali causes immediate decoloration. Toxoflavin is stable towards oxidising agents (nitric acid, hydrogen peroxide, bromine water). In weakly acid or alkaline solution the yellow colour is discharged instantaneously by sulphurous acid and it returns on shaking with air or addition of hydrogen peroxide or bromine water. On catalytic hydrogenation according to the selected conditions either approximately one or three hydrogen molecules are taken up by one molecule. One methylimide group was found. The murexide test is only positive if potassium chlorate and hydrochloric acid are used instead of nitric acid. As oxidation products alloxan (or methylalloxan), methylamine and ammonia were found. In concentrated aqueous solution toxoflavin forms a brick-red, sparingly soluble addition compound with bisulphite. The solutions of toxoflavin, especially in amyl alcohol, are stated to exhibit a green fluorescence.

The idea of carrying out the experiments which are subsequently described arose from the conclusion drawn by van Veen and Mertens from their findings that toxoflavin was to be regarded as a member of the series of flavin or lyochrome pigments recently studied by Warburg, Ellinger, Kuhn, Karrer, von Euler and by the present author.

This investigation was made possible by the generous gift of about 20 mg. of pure recrystallised toxoflavin by Dr A. G. van Veen to whom sincere thanks are due. He consented to the potentiometric and spectrographic examination of the pigment[1], on lines along which detailed information in respect to flavin pigments was available from this laboratory [Holiday and Stern, 1934; Stern, 1934, 2].

EXPERIMENTAL.

Material. The sample of toxoflavin which was used for the following experiments was sent from Batavia-Centrum in a sealed ampoule. The colour of the crystals, which is much like that of picric acid, is stated to change somewhat to a brownish tint in a tropical climate when exposed to the air, but the crystals did not show any detectable change during their 4 months' storage in a stoppered tube in this laboratory.

The crystals were found to be free from moisture (3·04 mg. when subjected to a slow current of air, previously dried over calcium chloride, for 3 hours at 75° in a platinum boat in Pregl's micro-desiccator (suction applied by high pressure water-pump) did not show any loss of weight detectable with a Sartorius microbalance).

The properties were identical with those described by van Veen and Mertens with the exception of the fluorescence which was found to be hardly perceptible even in a strong beam of Wood's light when the substance was dissolved in water, chloroform or amyl alcohol. The weakness of the fluorescence became especially obvious when as controls similar solutions of photo-hepatoflavin or of 9-methylalloxazin were used.

The aqueous solution of toxoflavin reacts weakly acid. A 10^{-4} M solution showed a p_H of 6·5 when measured with the glass electrode.

Toxoflavin does not couple with diazobenzenesulphonic acid. No free NH_2-group is detectable with 1: 2-naphthoquinone-4-sulphonic acid.

Methods. The arrangement and method of potentiometric measurements were the same as described in a study dealing with photo-flavin [Stern, 1934, 2]. The potassium ferricyanide preparation used for oxidative titrations of leuco-toxoflavin was an analytically pure sample. It was free from ferrocyanide, and on titration with permanganate after reduction with sodium peroxide 100 % of the calculated iron content was found. For the purpose of reductive titrations the technique described by Clark and Perkins [1932] was employed. The stock solution of chromous acetate was stored under hydrogen and delivered from a Bang microburette. To the tip of this burette a small vessel containing the necessary amount of buffer solution was attached. After thorough de-aeration with hydrogen or nitrogen the calculated amount of the stock solution was run into the buffer mixture. The receiving vessel was detached from the Bang burette and the diluted titrant was quickly covered with liquid paraffin. It was then drawn up into the actual microburette serving for the electrometric titrations protected by a paraffin seal. The strength of the chromous acetate stock solution was determined before and after the preparation of the dilution by means of a standardised ferric alum solution with ammonium thiocyanate as internal indicator.

The spectrographic measurements were made with the aid of a medium-size Hilger quartz spectrograph with attached Spekker quartz photometer. The condensed spark discharge between tungsten steel electrodes served as light source. The photographs were evaluated by the match point method.

For the manometric experiments the usual Barcroft-Warburg technique was employed.

---

[1] A short account of this work was presented jointly with Holiday at the Meeting of the Biochemical Society on November 16th, 1934 [Stern and Holiday, 1934, 2].

RESULTS.

Oxidation-reduction potentials of toxoflavin.

Nineteen titration experiments were performed covering the p_H range from 2·68 to 8·49. In accordance with the qualitative findings of van Veen and Mertens the stability of the pigment was sufficient for reproducible measurements only between p_H 4·6 and 8·3. At p_H 2·68 the oxidised (yellow) form of the system became unstable. At p_H 4·12 and 8·49 the reduced form was not sufficiently stable to allow the tracing of a definite titration curve. Between p_H 4·6 and 8·3 toxoflavin represents the oxidant of a stable, reversible and electro-active redox system. Titrations of the leuco-form with ferricyanide and of the oxidant with chromous acetate yield substantially consistent results. In the poising range of the system equilibrium is almost instantaneously reached, the potentials are stable in time, and individual electrodes differ seldom by more than 1 mv. Generally they agree in the range from 20 to 80 % oxidation within 0·1 mv.

Potential range. The normal potentials of toxoflavin as obtained by graphical interpolation from the individual titration curves at varying hydrogen-ion concentrations are given in Table I in column "E_0'". The potentials were measured against the saturated calomel half cell and the values with reference to the normal hydrogen electrode were then calculated therefrom. The curve combining these E_0' values is plotted in the right-hand part of the composite diagram in Fig. 1. It will be seen from this curve that the toxoflavin system is much more positive than the flavin systems studied by the writer. For instance, whereas E_0' for toxoflavin at p_H 7 is $-0·049$ v., the corresponding value for photo-hepatoflavin is $-0·227$ v. [Stern, 1934, 2] and for hepato-, malto- and uro-flavin the mean value is $-0·215$ v. [Stern, 1934, 1]. On the other hand the toxoflavin potential at p_H 7 is very near to the pyocyanin potential ($-0·034$ v. [Friedheim and Michaelis, 1931; Elema, 1931]).

The shape of the E_0'/p_H curve for toxoflavin reveals the existence of two dissociation constants in the range of stability of both components of the system: p_{K_1} about 5·8 and p_{K_2} about 7·2.

The slope of the curve from p_H 4·6 to 5·7 is $\frac{-\Delta E}{\Delta p_H}=60$ mv., from p_H 6·1 to 7 = 35 mv., and from p_H 7·4 to 8·3 = 19 mv. The changing of the slope of the curve, due to p_{K_1}, by approximately 30 mv. suggests that the nature of the system is a "two electron-system" ($n=2$). p_{K_2} however changes the slope in an atypical manner. This may possibly be explained by the assumption that the part of the curve extending from p_H 7·4 to 8·3 is eventually tending to a zero mv. slope. This hypothesis however cannot be tested experimentally in view of the instability of the system beyond p_H 8·3.

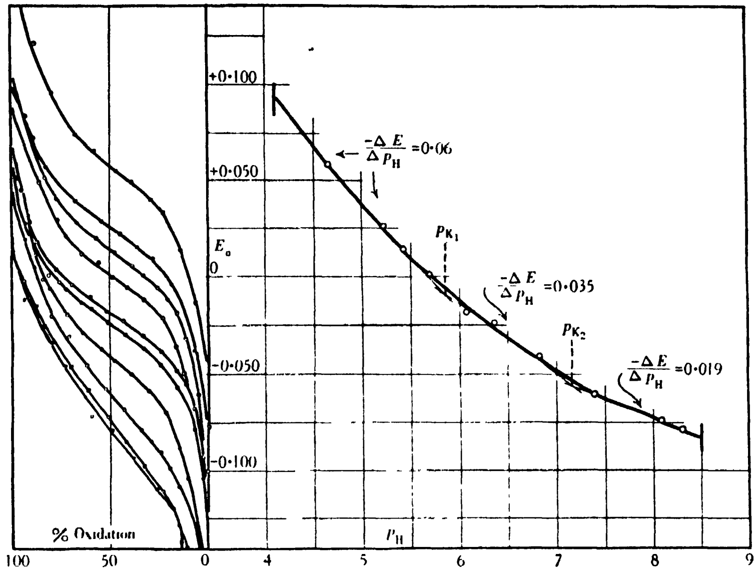

Fig. 1. Toxoflavin: Relation of E_0' to p_H.

The experiments which served for the compilation of Table I as well as for the diagram (Fig. 1) were all done by titrating leuco-toxoflavin with potassium ferricyanide.

Electron number. As will be seen by inspection of the individual titration curves plotted in the left-hand side of Fig. 1 as well as from the column "E_i" of Table I, the slope of these curves is throughout an atypical one. This is best demonstrated by the value of the so-called index potential (E_i), *i.e.* the potential difference between 50 and 25 % (or 75 % respectively) oxidation. Whereas E_i for a system losing two electrons in a single step on oxidation, which is the most common type of organic redox system, would amount to 14 mv., E_i for a one-electron system like cytochrome would be 28 mv.

With the present system E_i averages 21 mv. between p_H 4·6 and 6·4, and then increases with p_H, to become 34 mv. at p_H 8·3. A variation of E_i with p_H is also shown by the two step reduction systems recently studied by Michaelis [1933] and by Elema [1931; 1933], *e.g.* pyocyanin and chlororaphin. The flavins have been shown to belong to the same class of systems [Stern, 1934, 2]. A fundamental difference between the above-mentioned systems and toxoflavin however is the fact that the steepening of the titration curves and simultaneous visible semiquinone formation in the case of pyocyanin etc. is observed in the acid range, whereas with toxoflavin the change occurs in the alkaline range without any visible semiquinone formation[1].

---

[1] The only similar case of which the writer is aware is that of the pigment of *Halla parthenopea*—hallachrome—which was recently studied by Friedheim [1933]. Here E_i is about 20 mv. from p_H 0·19 to 9·8. Further towards the alkaline range E_i increases and becomes 34 mv. at p_H 11·47.

It follows therefore that the number of electrons involved in the process of oxidation-reduction of toxoflavin cannot be derived from the slope of individual titration curves. If the view be accepted that we are dealing here with a two-step reduction system, though no formation of an intermediary form may be detected by a colour change on reduction and though no complete separation of the two steps involved could be realised owing to the overlapping of the steps within the p_H range of stability, the complete process of reduction would consist in the uptake of two hydrogen equivalents or electrons. This conclusion is supported by the above-mentioned change in the slope of the E_0'/p_H curve of approximately 30 mv. by the first dissociation constant of the reduced form, and also by the observation of van Veen and Mertens that either one or three molecules of hydrogen are taken up by toxoflavin according to the conditions chosen. The uptake of one H_2 molecule would correspond to the reversible process amenable to electrometric study.

Treatment of toxoflavin as a two-step reduction system.

Assuming that toxoflavin is reduced in two steps increasingly overlapping towards the acid range and each involving the uptake of one electron, the process may tentatively be subjected to theoretical treatment along the lines developed by Michaelis and independently by Elema. These authors have shown how the distance of the normal potentials of the two single steps of such a system from the midpoint of the whole titration curve may easily be determined even in the range of considerable overlapping. Furthermore they have made available short cuts for obtaining the value of the characteristic "effective formation constant of the intermediary form (semiquinone)" at any given p_H value. The magnitude of this constant, K, is an adequate representation of the probability of free radical (semiquinone) formation and also of its stability. Michaelis [1933] for this purpose has compiled a table correlating the experimentally observed E_1 values with the distance of the separate normal potentials ($E_M - E_1 = E_2 - E_M$) from the midpoint of the titration curves and with $\log K$. Elema [1933] on the other hand has shown that a simple relation holds between K and the tangent to the titration curve at the midpoint. The height of ordinate defined by the midpoint of the curve and by the point of intersection of the tangent with the ordinate is called S. Then $K = (76{\cdot}63 . S - 2)^2$. In Table I both methods have been applied to the data obtained for toxoflavin. Since the intervals in the table of Michaelis are somewhat too large for simple interpolation ($E_M - E_1 = 0{\cdot}03 \log K$ being no linear function of E_1) a diagram was first constructed from the table of Michaelis and the values given in Table I were obtained by graphical interpolation. As will be seen from Table I, there is a general agreement between the K values derived by the methods of Michaelis and of Elema. Theoretically the agreement between the results of the two methods should be closer, which implies the conclusion that the differences actually found are to be ascribed to experimental errors.

Molecular weight of toxoflavin.

On the ground of molecular weight determinations by the cryoscopic method (solvent, water) and by Rast's method (solvent, camphor) van Veen and Mertens assign to toxoflavin the formula $C_6H_6O_2N_4$. The Rast determination is however invalidated by decomposition of the pigment in melting camphor. It was therefore thought to be desirable to obtain information about the molecular weight of toxoflavin by an independent method. In the case of pyocyanin Friedheim and Michaelis [1931] were able by the mere slope of the titration curves to establish the true molecular weight as half the value given by Wrede and Strack. In the case of toxoflavin where the slope of the titration curves is atypical throughout the whole p_H range the stoichiometric relations had to be taken into consideration. The basic assumption to be made was that two hydrogen equivalents are concerned in the reversible process of oxidation-reduction. No decision could be reached by oxidative titration experiments with potassium ferricyanide. In these experiments 10 ml. toxoflavin solution containing 0·166 to 0·167 mg. were reduced with palladium-hydrogen and then titrated with a $2{\cdot}10^{-3}\,M$ ferricyanide solution. For $n=2$ there should have been required 0·5 ml. ferricyanide if the molecular weight was 332, and 1·0 ml. for a molecular weight of 166. Actually the end-points observed on electrometric titration fell invariably near 0·7 ml. ferricyanide. The same irregularity has previously been observed in the case of photo-hepatoflavin [Stern, 1934, 2]. Better results were obtained by means of reductive titrations with chromous acetate. 10 ml. toxoflavin solution containing 0·166 mg. were titrated at p_H 5·67 with $5{\cdot}35.10^{-3}\,M$ chromous acetate solution. If the molecular weight of toxoflavin were 332, 0·187 ml. of the titrant, and if it were 166, 0·374 ml. should be required. As determined from the titration graph 0·32 M chromous acetate solution was necessary. In a similar experiment at p_H 4·6 the quantity of titrant used was 0·325 ml. of a $5{\cdot}16.10^{-3}\,M$ chromous acetate solution (calculated for mol. wt. 166:0·387 ml., for mol. wt. 332:0·193 ml.).

These experiments are therefore corroborative evidence in favour of the formula of toxoflavin proposed by the discoverers.

Results of spectrographic study.

The measurements of light absorption have been carried out by Dr Holiday at the Laboratories of the Medical Unit of the London Hospital Medical School [*cf.* Stern and Holiday, 1934, 2]. Their result was that a general resemblance exists between the patterns of the flavin and of the toxoflavin spectra. In aqueous solution (p_H 6·5) a steep main absorption band at 260$m\mu$ is accompanied by an inflection at 310$m\mu$ and by a lower and rather broad band centred at 405$m\mu$. The molecular extinction coefficients calculated for a mol. wt. of 166 amount

E. - - - - p_H 9·0 immediately after dissolving.
F. -·-·- p_H 11·0 immediately after dissolving.

to about one-half of the corresponding values for flavins. After standing for a short time at p_H 3 or p_H 11 the fading of the yellow colour is accompanied by an almost complete disappearance of specific light absorption. These results are illustrated in Fig. 2. At p_H 9 the height of the long wave band decreases and a distinct band is formed instead at $320 m\mu$. This band also slowly disappears with time.

The disappearance of specific absorption in acid and in alkaline solution seems to indicate an opening of a ring structure in the molecule.

Effect of toxoflavin on cell respiration.

Judged from the value of its normal potential toxoflavin should increase the oxygen uptake of non-nucleated red blood corpuscles to a similar extent to *e.g.* methylene blue or pyocyanin, assuming of course that the effect is not obscured by secondary factors such as toxicity or diffusibility.

Manometric experiments have been carried out by Mr Greville with human and rabbit erythrocytes. The result was that toxoflavin stimulates their respiration to about the same extent as thionine ($E_0' = +0{\cdot}062$ at p_H 7). The course of an experiment with rabbit blood corpuscles is illustrated in Fig. 3. In view of current discussion on the mechanism of stimulation of respiration in erythrocytes by oxidation-reduction systems it may not be without interest to mention that toxoflavin is capable of transforming oxyhaemoglobin with fair velocity into methaemoglobin.

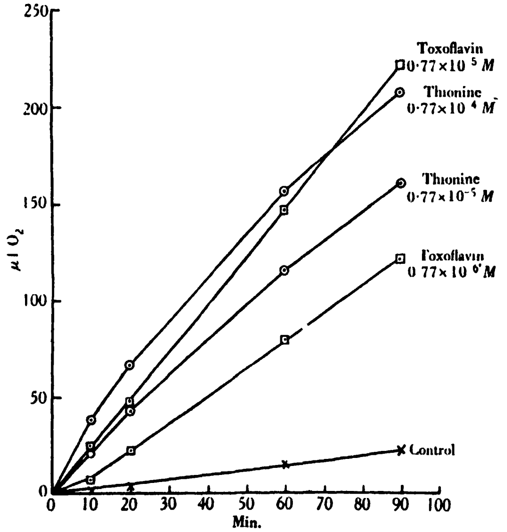

Fig. 3. Effect of toxoflavin and of thionine on respiration of rabbit erythrocytes in 0·2 % glucose.

The effect of toxoflavin on the respiration of Jensen rat sarcoma and on normal tissues (*e.g.* brain) is under investigation. Evidence so far available indicates that the respiration of Jensen rat sarcoma in glucose is also increased by toxoflavin (140 % increase by 2.10^{-5} mol. toxoflavin). The effect however decreases rapidly, probably because of a toxic action of the pigment which is shown better by brain slices, where a concentration of 10^{-5} mol. already strongly inhibits the respiration.

Discussion.

It is proposed to consider first the bearing of the results of this investigation on the question of a structural relationship between toxoflavin and the group of flavin (lyochrome) pigments. Van Veen and Mertens were led to assume such a relationship on the ground of similarities of a more qualitative nature, *e.g.* colour, fluorescence, stability towards oxidising agents and reversible reducibility. Though at the time of the completion of their paper (December, 1933) the flavin chemistry was still in its early stages, the authors were well aware of certain fundamental differences between toxoflavin and the other flavin pigments, *e.g.* in respect to behaviour towards radiation, formation of sparingly soluble silver salts and nitrogen content. In spite of the fact that the exact constitution of toxoflavin itself is still unknown, the rapid progress of flavin chemistry since the publication of Van Veen and Mertens's paper together with the data made available by the present experiments should furnish a definite answer to that question. If at the outset there existed a link of comparison between toxoflavin and the class of flavin pigments, such a link could only be seen in the photoflavins (or lumi-flavins), *i.e.* in the photo-decomposition products of the native flavins, but not in the native pigments themselves. Toxoflavin shares with a photo-flavin the solubility both in water and in chloroform, the stability towards oxidants, the reversibility of reduction and the presence of a methylimide group. There exists also a similarity in the general pattern of the absorption spectrum. On a closer examination of the data obtained on photo-flavins [Stern, 1934, 2] and on toxoflavin (this paper) with the same methods, these similarities turn out to be of a rather superficial nature. The major points are brought out in Table II.

Table II.

	Toxoflavin	Photoflavins
Range of stability	p_H 4 to 8	Conc. H_2SO_4—cold N NaOH
Normal potential at p_H 7	$E_0' = -0{\cdot}049$ v.	$E_0' = -0{\cdot}22$ v.
Slope of titration curves	Atypical throughout, increasing steepness towards alkaline range	Typical for $n=2$ in physiological range, increasing steepness toward acid range
Semiquinone formation	Not detectable; if any, then in alkaline range	Stable, red semiquinone in acid solution
Dissociation constants:		
p_K of reduced form	5·8 and 7·2	7·7
p_K of oxidised form	—	0·4 and 10
Maxima of light absorption	260; 310; 405 $m\mu$ (p_H 6·5)	267; 364; 440 $m\mu$ (p_H 7) (photo-hepatoflavin)

The data given in the column "Photoflavins" apply, with the noted exception of absorption bands, to the whole group of photoflavins, including those formed on irradiation of native flavins (discovered by Warburg and Christian [1932]) and the synthetic members of this group [Stern and Holiday, 1934, 1]. For further material for comparison in respect to the spectral behaviour of toxoflavin and the photoflavins, the reader is referred to the paper by Holiday and Stern [1934].

There are also several points of biological interest which deserve discussion. Whereas it is shown in this paper that toxoflavin in accordance with its potential may act as a stimulant after respiration of mammalian red blood cells and may convert oxyhaemoglobin into methaemoglobin, flavins do not possess such properties [Wagner-Jauregg *et al.*, 1933; 1934].

According to the description given by van Veen, toxoflavin seems to be present also outside the bacterium in the culture medium, though linked up to a high molecular complex. On the other hand bacterial flavin pigments have been found exclusively inside the cell in a non-diffusible form. Their concentration seems to be highest in strictly anaerobic organisms [Warburg and Christian, 1933], whereas toxoflavin is said not to be formed under anaerobic conditions. Finally, the flavin pigments so far investigated have all been found to be non-toxic.

It appears therefore that whatever similarity may have brought about the tentative classification of toxoflavin among the flavin series it is at present so much outweighed by fundamental differences between toxoflavin and all the known flavins, that this assumption were better abandoned. To our mind toxoflavin appears to be a new and interesting bacterial product of yellow colour without structural or functional relationship to the flavin pigments. The neighbourhood of its normal potential to that of pyocyanin suggests a similar function, probably that of an accessory respiratory catalyst [*cf.* Friedheim, 1931]. It is not unlikely that *Bacterium bongkrek* apart from toxoflavin will be found to contain a real flavin pigment concerned with a different phase of metabolism.

SUMMARY.

Toxoflavin, the prosthetic group of a yellow pigment formed by *Bacterium bongkrek* (van Veen and Mertens) represents the oxidant of an oxidation-reduction system which is fully reversible and electro-active between p_H 4 and p_H 8. The normal potential, as referred to the normal hydrogen electrode, at p_H 7·0 is $-0·049$ v. The slope of the individual titration curves is atypical throughout the p_H range investigated and shows an increasing steepness towards the alkaline range. Though no colour change indicating semiquinone formation was observed, the experimental data have tentatively been subjected to theoretical interpretation in the light of the theory of Michaelis and Elema of two-step reduction. The relation of toxoflavin to the group of flavin pigments is discussed.

The author wishes to thank Prof. E. C. Dodds for his interest and encouragement. Furthermore he wishes to thank him and the Council of the Middlesex Medical School for the hospitality afforded.

LVIII. THE INACTIVATION OF CATALASES FROM CERTAIN MARINE PLANTS BY OXYGEN.

By GRAHAM WALLACE MARKS.

Scripps Institution of Oceanography, University of California,
La Jolla, California.

(*Received November 2nd, 1934.*)

It has been shown [Marks and Fox, 1933; Marks, 1934, 1] that catalases from certain marine animals, on standing in air, slowly lose their ability to decompose hydrogen peroxide. This inactivation was found to be caused primarily by oxygen and the reaction to be pseudo-unimolecular under the given experimental conditions. The question arose as to whether or not catalases from marine plants would likewise be inactivated.

Methods.

The experimental procedure has already been described [Marks, 1934, 2]. Unless otherwise stated, the temperature at which extracts were stored and measurements were made was 20·0 ± 0·2°. The reaction time interval was 60 minutes.

Inactivation by oxygen. Solutions were prepared by extraction with a phosphate buffer of $p_{\rm H}$ 7·0, unless otherwise specified, of a number of species of marine plants. Portions were stored in air and under nitrogen or oxygen or both. Daily measurements were made on the quantity of hydrogen peroxide decomposed by 5 ml. samples after the addition of 2 ml. of the former. Controls were run simultaneously, using portions of extract that had been heated to boiling. The hydrogen peroxide solutions were prepared in the corresponding buffer or other corresponding medium and were 0·84–0·98 M.

It was found possible to apply the equation for a first order reaction to the inactivation reactions, as was previously done for other catalases [Marks, 1934, 1]. Thus, in the expression, $k=\frac{2\cdot303}{t}\log\frac{a}{a-x}$, let a = the initial number of mg. of hydrogen peroxide decomposed by 5 ml. of extract, and $(a-x)$ = the number of mg. of hydrogen peroxide decomposed by 5 ml. of extract at any time, t, in days after the start. It has been shown [Marks, 1934, 2] that the quantities of hydrogen peroxide decomposed by the catalases from *Corallina officinalis* and *Pikea californica* are directly proportional to the enzyme concentration at $p_{\rm H}$ 7·0. This has been assumed to be true for the catalases from other species of marine plants. The true concentration of enzyme would be given by multiplying a and $(a-x)$ by some unknown factor c. However, this cancels out in the logarithmic expression, and thus the procedure is justified.

Data are given in Table I and show that the rates of inactivation were always greater for the portions of extract kept under air than under nitrogen. However, since oxygen enters directly or indirectly into the inactivations, the reactions are pseudo-unimolecular [Taylor, 1930]. Thus, the true equation is $k=\frac{1}{tb}\ln\frac{a}{a-x}$, in which b is the concentration of oxygen or oxygen and unknown substances. This factor remains constant for any single experiment.

Table I. *The inactivation of catalases from marine plants.*

			Nitrogen	9	0·083–0·096	0·089
Polysiphonia verticillata	20	Phosphate buffer p_H 7·0	Air	5	0·262–0·273	0·267
			Nitrogen		Rate slower‡	

* Taken at 24 hour intervals.

† Although the range of *k* seems wide in some cases, actually most of the values clustered about the mean, and only one or two observations departed greatly therefrom.

‡ Rate did not conform satisfactorily to the unimolecular equation. Compare Marks and Fox [1933].

It was found that the catalases in 10–20 % extracts prepared from *Pelvetia fastigiata*, *Colpomenia sinnora*, *Dilophus flabellatus*, *Scytosiphon lomentarius* and *Sargassium agardianum* in a phosphate buffer at p_H 7·0 almost completely lost their activity on standing in air for 24 hours at 20°.

Inactivation at different p_H *values.* That the inactivation occurs irrespective of hydrogen ion concentration is shown in Fig. 1 for catalase from *Corallina officinalis*. It must not be inferred that because higher magnitudes of *k* are obtained at lower p_H values the reactions proceeded more rapidly. Reference to curves 1, 2 and 6 of Fig. 2 in the paper of Marks [1934, 2] shows that such results can be ascribed to the greater slope of portions of the proportionality curves. These portions do not pass through the origin. It is not now possible to say just what effect hydrogen ion and salt concentrations have on the reaction rates.

Previously, sharp changes in the slopes of the curves were noted when the data for the inactivation of catalases from certain marine animals were plotted logarithmically [Marks, 1934, 1]. Similar discontinuities (Fig. 1) have been found for the inactivation of catalase from *Corallina officinalis* at p_H 8·0 and 9·0. Again these changes are not to be ascribed to a difference in reaction rate, but to discontinuities in the proportionality curves. Thus, referring again to Fig. 2 [Marks, 1934, 2] for p_H 10·0, the change occurs at about 22 mg. on the ordinate, and in Fig. 1 (p_H 10·0) of the same paper, an apparent change in reaction rate is found at about 20 mg. ($\log_{10} = 1·30$), *i.e.*, both changes occur at approximately the same catalase concentration.

Inactivation of catalases at different temperatures. It is to be expected that the rate of inactivation will increase with rise in temperature. Extracts were prepared in phosphate buffer p_H 7·0, divided into several portions and stored at given temperatures which varied from their mean values by about ±0·2°.

Daily measurements were made at 20·0 ± 0·2°, the sample first being kept for 20–30 minutes in a room at this temperature before the introduction of hydrogen peroxide.

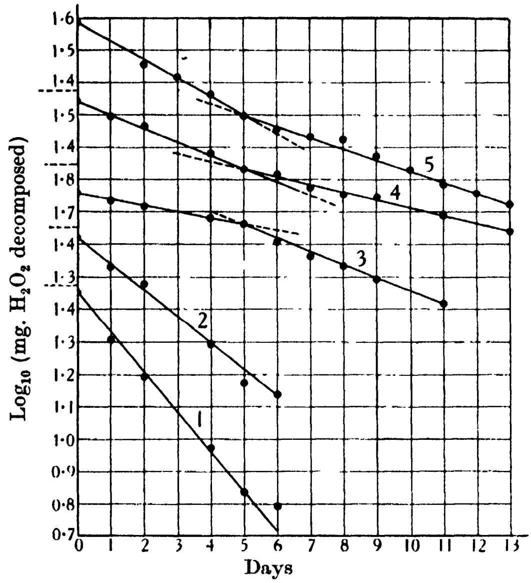

Fig. 1. Inactivation of catalase from *Corallina officinalis* at different p_H values. Respective concentrations of extracts and p_H of buffers used are in the order of the numbers of the curves: 40 %, 40 %, others 20 %; p_H 4·5, 6·0, 8·0, 9·0 and 10·0. All buffers phosphate except 9·0 and 10·0 which were H_3BO_3-KCl-NaOH mixtures.

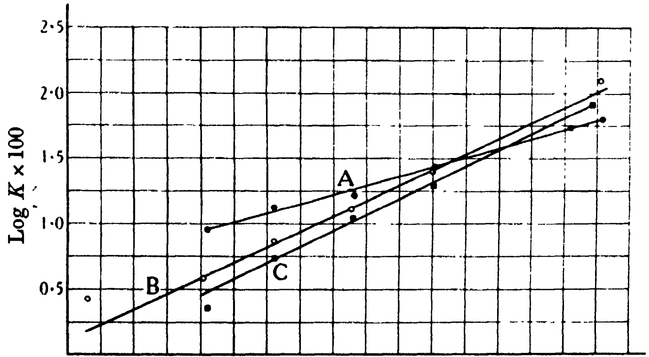

Fig. 2. Inactivation of catalases from marine plants. Curves showing the application of Arrhenius's equation for change in reaction rate with change in absolute temperature. Curves *A* and *B*, *Corallina officinalis* (20 % extracts); curve *C*, *Pikea californica* (40 % extract).

Initial values of *a* were determined by the extrapolation method [Marks and Fox, 1933]. These extrapolated values were not precisely the same for the different temperatures for a given extract, but only approximately so.

Application of Arrhenius's equation. Arrhenius's equation was previously found applicable to the change in inactivation rate with change in temperature for mussel catalase [Marks and Fox, 1933]. Since again it is assumed that unknown factors, including oxygen, remained constant under the given conditions, the integrated form of Arrhenius's equation [Taylor, 1930] may be written as follows:

$$2{\cdot}303 \log \frac{k_1}{k_2} = \frac{Q}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right),$$

where $k_1 = k'b$, and $k_2 = k''b$.

In Fig. 2 are plotted data obtained for catalases from *Corallina officinalis* and *Pikea californica*. Since the curves are straight lines, the Arrhenius equation is applicable. It is to be noticed that the slopes of curves *A* and *B* for two different extracts of *C. officinalis* having the same percentage concentration are quite different. Thus the values of *Q* are not the same in the two cases. This effect can be ascribed to an unknown factor or factors which remain constant for a given extract. It is hardly to be ascribed to oxygen alone as there is no reason for believing that the concentrations of this gas were significantly different in the two preparations at the different temperatures.

SUMMARY.

1. Catalases from certain species of marine plants are inactivated, directly or indirectly by oxygen and the reactions have been found to be pseudo-unimolecular under the given experimental conditions.

2. Catalase from *Corallina officinalis* slowly loses its activity over the p_H range 4·5–10·0 at 20·0 ± 0·2°.

3. The change in the rate of inactivation of catalases from *Corallina officinalis* and *Pikea californica* with change in temperature is expressed by the Arrhenius equation over a range of 4·0–37·5°.

The writer is indebted to Mr P. S. Barnhart for the identification of the marine plants.

LIX. THE EFFECT OF THYROTROPIC HORMONE UPON SERUM CHOLESTEROL.

By LEONARD IRVING PUGSLEY.

From the Department of Biochemistry, McGill University, Mon'real, Canada.

(*Received December 11th, 1934.*)

It has been shown by a number of workers that the administration of the thyrotropic hormone of the anterior pituitary has a stimulating effect upon the thyroid. The physiological properties and preparation of a highly active and purified extract containing this principle have been recently reported by Anderson and Collip [1934]. Hurxthal and his co-workers in a series of papers [1930; 1933; 1934] have shown that a reciprocal relationship exists between the blood cholesterol and the basal metabolic rate. Recently Cutting *et al.* [1934] have treated the published data on the relationship between basal metabolic rate and blood cholesterol statistically and have confirmed by a regression curve that an inverse relationship exists between these two variables. It has been shown experimentally by Westra and Kunde [1932] using rabbits, and Parhon and Derevici [1931] using dogs, that a decrease in blood cholesterol results from feeding desiccated thyroid and the injection of thyroxine.

In the light of this work, it seemed of interest to investigate the effect of the thyrotropic hormone upon serum cholesterol.

Methods.

A group of 15 adult rats weighing between 280 and 320 g. was chosen for the experiment. During the injection period, 3 or 4 rats were bled by heart puncture every second day. Successive samples were taken from each animal at 6-day intervals, in order to minimise the effects of haemorrhage. Between 1·2 and 1·5 ml. of blood were removed each time and 0·5 ml. of serum was used in the estimation of cholesterol, which was carried out by the method of Sackett [1925]. This amount of serum was found necessary on account of the low value for serum cholesterol in the rat. The normal level for cholesterol was obtained from a group of 12 rats and these were also bled at intervals of 6 days on different occasions to show that the removal of this quantity of blood did not interfere with the level of cholesterol.

The rats received twice daily 0·5 ml. of an active thyrotropic extract which was shown to contain 50 units of the hormone per ml. as assayed on the hypophysectomised rat.

Results.

The results are shown in Table I. The normal values for serum cholesterol of rats varied between 64 and 75 mg. per 100 ml. with an average value of 70 mg. per 100 ml. Upon injection of the thyrotropic hormone, the serum cholesterol decreased markedly, reaching its lowest level on the 8th to 10th day of injection and then returning to the normal level or slightly above in the course of 2 weeks. The values are expressed graphically in Fig. 1. This graph has a striking reciprocal relationship to the basal metabolic rate curves shown by Pugsley *et al.* [1934] in their study of the effect of thyrotropic hormone upon creatine and creatinine excretions of normal and hypophysectomised rats.

Table I. *The effect of thyrotropic hormone upon the serum cholesterol of rats.*

The values are expressed in mg. per 100 ml. of serum.

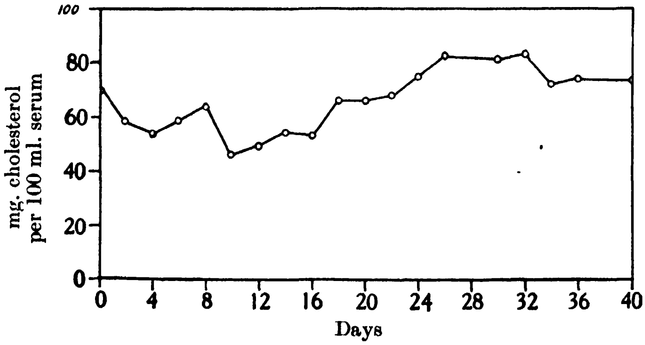

Fig. 1. The effect of thyrotropic hormone upon the serum cholesterol of rats.

The serum cholesterol has also been studied in dogs after intravenous and intraperitoneal injections of the thyrotropic hormone. The results are shown in Table II. In dog no. 1 it is seen that the injection of a potent thyrotropic extract caused a marked decrease in the serum cholesterol. This is confirmed in dog no. 2, using the extract employed in the experiments on rats. When the injections were discontinued the cholesterol values returned to the control level within 2 weeks. With continued injections, as is shown in dog no. 1 B, the same decrease in cholesterol was found, but the values did not return to the control level as rapidly as they did in the chronically-treated rats. The injections were continued for 68 days and the serum cholesterol was determined every second day; during this time the values ranged between 125 and 145 mg. per 100 ml. In dog no. 1 C it is shown that boiling the thyrotropic hormone at p_H 6·0 for 30 minutes in an open flask completely destroys its effect in lowering the serum cholesterol.

Table II. *The effect of thyrotropic hormone upon the serum cholesterol of dogs.*

The values are expressed in mg. per 100 ml. of serum.

Dog no. 1. Male. Wt. 16 kg. 10 ml. b.i.d. Extract 1 intravenously for 10 days.
Dog no. 2. Male. Wt. 15 kg. 5 ml. b.i.d. Extract 2 intraperitoneally for 12 days.
Dog no. 1 B. Male. Wt. 16 kg. 5 ml. b.i.d. Extract 2 intravenously for 68 days.
Dog no. 1 C. Male. Wt. 16 kg. 10 ml. b.i.d. Extract 1 intravenously (boiled) for 8 days.
Dog no. 3. Female. Thyroparathyroidectomised-hypophysectomised. Wt. 12 kg. 5 ml. b.i.d. Extract 2 intraperitoneally for 20 days.

The effect of the thyrotropic hormone upon the serum cholesterol of a thyroparathyroidectomised-hypophysectomised dog has been studied (dog no. 3). The completeness of these operations has not been established as yet. However, the thyroparathyroidectomy appears to be complete, since the serum calcium showed a marked decrease following the operation (11·6 to 7·8 mg. per 100 ml.). The animal received parathyroid hormone (Eli Lilly and Company) for some time, but during the administration of the thyrotropic hormone no parathyroid hormone was given. The dog was in good health and showed no symptoms of tetany during this time. The serum calcium which was also followed ranged between 7·0 and 8·0 mg. per 100 ml. In this dog no significant decrease in the cholesterol was observed as a result of the injections. This observation is in agreement with the reports of Verzar and Wahl [1931] and others that the thyrotropic hormone does not function in thyroidectomised animals.

SUMMARY.

The intraperitoneal injection of the thyrotropic hormone caused a marked decrease in the serum cholesterol of rats and dogs.

The serum cholesterol curve shows a reciprocal relationship to the basal metabolic rate curve of rats receiving chronic injections of the thyrotropic hormone.

I wish to express my indebtedness to Prof. J. B. Collip and to Dr D. L. Thomson for advice during the course of this work.

LX. STUDIES ON THE PHOSPHATASES.

THE INFLUENCE OF SOME ELECTROLYTES ON THE PHOSPHATASES OF ANIMAL TISSUE. PHOSPHATASES OF THE LIVER, KIDNEY, SERUM AND BONES OF THE RABBIT.

By SERAFINO BELFANTI, ANGELO CONTARDI and ALBERTO ERCOLI.

From the Istituto Sieroterapico Milanese and R. Istituto Superiore Agrario, Milan.

(*Received December 10th, 1934.*)

In recent work Davies [1934] found that the autolysed extracts of liver and spleen hydrolyse sodium β-glycerophosphate at two different optima of acidity, namely p_H 4·5–5 and p_H 8·9, and he expressed the opinion that there were two different phosphatases: however, it was not possible for him to purify the extracts in such a way as to obtain from them two fractions each containing one of the two distinct enzymes.

An analogous fact had been observed for the phosphatases of hog kidney by Kurata [1931] who had succeeded in obtaining, by adsorption processes and from the same starting material, two different enzymic solutions, one having an optimum of phosphatase activity at p_H 3, the other at p_H 9.

Recently some Japanese authors of Akamatsu's school [Usawa, 1932: Munemura, 1933, *etc.*] came to the conclusion that the enzymes which hydrolyse the monoesters of phosphoric acid belong to three types:

(*a*) A phosphomonoesterase type I, p_H optimum 3, extracted by Manaka [1931] from takadiastase.

(*b*) A phosphomonoesterase type II, p_H optimum 5·4–5·6, extracted by Usawa [1932] from rice husk and purified by an adsorption process.

(*c*) A phosphomonoesterase type III, p_H optimum 9–10, studied by Asakawa [1928; 1929] in kidney extracts.

Hori [1932], confirming the results obtained by Roche [1931], reported the presence of a phosphomonoesterase of type II in erythrocytes. In this way, according to the Japanese authors quoted, phosphomonoesterases of all three types are to be found in animal tissues, whereas type III phosphomonoesterase would appear always to be absent from vegetable tissues.

A study of the behaviour of the three phosphomonoesterases in the presence of different electrolytes has been made by Munemura [1933], who made his experiments on purified solutions of extracts of takadiastase, of rice husks and of hog kidney, chosen as being representative of the three types of phosphomonoesterase. Starting from the presupposition that all the enzymes which hydrolyse the monoesters of phosphoric acid and which exist in nature are included in these three types, he generalised the results thus obtained.

We wished to study the influence of some inactivating agents and, in particular, of sodium fluoride and oxalate, on the phosphatase activity of extracts of liver, kidney, bone and serum of the rabbit. It seems to us that the results we obtained lead to deductions which are somewhat different from those arrived at by the Japanese authors.

EXPERIMENTAL.

Technique.

The general method of research was as follows. In a series of 25 ml. flasks were placed: 1 ml. of a solution of sodium glycerophosphate (5 % of the anhydrous salt); 2·5 ml. of a solution of sodium acetate and sodium veronal in concentration double that prescribed by Michaelis [1930], containing 38·856 g. of $CH_3COONa, 3H_2O$ and 58·856 g. of sodium veronal per litre of solution; 2 ml. of an 8·5 % solution of pure NaCl. To each of the flasks was added, in order to obtain the desired p_H value, that quantity of HCl prescribed by Michaelis for the purpose; when it was desired to examine the action of some inhibiting agent a measured quantity of a concentrated solution of that agent was also added. Finally, 5 ml. of the enzymic solution under examination were placed in each flask and the liquid brought to the mark. In view of the fact that the enzymic extracts, like the solutions of oxalate and of fluoride, often notably displace the p_H of the buffer solutions, the p_H was controlled electrometrically on an aliquot part of the solution. The remainder was distributed in portions of 5 or 10 ml. in thick-walled test-tubes which, after the addition of a drop of toluene, were tightly closed and left in the thermostat at 37° for 16 hours. At the end of that time, a measured quantity of 10 % trichloroacetic acid was added to each test-tube. The contents were filtered and inorganic phosphorus was determined in the filtrate using Lohmann and Jendrassik's [1926] modification of Fiske and Subbarow's [1925] method. The values thus ascertained were then calculated to 1 ml. of the solution under examination.

We used the acetate-veronal buffer according to Michaelis, notwithstanding its weak buffering powers, because it offers the advantage of an extremely wide range of acidity, between p_H 9·64 and 2·62, simply by adding different amounts of hydrochloric acid. When it was necessary to use still higher p_H values (10 to 11), we added a few drops of dilute solution of sodium hydroxide to the veronal buffer, counting also on the buffering power of the enzymic solutions themselves. In this way we excluded the possibility of the enzymes being diversely influenced by the different nature of the buffer.

The crystallised sodium glycerophosphate used by us, and placed on the market by Messrs Carlo Erba of Milan, was composed exclusively of the β-form [Carrara, 1932].

Phosphatases of liver and kidney extracts.

The tissues used in these experiments were taken from adult and normal rabbits. The technique employed for the preparation of the extracts had many points of similarity with that adopted by Asakawa [1928]. The animals were killed by cutting the carotid. The abdominal cavity was then immediately opened, a cannula needle was introduced into the vena cava and, after ligaturing the portal vein, the blood vessels were washed with physiological salt solution at 37°. The organs were then removed and, after being freed from the residues of surrounding tissues, were rapidly washed with physiological salt solution, weighed, triturated with sand in a mortar and placed in an Erlenmeyer flask together with ten times their weight of sterile distilled water and a few ml. of toluene. The whole was then placed in a thermostat at 37° and allowed to autolyse for 48 hours. It was afterwards filtered through a folded filter. The clear filtrate was dialysed for 36 hours in small bags of collodion placed in distilled water. The dialysed extracts were again filtered, a small quantity of toluene was added and the whole kept in an ice-chest. The extracts thus prepared do not contain enzymes from the blood when the operation of washing with physiological salt solution has been conducted properly. They are, moreover, extremely poor in albuminous substances and keep their phosphatase activity for a fair length of time. Again, possible sources of error, including those due to the hydrolytic action of phosphodiesterases and pyrophosphatases, are avoided because the phosphorylated organic compounds pre-existing in the tissues are decomposed during the digestion in the thermostat and the inorganic phosphates are eliminated wholly by means of the dialysis. The determinations themselves thus become less laborious because controls are not necessary.

Table I shows that, within very wide limits, the effect of sodium fluoride on the phosphatase activity of a liver extract does not change with variations in the degree of concentration of this salt.

Table I. *Inhibitory action of sodium fluoride on the phosphatase activity of rabbit liver extracts.*

p_H of the buffer solution	mg. P hydrolysed in the presence of NaF				mg. P hydrolysed in the absence of NaF
	$M/50$	$M/7$	$M/4$	$M/2$	
3·6	—	0·006	—	—	0·034
5·5	0·003	—	0·005	0·007	0·067
7·5	0·040	—	0·039	0·040	0·050
8·3	0·067	0·066	0·067	0·065	0·065

From Fig. 1, which represents the results of an experiment carried out by acting contemporaneously with an extract of rabbit liver on sodium glycerophosphate in the absence of inhibitory agents (Curve A), in the presence of $M/50$ NaF (Curve B), and in the presence of sodium $M/50$ oxalate (Curve C), it may be seen that, analogously with the results obtained by Davies [1934], the

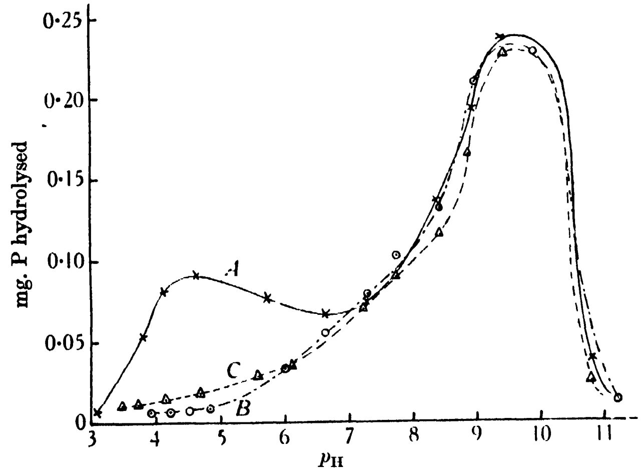

Fig. 1. The hydrolysis of β-glycerophosphate in the absence and presence of added fluoride and oxalate by rabbit liver extracts under varying conditions of hydrogen ion concentration.

Curve A. × ——— × Hydrolysis in absence of inactivating agents.
Curve B. ⊙ — — —⊙ Hydrolysis in presence of added fluoride.
Curve C. ▲- - - - ▲ Hydrolysis in presence of added oxalate.

phosphatase of the liver acts at two different p_H optima, one in an alkaline zone and the other in an acid zone. It is also clearly shown that the two inhibitory agents examined leave the "alkaline" phosphatase activity almost unaltered and that they affect only the "acid" phosphatase activity. As this inactivation is very profound and the residual activity from p_H 3 to 6 is almost negligible, it may be held that the problem set by Davies [1934] to separate the two phosphatases has been solved at least in part.

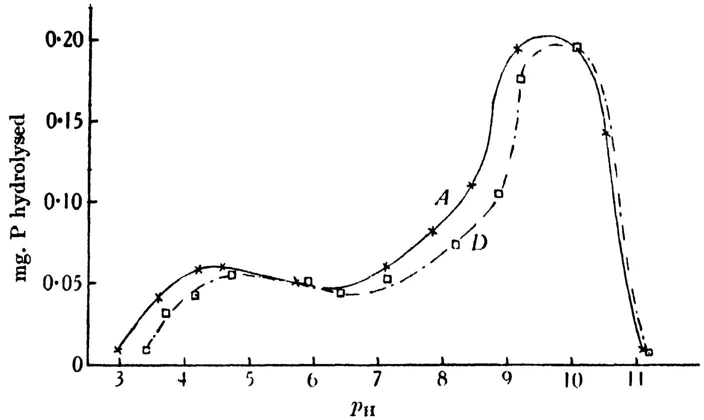

Fig. 2. The hydrolysis of β-glycerophosphate in the absence and presence of added iodoacetate by liver extracts (rabbit) under varying conditions of hydrogen ion concentration.

Curve *A*. ×——× Hydrolysis in absence of added iodoacetate.
Curve *D*. ⊡—·—·⊡ Hydrolysis in presence of added iodoacetate.

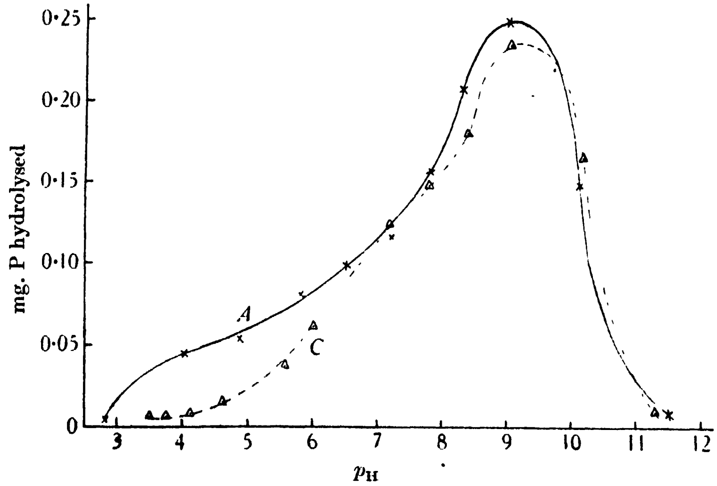

Fig. 3. The hydrolysis of β-glycerophosphate in the absence and presence of added oxalate by kidney extracts (rabbit) under varying conditions of hydrogen ion concentration.

Curve *A*. ×——× Hydrolysis in absence of added oxalate.
Curve *C*. △----△ Hydrolysis in presence of added oxalate.

The results of this experiment are not in agreement with the views of some of the Japanese authors mentioned above. In fact, according to Munemura [1933], sodium oxalate completely inhibits the activity of the phosphatase type

III (alkaline) whereas this did not occur in our case. Again, according to the same author the oxalate should not have a very noticeable action on type II phosphatase at a p_H optimum of 5·5. It should be observed, however, that, in analogy with what was found by Kobayashi [1927] and Inouye [1928] in the case of the phosphatase of *A. oryzae*, our acid phosphatase might also be a type I phosphatase modified in its properties by the presence of a substance *X*.

Table II. *Inhibitory action of sodium trichloroacetate on the phosphatase activity on extracts of rabbit liver.*

p_H of the buffer solution	mg. P hydrolysed		
	In the presence of CCl_3COONa		In the absence of CCl_3COONa
	M/50	*M*/20	
3·2	0·0089	0·0067	0·0338
5·3	0·0674	0·0686	0·0649
8·9	0·0828	0·0805	0·0828

From Table II it may be seen that sodium trichloroacetate has a similar action to those of sodium fluoride and oxalate on the phosphoesterase of the liver.

Fig. 2 shows the behaviour of the same extract of liver on sodium β-glycerophosphate in the presence and in the absence of *M*/50 sodium iodoacetate. This liver extract was the same as that used for the experiment illustrated in Fig. 1. The experiment was, however, carried out 6 days later with the same enzymic solution which had been kept in the ice-chest in the meantime. As may be seen, whilst the "alkaline" phosphatase activity remained almost unaltered, the "acid" phosphatase underwent a much more noteworthy inactivation. The iodoacetate acts extremely weakly on the acid phosphatase, and it appears to have only the same weak influence on the alkaline phosphatase as have oxalate and fluoride.. The determinations of the p_H in the presence of iodoacetate under alkaline conditions were carried out by means of the colorimeter because the iodoacetate poisons the hydrogen electrode.

Fig. 3 shows the action of the phosphatase of a rabbit kidney extract on β-glycerophosphate in the absence (Curve *A*) and in the presence (Curve *C*) of *M*/50 sodium oxalate. In Curve *A*, besides the optimum of activity at p_H 9·2, the existence of a second optimum in the acid zone is not to be found. However, in the presence of sodium oxalate under acid conditions there is a marked inhibition of the phosphatase activity, analogous to that which occurs in the case of liver extracts. Therefore, in this case also one may suppose the presence of an "acid" phosphatase. The considerations already set forth in the matter of the "acid" phosphatase of the liver hold good also in this case and are supported by the experiments, of which we have already made mention, carried out by Kurata [1931] on the phosphatases of hog kidney.

As regards the "alkaline" phosphatase, we were not able to find inactivation by sodium oxalate in extracts of rabbit kidney prepared by the method used by Asakawa and by Munemura. This is the contrary of what Munemura found when experimenting with extracts of hog kidney.

On the whole, the behaviour of the phosphatases of the liver and those of the kidney, in the presence of inactivating agents, is such as to cause one to admit the qualitative identity of the two enzymic systems.

Phosphatases of rabbit and horse blood serum.

We used the serum from 8 rabbits which were kept without food for 24 hours. The blood was taken from the carotid. The horse serum was obtained from an animal which had been kept without food for 24 hours. In this case, the blood was taken by opening the external jugular vein.

The sera thus obtained were dialysed directly, without predigestion in the thermostat, in small bags of collodion placed in distilled water for 36 hours. Fig. 4 shows the hydrolysis of β-glycerophosphate produced at different p_H values in the absence of inhibitory agents (Curve *A*), in the presence of *M*/50 NaF (Curve *B*), in the presence of *M*/50 sodium oxalate (Curve *C*) and in the presence of *M*/100 sodium iodoacetate (Curve *D*).

Fig. 5 shows the hydrolysis produced by dialysed horse serum in the absence of inhibitory agents (Curve *A*), in the presence of *M*/50 NaF (Curve *B*), and in the presence of *M*/50 sodium oxalate (Curve *C*).

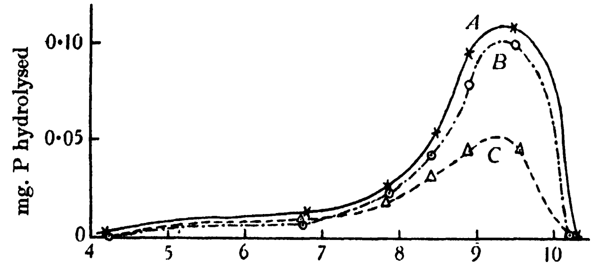

Fig. 5. The hydrolysis of β-glycerophosphate in the absence and presence of added fluoride and oxalate by horse serum under varying conditions of hydrogen ion concentration.

Curve *A*. × ——— × Hydrolysis in absence of inactivating agents.
Curve *B*. ⊙—·—·⊙ Hydrolysis in presence of added fluoride.
Curve *C*. △- - - -△ Hydrolysis in presence of added oxalate.

In serum one also observes the presence of an acid phosphatase, although very weak. In the presence of inhibitory agents, it behaves in the same way as the extracts of liver and kidney. As regards the alkaline phosphatase, this is not inactivated by sodium fluoride but is greatly inhibited by the action of sodium

oxalate. As in the case of the liver extract, iodoacetate does not much affect the acid phosphatase; it acts on the alkaline phosphatase, at least up to the p_H values employed in the same way as sodium oxalate.

The phosphatases of bone.

The femora, tibiae and humeri of a 25-day old rabbit were carefully freed from their soft parts. The epiphyses were detached, the bones split along their

Curve C. △- - - -△ Hydrolysis in presence of added oxalate.

length and the marrow carefully removed. They were then rapidly washed with physiological salt solution. The shafts and the epiphyses, after having been broken up separately in a mortar with quartz sand, were subjected to the treatment described in connection with the extracts of kidney and liver.

Figs. 6 and 7 show the hydrolyses produced respectively by the extracts of shaft and of epiphysis at various degrees of acidity in the absence and in the presence of fluoride and of oxalate. As may be seen, the two extracts behave in an analogous manner.

Examination of the two diagrams shows that the considerations set forth in the case of the phosphatases of serum may be repeated in the case of bone. The two systems behave in a markedly similar manner towards oxalate and fluoride. In young animals the phosphatase of the bone is much more active than that of the serum.

DISCUSSION.

Examination of the diagrams previously explained shows the following facts.

(1) Extracts of liver and kidney contain, besides the alkaline phosphatase which is that which up to the present has most attracted the attention of research workers, an "acid" phosphatase which has some activity but,in any case is not negligible. It seems probable to us that this "acid" phosphatase has a physiological function.

(2) In bones (shaft and epiphyses) and in blood serum, the activity of the "acid" phosphatase is extremely slight.

(3) In extracts of bone and in serum, the "alkaline" phosphatase is sharply differentiated from the corresponding one present in extracts of liver and kidney by the fact that sodium oxalate reduces its activity in greater measure.

(4) Near neutrality, the influence of the inactivating agents which we have considered is negligible. One might therefore distinguish three different systems of phosphatase enzymes in animal tissues: that of the liver and of the kidney (and probably also of the spleen [Davies, 1934]) characterised by the presence of an "acid" and an "alkaline" phosphatase, the latter not being inhibited by sodium oxalate; that of serum and of bone characterised (the acid phosphatase being nearly negligible) by the presence of an "alkaline" phosphatase which is partially inhibited by sodium oxalate;[1] and lastly, that of the erythrocytes characterised, according to the statements of Roche [1931] and Hori [1932], by the presence of the acid phosphatase only. Moreover, according to Hori, this phosphatase of the erythrocytes (p_H optimum 5·5) is different from that of the kidney (p_H optimum 3).

In order to explain the negligible activity of the "acid" phosphatase of bone extract, one might put forward the hypothesis that the accumulation in the bones of notable quantities of fluoride which, as we have seen, inhibits the activity of this phosphatase, contributes to this fact.

We are working on the influence of fluorides on phosphatases; the results of our experiments will be given in one of our next communications.

We believe in fact that fluorine plays an important part in the phenomena of calcification and decalcification of bone and that by carrying research work still farther in this direction, it may be possible to obtain some light on this complicated question.

---

[1] We wish to observe in this connection that most authors, on the basis of Kay's work [1930], hold that the phosphatase of serum is of osseous origin: latterly however the work of Bodansky [1934] and of Bodansky and Jaffe [1934] tends to show that, except in cases of disease of the bone, the phosphatase of serum is of different origin.

Many considerations confirm this point of view.

(*a*) The fixation of fluorine by the bone, a phenomenon which in itself must surely have some physiological meaning.

(*b*) The phenomena consequent on chronic fluoride poisoning. These phenomena, on which a vast literature already exists [McClure, 1933], may easily be associated with a degenerated phosphatase activity of the osseous tissues.

(*c*) The alterations of the phosphatase activity of the plasma recently observed by Phillips [1934] in cows suffering from fluorosis. In this connection we have already referred to the analogy which exists between the phosphatase system of serum and that of bone.

(*d*) The fact, discovered by Robison and Rosenheim [1934],[1] that the addition of sodium fluoride, even in extremely small quantities, impedes *in vitro* the deposition of calcium on the ossifying cartilage.

To these considerations it may be objected that, in all the cases observed up to the present, the fluoride acts only on the acid phosphatases and not on the alkaline ones which appear, as regards the process of calcification of the bones and having regard to the reaction of the media in which they must operate, to be the most important. Robison and Rosenheim [1934] have observed that fluoride does not depress the activity of the bone phosphatases (alkaline). Furthermore, it may be objected that, in the phenomena of calcification, the two mechanisms admitted by Robison (scission of the phosphoric ester and precipitation of the calcium phosphate) may occur even at different hydrogen ion concentrations. Experiments not yet completed demonstrate that in certain conditions fluorides may also inhibit the activity of the alkaline phosphatases.

At this point we wish to recall attention to the classification of the phosphatases proposed by the Japanese authors. It has already been said that Akamatsu and his collaborators distinguish three types of phosphomonoesterase corresponding to the three different degrees of dissociation of a monoester of phosphoric acid (the hydrogen of both hydroxyls not replaced, p_H 2·8–3; that of one hydroxyl replaced, p_H 5·5; that of both hydroxyls replaced, p_H 9–10) and analogous to the three types of proteinase: pepsin, papain and trypsin-kinase. From several points of view, this classification appears to be most suggestive, but it is difficult to accept entirely the views of the Japanese school on the behaviour of these three types of phosphatase as regards inhibitors and chemical activators. For example, we have seen how, according to Munemura [1933], the activity of the alkaline phosphatase should be completely inhibited in the presence of sodium oxalate. We found instead, in some of the cases examined, only partial inactivation, whilst in other cases the inactivation was practically nil. From this, ought one to deduce that there exists a fourth type of phosphatase having an optimum of activity at the same p_H as the third type, but which can be distinguished from the latter because it maintains its activity even in the presence of sodium oxalate? It appears to us that it is more probable that the inactivation of the enzymes by inhibitory agents as commonly used may be exerted, at least in certain cases, not on the haptophore groups but on the colloidal carriers of the enzyme itself. In these cases, therefore, one and the same enzyme changes its properties towards activating and inactivating agents when there are changes in the colloidal carrier. Objections might be raised to the technique employed by us because the determinations were made after a somewhat lengthy period of digestion in the thermostat (16 hours) so that the hydrolysis of the substrate, at the optimum p_H, in some cases reached 80 %. Moreover, the experiments were made with a veronal buffer. The determinations carried out by Munemura [1933], using a glycine buffer with an extract of hog kidney in the presence and in the absence of sodium oxalate, were made when the hydrolysis of the glycerophosphate, in the absence of oxalate and at the optimum p_H, was about 50 %. It may be suspected that this is the cause of the notable difference between our results and those of the Japanese author.

---

[1] For the sake of brevity, we have omitted to cite the other works of Robison to whom, together with Kay, belongs the merit of having commenced and of having given great impulse to the study of the phosphatases. On the other hand, the works of both these authors and of their collaborators, published for the greater part in this *Journal* since 1923, are well known to all those who are interested in this subject.

Preliminary experiments have however shown us that the conclusions are not substantially changed either when the hydrolysis is interrupted at 50 % or when it is still further prolonged, and this both in the presence of veronal buffer and in that of glycine buffer.

This preliminary examination led, among other things, to interesting observations on which we will report in our next communication.

On the other hand, when carrying out the inorganic phosphorus determinations we found it possible to obtain, after a sufficiently long space of time, detectable quantities of phosphorus even at acid p_H values and thus to have the possibility of a simultaneous and accurate measure of the activities of both acid and alkaline phosphatases.

We feel that it is opportune to make a further remark in connection with the use of sodium oxalate as an anticoagulant for the taking of blood for research work on the phosphatases of the plasma. It is clear, from what we have explained, that by operating in this manner, the action of the phosphatases present is greatly inhibited. Bodansky [1933] in fact observed that the phosphatase activity of oxalated plasma was about 10 % lower than that of heparin plasma. He, however, attributed this to the increase in osmotic pressure due to the potassium oxalate and to the consequent dilution of the plasma.

For the same reasons it is inadvisable to employ trichloroacetate which some authors have used when studying the scissions of the phosphorylated compounds of the blood.

SUMMARY.

1. Extracts of liver and kidney contain, besides an "alkaline" phosphatase, an "acid" phosphatase, the activity of which is not negligible.

2. The activity of the "acid" phosphatase of liver and kidney extracts is inhibited by the fluoride, oxalate and trichloroacetate of sodium, that of the "alkaline" phosphatase of the same extracts is not influenced by these electrolytes. In this connection the two enzymic systems are qualitatively similar.

3. The activity of the "acid" phosphatase is extremely low in bone and serum.

4. In serum and extracts of bone, the "alkaline" phosphatase is partially inhibited by sodium oxalate. From this point of view these two enzymic systems may be considered to be qualitatively identical.

5. Near neutrality the influence of the inactivating agents which we have considered is negligible.

6. The influence of fluorides on the processes of calcification and decalcification of bone is discussed.

LXI. STUDIES ON THE ANAEROBIC DECOMPOSITION OF PLANT MATERIALS.

I. THE ANAEROBIC DECOMPOSITION OF RICE STRAW (*ORYZA SATIVA*).

BY CADAMBI NARASIMHA ACHARYA.

From the Fermentation Department, Rothamsted Experimental Station, Harpenden, Herts.

(*Received December 30th, 1934.*)

THE aerobic decomposition of plant materials has in recent years attracted much attention, on account of its importance in the formation of synthetic manure, in the decomposition of soil organic matter, in the purification of sewage and trade wastes, in the decay of wood *etc.*, but comparatively little is known regarding the course and rate of decomposition under anaerobic and partially aerobic conditions. Tenney and Waksman [1930] have reported some data in this connection and a certain amount of work has been done in regard to the changes in organic matter in marshy and peaty soils, generally associated with such conditions. While the agricultural importance of such soils is comparatively limited, in other cases anaerobic and semi-aerobic conditions have played a significant rôle in increasing crop production and have been objects specially aimed at in the system of cultivation, *e.g.* in the production of rice under swamp or water-logged conditions as practised in most parts of India and China and to an increasing extent in Burma. The biochemistry of the changes in organic matter and other constituents in such soils has been examined by Nagaoka [1905], Daikuhara and Imaseki [1907], Harrison and Iyer [1913; 1914; 1915; 1916; 1919; 1920], Panganiban [1923], Subrahmanyan [1927; 1929; Subrahmanyan and Sreenivasan, 1934], Itano and Arakawa [1927; 1932], Metzger [1929; Metzger and Janssen, 1928], Joachim and Kandiah [1929], Misu and Shimohira [1929], Bartholomew [1929], Robinson [1930], Osugi *et al.* [1931; 1932] and others. But their work has been done mostly under the semi-aerobic conditions of the water-logged soil and no detailed study of the decomposition of organic matter under strictly anaerobic conditions has been reported. Data under such conditions, it was thought, might serve not only for purposes of comparison, but might also help in the interpretation of the results obtained already under water-logged conditions.

The object of the experiments reported in this and succeeding papers was to examine in detail the course of anaerobic decomposition of a variety of plant materials by themselves and in admixture with soil, as compared with the course of aerobic decomposition on the one hand and with the decomposition under water-logged or swamp soil conditions, on the other.

Recently much work has been reported on the anaerobic digestion of sewage and trade wastes, with special reference to securing the maximum evolution of combustible gases [*cf.* Whitehead and O'Shaughnessy, 1931; Adeney, 1932; Heukelekian, 1933; Rudolfs, 1932; Rudolfs and Heukelekian, 1932; Rudolfs and Setter, 1932; Buswell and Boruff, 1932; Larson *et al.* 1934]. But it should be noted that the conditions influencing the decomposition of trade wastes or sewage, where the concentration of the dissolved or suspended matter is comparatively low, may vary markedly from those controlling the decomposition of plant materials in much higher concentrations and in presence of soil. Comparisons of data obtained under the two sets of conditions may, however, be made with advantage and will be discussed later.

A different aim has guided several workers [Richards and Amoore, 1920; Fowler and Joshie, 1920; Langwell and Lymn, 1923; 1932; Boruff and Buswell, 1929], who have examined the anaerobic or semi-aerobic decomposition of plant materials on the technical scale with a view to obtaining the maximum yield of gaseous products. As their results bear close comparison with some data obtained during the course of the present experiments, their work may be considered in somewhat greater detail. Fowler and Joshie [1920] fermented various cellulosic materials and found that maximum gas evolution occurred at 30°, the mixed gases evolved having an average composition of 80–90 % CH_4, 4–12 % H_2 and 3–7 % CO_2. Hemicelluloses gave maximum gas production, and an acidity of more than 1 % retarded further fermentation. Langwell and Lymn [1923; 1932] adopted thermophilic digestion at 60° and observed that celluloses from different sources, hemicelluloses, starches and sugars could be easily fermented while the so-called ligno- and cuto-celluloses were unfermentable. Cereal straws were intermediate between true and ligno-celluloses and left an unfermentable residue of cellulose, apparently in combination. The addition of phosphorus and nitrogen was found to promote the fermentation. Aeration of the medium increased the amount of ethyl alcohol produced and a portion of the methane was replaced by hydrogen. Richards and Amoore [1920] working with straw and Nile sudd found that the optimum conditions for the production of methane were (1) a temperature between 35 and 40°; (2) exclusion of air; (3) ample water supply; (4) presence of some available nitrogen compound and (5) absence of acidity, which could be secured by addition of $CaCO_3$.

The methane fermentation of simple organic compounds and of sewage sludge has been followed by Buswell and co-workers [Buswell and Boruff, 1932; Symons and Buswell, 1933; Tarvin and Buswell, 1934; Boruff and Buswell, 1934]. This type of fermentation is held to be an oxidation-reduction reaction under anaerobic conditions, catalysed by bacteria and resulting in the production of almost theoretical quantities of CH_4 and CO_2: the primary products appear to be CO_2 and H_2, which react to form methane. Decarboxylation, deamination and hydrolysis were the principal means of decomposition, while the lower fatty acids were the chief intermediate compounds produced. A larger weight of substance was found as gas than was decomposed as organic matter, owing to the water present taking part in the reactions.

TECHNIQUE.

Rice straw from the Government Central Farm, Coimbatore, India, was chaffed into pieces about an inch long, and weighed quantities were packed into bottles of known volume fitted with rubber stoppers carrying exit tubes and pinch-cocks. Mineral nutrients, soil inoculant and distilled water in the quantities specified in the experiments described below were added, the contents well mixed and the stoppers secured by wiring with copper wire and then coating with paraffin wax. The enclosed air was removed by suction and the bottles were incubated at the required temperature. At specified intervals, generally once a week, the accumulated gases were tapped off through the exit tube into a Hempel's burette, measured and analysed for CO_2, CH_4, H_2 and N_2. At the end of the period of incubation, usually determined by the stoppage of gas evolution, or at intermediate intervals, samples were opened and the contents analysed. The liquid portion was separated from the solid matter by filtration through a

Büchner funnel and washing. The residue was dried, weighed and analysed for cellulose, lignin, furfuraldehyde-yielding compounds, protein and ash. The filtrate was made up to a known volume and aliquots were taken for the determination of volatile and non-volatile acids, total, ammoniacal, protein-, nitrate- and amino-nitrogen and carbonates.

Cellulose was determined by the method of Norman and Jenkins [1933]. Furfuraldehyde was estimated by Kröber's phloroglucide method, with final treatment of the phloroglucide with boiling alcohol to remove non-pentosan derivatives. The total furfuraldehyde yield and that obtained from the cellulose fraction are expressed in the accompanying tables in terms of xylan, for purposes of comparison of the hemicellulose fractions associated with cellulose and not so associated. It is realised that a portion of the total furfuraldehyde yield may be due to uronic acid derivatives, and that the hemicelluloses in rice straw may not all be in the form of xylan. Norman [1929] found that in oat and rye straws, the furfuraldehyde contributed by uronic acids was about 6–7 % of the total furfuraldehyde yield and it is probable that the correction necessary in the present case may be of the same order.

Lignin determinations were made by the 72 % sulphuric acid method (15 hours, below 15°) both on the material without any treatment (referred to in the tables as "lignin direct") and after hydrolysing it with 5 % sulphuric acid (referred to in the tables as "lignin after hydrolysis") [*cf.* Norman and Jenkins, 1933, p. 826]. It was found that the latter method gave uniformly lower results than the former, the difference varying from 10 to 30 % of the "lignin-direct" figure. In both cases, the ash content and nitrogen calculated as protein were deducted before arriving at the lignin figures. The allowance for nitrogen on the basis of its protein value is made in the absence of any definite knowledge of the form in which nitrogen is associated with lignin, though recent evidence [Norman and Jenkins, 1934] tends to show that the correction "factor" for nitrogen is liable to considerable variation depending on the nature of other substances present, especially furfuraldehyde-yielding compounds.

Volatile acids were estimated by steam-distillation, and the proportion of the constituents in the distillate was determined by the method of Virtanen and Pulkki [1928]. The fractional distillation constants obtained by this method for successive 25 ml. fractions agreed with the equations for a mixture of acetic and butyric acids. Qualitative tests on the distillate showed that it was almost wholly a mixture of acetic and butyric acids; there were only traces of formic, propionic and valeric acids.

Lactic acid was determined on the non-volatile liquid residue and, for comparison, also on an aliquot of the original solution, by the permanganate oxidation method of Friedmann and Graeser [1933]. Only negligible amounts of lactic acid could be detected at any stage.

Amino-nitrogen was estimated by Foreman's formaldehyde titration method as outlined by Brown [1923].

Determinations of the total, ammoniacal, nitrate- and protein-nitrogen were made by the methods recommended by the Association of Official Agricultural Chemists, U.S.A. [1930]. Volumes of gases have been given in the Tables after reduction to N.T.P.

EXPERIMENTAL.

Preliminary experiments showed that temperature and reaction exerted a profound influence on the rate and course of anaerobic fermentation. The extent of this influence and that due to other factors will be examined in detail in a later communication, but it may be noted here that a range of 30–35° and a slightly alkaline reaction (p_H 7·5–8·0) were found optimum for the progress of the decomposition. The maintenance of an alkaline reaction offered special difficulties on account of the large amount of organic acids formed rapidly in the early stages of the decomposition. The use of buffers at the high concentrations necessary to maintain constancy of the reaction, effectively inhibited bacterial activity as shown by absence of decomposition. Calcium carbonate, generally recommended in bacterial technique for use with gas-forming anaerobes was found (*cf.* Exp. 2 below) ineffective for maintaining a neutral reaction, especially in presence of CO_2 under pressures higher than atmospheric, and gas production was greatly inhibited even though there was excess of $CaCO_3$ present. It was found that the addition of a sufficient amount of ammonium carbonate (to the extent of 2 % nitrogen on the rice straw) served to maintain the p_H on the alkaline side. Sodium nitrate, when added to straw at the rate of 2 % nitrogen, also produced, after denitrification, sufficient alkali to neutralise the acids formed. In a few cases, however, the above proportion of sodium nitrate was found to result in too great an alkalinity in the early stages, while the amount of ammonium carbonate at 2 % nitrogen on straw taken was found insufficient to neutralise the acids formed; in these cases gas production was impeded. So in later experiments, attempts were made to maintain the p_H by an addition of other neutralising agents like $KHCO_3$, $NaHCO_3$, NH_4HCO_3 *etc.* and also by the addition of alkali at regular intervals. A discussion of these experiments will be reported later.

Exp. 1. Course of decomposition of rice straw without the addition of nitrogen or calcium carbonate. To 20 g. portions of rice straw were added 10 ml. of an aqueous extract of a garden soil (1 g. soil to 50 ml. water), 0·5 g. K_2HPO_4, 0·05 g. $MgSO_4, 7H_2O$ and enough distilled water to make up 200 ml. in all. The bottles were evacuated, sealed and incubated as described above. At the end of stated intervals one of the bottles was opened and the contents analysed. There was no gas evolution from any of the bottles though a certain amount of CO_2 was found in solution. The results of analysis, calculated per 100 g. original straw taken, are given in Table I.

It will be noted that the p_H of the medium falls at the end of the decomposition to 4·4. The accumulation of acids amounts to about 6·6 g. of which the major portion is acetic (about 4·0 g.) and the remainder butyric. About 20 % of the total hemicelluloses expressed as xylan, 8–9 % of cellulose and 5–7 % of lignin, as well as 35–37 % of the proteins, have been decomposed. The almost stationary state of the decomposition figures after the first month, during which most of the acid formation takes place (Table I), indicates that the progress of the decomposition is inhibited by the accumulation of acids and consequent lowering of p_H (*cf.* Exps. 4–6).

As regards nitrogen distribution, it is interesting to note that the major portion of the nitrogen which goes into solution remains in the form of protein and only a small portion is liberated as ammonia. Of the total nitrogen originally present in the straw, about 65 % remains in the solid residue, about 25 % is present in solution in the form of protein and only about 8–10 % is converted into ammonia. A similar kind of nitrogen distribution is also to be found in the succeeding experiments.

Exp. 2. Decomposition of rice straw without the addition of nitrogen but with $CaCO_3$ added as neutralising agent. To 20 g. portions of rice straw, 4 g. of $CaCO_3$ were added to neutralise the acids formed. The other experimental details were the same as in Exp. 1.

The results of analysis are shown in Table II. They show that in the presence

of $CaCO_3$ the reaction proceeds a stage further than in Exp. 1, both as judged by the amount of acids and gases formed as well as by the percentage losses of the straw constituents. Larger amounts of cellulose (20–23 %) and xylan (25–26 %) have been decomposed, and the acids formed amount to about 9·0 g. of which about 6·1 g. are acetic and the rest butyric.

Table II. *Decomposition of rice straw in presence of $CaCO_3$ (no nitrogen added).*

It will be noted that even in presence of $CaCO_3$ the p_H of the medium falls below 5·0. This is in agreement with the p_H of bicarbonate mixtures in presence of CO_2, especially under pressures higher than atmospheric [Banta and Pomeroy, 1934]. As a result of the fall in p_H, further decomposition and gas production have been arrested, and only 1055 ml. of gas, mostly CO_2, have been evolved. The proportions of protein-nitrogen going into solution (16–18 %) and of ammoniacal nitrogen (about 5 %) are lower in presence of $CaCO_3$ than without it.

Exp. 3. Decomposition of rice straw in presence of $CaCO_3$ and ammonium carbonate. 5 g. $CaCO_3$ and ammonium carbonate to the extent of 1 % nitrogen on the straw taken were added to 20 g. portions of rice straw. The other experimental details were the same as in the previous experiments. The results are shown in Table III.

p_H of medium	7·8	5·4	5·2	5·0	5·0	4·8

They show that a mixture of $CaCO_3$ and ammonium carbonate at 1 % N on straw is satisfactory from the point of view of losses of the different constituents, about 45–50 % of cellulose, 45–47 % of the total xylan and 14–15 % of the lignin being decomposed, but fails to keep the medium from turning acid, in spite of excess of $CaCO_3$, being present at the end of the reaction. This result is probably due to insufficiency of the ammonium carbonate added to neutralise the acids formed and the inability of $CaCO_3$, as already noted under Exp. 2, to prevent the fall in p_H. The p_H of the medium falls to 4·8 and the acids accumulate to 20·2 g. of which 14·23 g. are acetic and the remainder butyric. 3735 ml. of CO_2 and 475 ml. of CH_4 are evolved, most of the CO_2 coming from the interaction of the organic acids formed with the added $CaCO_3$. By comparison with the results of Exps. 4 and 6, the small amount of CH_4 evidently results from the fall in p_H and consequent inhibition of the decomposition of organic acids formed into gaseous products.

Exp. 4. Decomposition of rice straw in presence of ammonium carbonate: $CaCO_3$ absent. To 20 g. portions of rice straw was added ammonium carbonate at the rate of 2 % nitrogen on the straw taken, but no $CaCO_3$. Other experimental details were as before. The initial p_H was 7·8–7·9. In a few cases, the progress of the reaction was hindered by too rapid an accumulation of acids in the early stages and a corresponding decrease in the rate of gas production; but in others the two reactions proceeded at comparable rates and the p_H was maintained at about 7·4–7·8. This improved considerably the yield of combustible gases.

The results of the experiment are given in Table IVA. A comparison of these figures with those obtained in Exp. 3 using $CaCO_3$ and ammonium carbonate at

1 % nitrogen on the straw shows that the essential difference lies in the degree of gas production in the two cases. Whereas in Exp. 3 the acids formed accumulated to 20·2 g. and the p_H fell to 4·8, the total acids formed in the present experiment gave a maximum value of 8·95 g. at the end of 2 months and then decreased steadily to 1·3 g. at the end. Corresponding with this variation in the amount of acids, the p_H of the medium first showed a fall from 7·9 to 6·4 at the end of 2 months after which it registered a steady rise to 7·8. Evolution of appreciable amounts of combustible gases, principally methane, began at the end of the second month and showed a rapid increase in that period when the acids were rapidly falling.

The gas evolution, corrected for CO_2 evolved by the interaction of added carbonates with the organic acids formed, amounted in the present experiment to 19,505 ml. containing 9585 ml. methane. In Exp. 3 the corresponding figures were 1015 and 475. That the much larger amount of methane produced in the present experiment has in all probability resulted from the decomposition of the organic acids which accumulated in Exp. 3 is shown by a comparison of the total possible methane production in the two cases, given in Table IV B.

CH_4 equivalent to acetic acid present	5311 ml.	399 ml.
CH_4 equivalent to butyric acid present	4588 ml.	176 ml.
Total capacity for methane production	10374 ml.	10,160 ml.

The similarity of the total volumes of methane derivable from the organic acids produced in the two experiments supports the hypothesis that the lower organic acids are the chief intermediate compounds formed in the breakdown of the constituents of straw, and that the organic acids are further split up into CH_4 and CO_2 [*cf.* Buswell and Boruff, 1932; Tarvin and Buswell, 1934]. The evidence obtained in these experiments does not support the theory that CO_2 and H_2 are the first products of decomposition and that a portion of the CO_2 is reduced by hydrogen to CH_4 and organic acids.

It is worth noting that if the total yield of CO_2 in both Exps. 3 and 4 is corrected for that portion evolved from added carbonates by the action of acids formed, the CO_2/CH_4 ratio is almost unity at successive stages of decomposition. Such a constant ratio may not be expected on the basis of a partial reduction of CO_2 by H_2 but agrees well with the decomposition of organic acids into equivalent amounts of CH_4 and CO_2.

The total yield of gases is about 19,500 ml. per 100 g. of straw, and allowing for the residual 1·3 g. of acid present, the yield will rise to about 20,500 ml., containing about 50 % methane. This corresponds to a yield of about 7200 cb. ft. of gas per ton of straw.

Another interesting point to be noted from Table IV is the low nitrogen requirement for anaerobic digestion. Rege [1927] and Richards and Norman [1931] found that for aerobic decomposition the "nitrogen factor" (the amount of nitrogen converted from the mineral into protein form per 100 g. of material taken) ranged from 0·7 to 0·9 for rice straw, whereas the highest factor obtained in the present experiment was about 0·1. The above authors found a nitrogen equivalent (the amount of nitrogen immobilised per 100 g. of material destroyed) of about 2 for rice straw. For anaerobic decomposition, the nitrogen equivalent varies from nil to 0·25.

Exp. 5. Decomposition of rice straw in presence of varying amounts of sodium nitrate. It is well known that under anaerobic conditions nitrates are rapidly denitrified in presence of organic matter, leaving an alkaline residue which serves the purpose of a neutralising agent. To 20 g. portions of rice straw was added sodium nitrate at the rate of 0·5, 1, 2 and 3 % nitrogen on the straw. No $CaCO_3$ was added and other experimental details were as before.

The data obtained are given in Table V. They show that by the use of sodium nitrate in proper amounts, successful decomposition of rice straw could be brought about which would compare favourably with the decomposition accomplished by the use of ammonium carbonate. The amount of decomposition increases with increasing doses of $NaNO_3$ up to an amount representing 2 % N on the straw, after which the reaction becomes presumably too alkaline to permit favourable decomposition.

Table V. *Decomposition of rice straw with different doses of sodium nitrate.*

The action of sodium nitrate is evidently two-fold, the first stage being denitrification of nitrate (accompanied by evolution of free nitrogen) and oxidation of organic matter (with evolution of CO_2) and the second being the usual type of anaerobic decomposition with formation of organic acids and evolution of combustible gases met with in the experiments above described. No methane or hydrogen could be detected till all the nitrate had been reduced and the evolution of free nitrogen had ceased. It is interesting to compare in this connection the observations of Elma *et al.* [1934] who found that the oxidation-reduction potential of a nitrate or nitrite medium undergoing denitrification by *Micrococcus denitrificans* was maintained at a steady level depending on the p_H of the medium till all the nitrite or nitrate had been reduced, after which it showed an immediate and great fall. It is suggested that this stage corresponds in the present experiment to the starting of the second stage of anaerobic decomposition accompanied by the formation of acids and evolution of combustible gases; but the point needs further examination.

It would appear from Table V that sodium nitrate at the rate of 2 % N on the straw would, after denitrification, yield enough alkaline residue to neutralise the acids formed in the second stage of decomposition and maintain the alkaline reaction so essential for the further progress of the reaction. With a view to examining the course of the decomposition in more detail, the experiments with sodium nitrate were repeated at the above concentration, samples being examined after definite time intervals.

Exp. 6. Decomposition of rice straw in presence of sodium nitrate equivalent to 2 °/₀ N on straw. A number of bottles were set up with 20 g. portions of rice straw and sodium nitrate at the rate of 2 % N on the straw, and samples were taken out for analysis at intervals. The results obtained are given in Table VI.

A comparison of the results obtained in Exps. 6 and 4, using sodium nitrate and ammonium carbonate respectively, shows essential differences in the course of the two reactions, especially in the earlier stages. With sodium nitrate denitrification of nitrate and oxidation of the organic matter proceed quite rapidly. At the end of one month the sodium nitrate culture has oxidised about 13 % of cellulose and 31 % of total xylans, as compared with 8·4 and 26 % respectively in the ammonium carbonate culture. However, with sodium nitrate only 2·8 g. of organic acid are present at the end of one month while 7·5 g. are present after the same period when ammonium carbonate is used. After the denitrification stage is completed the usual type of anaerobic degradation begins, as evidenced by the accumulation of organic acids and evolution of CH_4.

It is interesting to note from Table VI that practically the whole of the added nitrate is lost, so far as the non-gaseous portion is concerned, the actual amount of nitrate-nitrogen converted into protein or ammoniacal form being negligible. In spite of the comparatively large amount of protein in solution, the level of ammoniacal nitrogen is quite low, there being only 5–10 mg. in a volume of 200 ml. This low level of ammoniacal nitrogen, even in cultures where decomposition has been active, confirms what has already been noted, namely, that a small supply of available nitrogen is enough to sustain anaerobic decomposition and that there is no advantage gained by adding larger amounts of ammonium salts than may be used to neutralise the organic acids formed.

DISCUSSION.

The experiments outlined above show that the first phase of anaerobic decomposition is the rapid formation of organic acids and considerable loss of organic matter in the early stages. The evolution of combustible gases, *e.g.* methane, appears to be a secondary reaction, and from the relative amounts of acids and gases produced under differing conditions it seems that the organic acids first formed are decomposed further into CO_2 and CH_4, though at a rate much slower than the speed of acid formation. This second stage of gas production appears to be more sensitive to the influence of p_H than the first and proceeds best at a slightly alkaline reaction (about p_H 7·5). The rapid progress of anaerobic decomposition therefore depends primarily on the maintenance of a favourable p_H range, which is much narrower than that for aerobic decomposition.

A second point brought out by these experiments is the very low nitrogen requirement for anaerobic decomposition. Hutchinson and Richards [1921; 1925] have shown that for rapid conversion of waste materials into manure under aerobic conditions, the addition of nitrogen at the rate of about 0·7 % on the material taken is necessary. With anaerobic decomposition, however, additions of nitrogen above a low minimum value appear to exert no direct beneficial influence. Using rice straw, about 30 % of the total protein goes into solution even in the early stages and about 5–10 % is converted into ammonia. The insoluble residue at the end of the decomposition contains only about 70 % of the original nitrogen present in the straw, even though large additions of ammonia in the form of ammonium carbonate are made. This no doubt is [illegible]ble on the assumption that anaerobic decomposition is one of reduction to [illegible] products and hence very little synthesis of added ammonia into protein [illegible]ce under these conditions. The bacterial population is conceivably o[illegible]ture and there is probably a continuous cycle of microbial synthes[illegible]gration, making the nitrogen requirement much less than under aerob[illegible]s. It has been noted under Exp. 4 that even under the most favoura[illegible]ons, the nitrogen factor [Rege, 1927] is only of the order of 0·1, while the nitrogen equivalent [Richards and Norman, 1931] is about 0·2–0·25, as compared with the values of 0·7–0·9 and 1·8–2·0 respectively obtained for aerobic decomposition. In several cases the values have been negative, showing that under anaerobic conditions the net tendency is towards hydrolysis rather than towards synthesis of nitrogen compounds.

The apparent stimulating effect of additions of ammonium carbonate seen in Exps. 3 and 4 therefore seem to be due to its neutralising effect on the acids formed and the maintenance of an alkaline reaction rather than to the supply of available nitrogen.

The products obtained as a result of anaerobic decomposition have been of a simple character, the organic acids formed being mainly acetic and butyric and the gases evolved being mostly CO_2 and methane. Only negligible amounts of hydrogen are evolved at any stage. Where carbonates are used to neutralise the acids formed, nearly the whole of the gas first evolved is CO_2. Later, when the decomposition of organic acids into CO_2 and CH_4 occurs, larger and increasing proportions of CH_4 are formed, rising to 70–80 % of the gases evolved. When, however, allowance is made for the amount of CO_2 evolved from added carbonates and that retained in solution, the CH_4/CO_2 ratio is nearly unity at successive stages of the decomposition.

As regards the extent of decomposition, under optimum conditions 40–45 % of ash-free dry matter, about 45 % of cellulose and 60 % of the hemicelluloses, in terms of furfuraldehyde yield, are decomposed. The hemicelluloses are more rapidly attacked in the early stages, but at the end of the reaction there is a larger total amount of cellulose decomposed than of hemicelluloses. In this respect the course of decomposition is similar to that under aerobic conditions, though the relative percentages are lower [*cf.* Rege, 1927; Tenney and Waksman, 1929]. Under conditions favourable to the accumulation of acids it is possible to obtain as much as 20 g. of acids per 100 g. of straw taken. Under other conditions which favour gas production, over 20 litres of gas containing about 50 % methane could be obtained from the same amount of straw. This corresponds to a yield of about 7200 cb. ft. gas per ton of straw and is comparable with the yields of 4400 cb. ft. per ton of wheat straw and 9360 cb. ft. per ton of Nile sudd obtained by Richards and Amoore [1920].

A significant point brought out by these experiments is the degree to which lignin appears to have been decomposed. About 25–30 % of the lignin, as determined both directly on the material as well as after a preliminary hydrolysis with 5 % H_2SO_4 [Norman and Jenkins, 1933], has undergone decomposition. This is in marked contrast to the difficulty with which lignin is attacked under aerobic conditions. Boruff and Buswell [1934] have also found a similar considerable loss of lignin content, in some cases amounting to 50 % of the total lignin, when corn stalks were decomposed under anaerobic conditions. It should be noted however that much confusion exists at present in methods adopted for lignin determination and errors and differences of a serious nature may be obtained, due to differences in technique or the presence of interfering substances [Phillips, 1934; Norman and Jenkins, 1934].

SUMMARY.

1. The course of anaerobic decomposition of rice straw has been followed with reference to losses of its major constituents, such as cellulose, furfuraldehyde-yielding compounds, lignin, proteins *etc.*, and the formation of organic acids and gases.

2. Of the straw constituents about 60 % of the hemicelluloses, 45 % of the cellulose and 25–30 % of lignin are decomposed. The ultimate loss of ash-free dry matter is about 40–45 %.

3. Acetic and butyric acids, CO_2 and methane are the main products formed. From 100 g. of straw, either about 20 g. of organic acids or over 20 litres of gases containing about 50 % methane are obtainable. This is equivalent to about 7200 cb. ft. of gas yield per ton of straw.

4. The decomposition appears to proceed in two distinct stages, the first involving the formation of organic acids and the second the conversion of these into gaseous products. A slightly alkaline reaction, a p_H of about 7·5, is important for the progress of the second stage of decomposition. The uses of $CaCO_3$, $NaNO_3$ and ammonium carbonate for this purpose have been compared. Ammonium carbonate in sufficient amount to neutralise the acids formed was found most suitable.

5. The reaction with $NaNO_3$ proceeds in two stages, the first being denitrification of the nitrate and oxidation of the organic matter; the alkaline residue left after denitrification serves to neutralise the organic acids formed in the second stage, which is the usual type of anaerobic fermentation accompanied by the evolution of combustible gases.

6. While the supply of available nitrogen is of paramount importance for the aerobic decomposition of plant substances, it is relatively insignificant in anaerobic decomposition. 100 g. of rice straw require about 0·7 part of nitrogen for decomposition aerobically but only 0·1 part or even less under anaerobic conditions.

The author's thanks are due to Sir E. J. Russell for placing the facilities of the Rothamsted Experimental Station at his disposal, to Mr E. H. Richards for guidance and to Drs. S. H. Jenkins and A. G. Norman for helpful criticism.

LXII. THE SYNTHESIS OF AMINO-ACIDS.

I. PIPERIDINE AND DIETHYLAMINE AS CATALYSTS IN THE CONDENSATION OF AROMATIC ALDEHYDES WITH HYDANTOINS.

By WILLIAM JOHN BOYD and WILLIAM ROBSON.

From the Department of Physiology, University of London King's College.

(*Received January 10th, 1935.*)

An important method of synthesising aromatic α-amino-acids is that of Wheeler and Hoffman [1911] which involves in its first stage the condensation of the appropriate aldehyde with hydantoin, the reaction being carried out in hot glacial acetic acid containing anhydrous sodium acetate. The yield of the condensation product so obtained varies considerably according to the aldehyde used. For example benzalhydantoin may be prepared in a yield of 80 % of the theoretical whilst indolalhydantoin is only obtainable in a yield of 47 %. Majima and Kotake [1922], who first prepared the latter compound from indole-3-aldehyde and hydantoin, found that it was necessary to substitute acetic anhydride for acetic acid in the condensation. Besides indolalhydantoin they also obtained unspecified amounts of acetylated indolalhydantoin, unchanged indole-3-aldehyde and another unidentified substance. From a study of the same reaction in this laboratory it appears, however, that the low yield obtained is due not so much to incomplete reaction or to acetylation as to the formation of tarry products of complex character.

Whatever be the cause, such a loss of material becomes a matter of no small importance when the parent aldehyde, *e.g.* indole-3-aldehyde, is not easy of access. Since moreover a scheme of study in this laboratory involved the condensation of such aldehydes with hydantoin, it was decided, as a first measure, to investigate the possibility of carrying out the reaction in solvents other than glacial acetic acid and with catalysts other than anhydrous sodium acetate.

The reaction under study falls into the class of condensations between an aldehydic and a reactive methylene group with elimination of a molecule of water. From a consideration of the reaction in its various aspects there seemed to be no apparent reason why the organic bases, diethylamine, aniline, piperidine, nicotine *etc.*, used with such success by Knoevenagel [1894] for effecting similar condensations, should not be equally applicable in this case.

That these bases can be so used has now been proved experimentally. It soon became clear however that in specific cases individual catalysts are more effective than others. For example, in attempting the condensation of benzaldehyde, *p*-hydroxybenzaldehyde or *p*-methoxybenzaldehyde with hydantoin by means of piperidine, using pyridine as solvent, poor yields accompanied by much tar were obtained. On substituting 3-acetyl-2-thiohydantoin for ordinary hydantoin, there resulted practically quantitative yields of condensation products of a high degree of purity. Replacement of piperidine by diethylamine as the catalyst employed gave good yields in the case of ordinary hydantoin, and it is notable that the recrystallised product was not straw-coloured, as when made by the Wheeler-Hoffman technique, but colourless. A series of experiments on the above lines with 1-phenylhydantoin gave results analogous to those obtained with ordinary hydantoin; owing to its high cost however 1-phenylhydantoin is of little importance in schemes of synthesis of α-amino-acids. The substitution of absolute alcohol for pyridine as the solvent, in conjunction with diethylamine as catalyst, gave only a 25 % yield of benzalhydantoin after heating for 24 hours; it is probable that a longer period of heating would improve the yield.

The results described in the experimental section may be briefly summarised thus:

Reactants	% yield of condensation product	
	Piperidine	Diethylamine
Benzaldehyde and hydantoin	33	76
,, acetylthiohydantoin	92·5	
Anisaldehyde and hydantoin	14	94
,, acetylthiohydantoin	95	
p-Hydroxybenzaldehyde and hydantoin	25	65
,, acetylthiohydantoin	95–100	

It will be clear that the work herein described is capable of extension in several directions. For example, whilst it will be noted that the condensations described have all been carried out at 100°, nevertheless evidence is not lacking that they may proceed at a very much lower temperature. Moreover, of the bases originally employed by Knoevenagel only diethylamine and piperidine have been used up to the present, and it is proposed to extend the study to include others of those mentioned above. Finally, reference may be made to one other important phase of this problem. Whilst the Wheeler-Hoffman process has been of considerable value in the synthesis of aromatic α-amino-acids the applicability of the method to the synthesis of aliphatic α-amino-acids has never been demonstrated. The introduction of new solvents and catalysts for promoting the reaction between aldehydes and hydantoin suggests new lines of attacking the problem of synthesising aliphatic α-amino-acids by way of the hydantoins. This aspect of the investigation is receiving attention.

EXPERIMENTAL.

Experiments involving piperidine as catalyst.

4-Benzalhydantoin. Pure benzaldehyde (2·2 g.), hydantoin (2·0 g.) and piperidine (2 ml.) were boiled together for 1 hour. The product was treated with 100 ml. of hot water and filtered, whereby some tarry material was removed. The filtrate was neutralised with dilute hydrochloric acid, whereupon benzalhydantoin separated in characteristic rhombic plates. It was recrystallised from dilute alcohol and had M.P. 220°; N 14·72 %. Wheeler and Hoffman [1911] give the same melting-point. $C_{10}H_8O_2N_2$ requires 14·90 % N. The yield was 1·6 g. or 33 % of the theoretical value.

Benzalthiohydantoin. The acetylthiohydantoin required in this experiment was prepared from glycine and ammonium thiocyanate as described by Johnson and Nicolet [1911]. Benzaldehyde (2·5 g.) and acetylthiohydantoin (3 g.) were dissolved in pyridine (5 ml.). On adding piperidine (3 ml.), the mixture became warm and deep yellow in colour. It was boiled for 2 minutes and then water (100 ml.) was added. The resulting aqueous solution was acidified by the addition of acetic acid and warmed until the oily mass which separated had given place to a yellow crystalline deposit. The mixture was cooled and kept overnight. The yellow crystals which had then separated were collected, washed with cold water and recrystallised from dilute alcohol. They weighed only 2·4 g., but further crops were obtained after the mother-liquor had stood for some days. The total yield was 3·65 g. or about 92·5 % of the theoretical figure; M.P. 258° (Johnson and Nicolet give 258°). Found N 13·59 %. $C_{10}H_8ON_2S$ requires N 13·73 %.

Benzalhydantoin from the above benzalthiohydantoin. A portion of the benzalthiohydantoin (1·3 g.), synthesised according to the procedure detailed above, was boiled with 50 % chloroacetic acid (20 ml.) for 3 hours. The resulting clear solution was evaporated to small volume *in vacuo* and the residue diluted with water. A slightly yellow crystalline substance separated and after some time was filtered off and washed with cold water. Without recrystallisation, it weighed 0·92 g., melted at 220° and contained 14·8 % N. The yield, referred back to the original acetylhydantoin, was 77 % of the theoretical.

p-*Methoxybenzalhydantoin.* This experiment was carried out as described for benzalhydantoin. From 2·64 g. of anisaldehyde, 0·45 g. (14 %) of *p*-methoxybenzalhydantoin was obtained together with much tar. After recrystallisation from dilute alcohol the M.P. was 243° (Wheeler and Hoffman quote 243–244°). Found N 12·79 %. $C_{11}H_{10}O_3N_2$ requires N 12·85 %.

p-*Methoxybenzalthiohydantoin.* *p*-Methoxybenzalthiohydantoin was prepared from anisaldehyde (2·5 g.) and acetylthiohydantoin (3 g.) as described for benzalthiohydantoin. The yield of uncrystallised product was 4·33 g. or 95 % of the theoretical calculated on the acetylthiohydantoin taken. After crystallisation from alcohol, the product melted at 256° (Johnson and O'Brien [1912] give 257°). Found N 12·14 %. $C_{11}H_{10}O_2N_2S$ requires N 11·97 %.

p-*Methoxybenzalhydantoin from the above* p-*methoxybenzalthiohydantoin.* *p*-Methoxybenzalthiohydantoin (5 g.), obtained as in the preceding experiment but without recrystallisation, was boiled with a mixture of 50 % chloroacetic acid (50 ml.) and acetic acid (150 ml.) for 4 hours. The substance was very insoluble and only went into solution gradually. The resulting solution was evaporated to small volume *in vacuo* and the residual fluid was diluted with water. A yellow crystalline substance separated from the cold solution and was, after some time, collected and washed with cold water. The yield was 94 %. It melted at 247° before recrystallisation, and contained 12·79 % N. Referred back to the acetylthiohydantoin used for the preparation of the *p*-methoxybenzalthiohydantoin, the yield was equivalent to 85–90 %.

p-*Hydroxybenzalhydantoin.* This substance was prepared in the same manner as benzalhydantoin. From 2·4 g. of *p*-hydroxybenzaldehyde, 0·75 g. (25 %) of the desired product was obtained. The product separated from alcohol in needles which melted at 315°. Found N 13·62 %. $C_{10}H_8O_3N_2$ requires N 13·72 %.

p-*Hydroxybenzalthiohydantoin.* The compound was prepared from *p*-hydroxybenzaldehyde (2·5 g.) and acetylthiohydantoin (3 g.) as described for benzalthiohydantoin. The yield of recrystallised product was 4·2 g. which is practically theoretical. The purified product melted at 305° and contained 12·82 % N. $C_{10}H_8O_2N_2S$ requires N 12·73 %.

p-*Hydroxybenzalhydantoin from* p-*hydroxybenzalthiohydantoin.* *p*-Hydroxybenzalthiohydantoin (4·0 g.), obtained in the preceding experiment but not recrystallised, was boiled with 50 % chloroacetic acid (50 ml.) for 3 hours. The solution was evaporated to small bulk *in vacuo* and the residual liquor diluted with water. A yellow crystalline substance separated; this was collected after some time and washed with cold water. After crystallisation from alcohol it weighed 2·9 g., melted at 314° and contained 13·84 % N. The yield of the desulphurised hydantoin was thus 85 % of the theoretical calculated on the weight of the acetylthiohydantoin used.

Experiments involving diethylamine as catalyst.

Benzalhydantoin. Benzaldehyde (5·5 g.), hydantoin (4·5 g.), pyridine (5 ml.) and diethylamine (6 drops) were heated together at 100° for 22 hours in a closed bottle. On cooling the mixture became solid. The contents of the bottle were dissolved in alcohol and evaporated to dryness. The product so obtained was crystallised from alcohol and it then melted at 220° and contained 14·95 % N. The yield of recrystallised material was 6·4 g. or 76 % of theory.

Another experiment, carried out under the same conditions but with the addition of 0·5 ml. of water, gave only 4·0 g. of product.

A third experiment carried out under the same conditions as the first, the temperature being raised to 120°, yielded a slightly sticky product which gave 70 % of the theoretical amount of recrystallised material.

p-*Methoxybenzalhydantoin.* Anisaldehyde (6·0 g.), hydantoin (4·5 g.), pyridine (5 ml.) and diethylamine (3 ml.) were heated together at 100° for 22 hours in a closed bottle. The product was worked up as in the preparation of benzalhydantoin by means of diethylamine. The *p*-methoxybenzalhydantoin was not recrystallised but was washed with a little cold benzene and dried. It then melted at 240–244° and contained 12·82 % N. The yield was 94 % of the theoretical calculated on the hydantoin used.

p-*Hydroxybenzalhydantoin.* A mixture of *p*-hydroxybenzaldehyde (6·0 g.), hydantoin (4·5 g.), pyridine (5 ml.) and diethylamine (3 ml.) was heated in a closed bottle at 100° for 22 hours. The product was worked up as in the analogous preparation of benzalhydantoin. It was recrystallised from alcohol after being washed with cold benzene. In this way 5·1 g. of *p*-hydroxybenzalhydantoin were obtained. It melted at 312°. The yield approximated to 65 % of the theoretical.

SUMMARY.

The original method of Wheeler and Hoffman of effecting the condensation of aromatic aldehydes with hydantoins by heating a mixture of these substances in glacial acetic acid containing anhydrous sodium acetate may be modified with advantage.

Instead of the mixture of acetic acid and sodium acetate, mixtures of pyridine and piperidine or of pyridine and diethylamine or even piperidine alone in some cases can be successfully substituted.

A table summarising the results is given. From this, it will be seen that the relative efficiencies of piperidine and diethylamine as catalysts vary according to the reactants involved.

LXIII. THE SYNTHESIS OF AMINO-ACIDS.

II. SULPHIDES AS REDUCING AND HYDROLYTIC AGENTS IN THE HYDANTOIN SYNTHESIS OF AMINO-ACIDS.

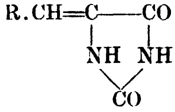
By WILLIAM JOHN BOYD and WILLIAM ROBSON.

From the Department of Physiology, University of London King's College.

(*Received February 1st, 1935.*)

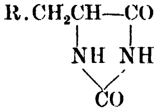
In the preceding paper of this series [1935] the authors have shown how the first, *i.e.* the condensation, stage of the Wheeler-Hoffman [1911] process of synthesising aromatic α-amino-acids may be modified, not only with regard to the catalyst but also the solvent employed, so that the yield and, in certain cases, the purity of the product may be improved.

The second and third stages of the synthesis consist respectively of the reduction of the unsaturated hydantoin (I), formed in the condensation stage referred to above, and of the hydrolysis of the resulting saturated hydantoin (II)



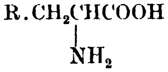
$$\begin{array}{l} R.CH{=}\underset{\displaystyle NH}{\underset{|}{C}}{-\!-}\underset{\displaystyle NH}{\underset{|}{CO}} \\ \qquad\quad \diagdown\!\diagup \\ \qquad\quad\; CO \end{array}$$

(I)



$$\begin{array}{l} R.CH_2\underset{\displaystyle NH}{\underset{|}{C}}H{-}\underset{\displaystyle NH}{\underset{|}{CO}} \\ \qquad\quad \diagdown\!\diagup \\ \qquad\quad\; CO \end{array}$$

(II)



$$R.CH_2\underset{\displaystyle NH_2}{\underset{|}{C}}HCOOH$$

(III)

to the amino-acid (III). These two stages of reduction and hydrolysis, as shown by Wheeler and Hoffman, can be effected by one and the same reagent, *viz.* hydriodic acid and red phosphorus. By such means they obtained phenylalanine from benzalhydantoin and tyrosine from *p*-methoxybenzalhydantoin, whilst, more recently, Harington [1926] following the same procedure, prepared thyronine from 4-(4′-methoxyphenoxy)benzalhydantoin. When, however, the former workers attempted, by shortening the duration of treatment with hydriodic acid, to limit the process to one of reduction only, they found that, whilst the main product was the saturated hydantoin, it was invariably accompanied by amino-acid; in other words a certain degree of hydrolysis was inevitable. This difficulty can be readily overcome by the method adopted by Lamb and Robson [1931] who used a strictly limited quantity of hydriodic acid (dissolved in glacial acetic acid) and red phosphorus for the reduction of α-benzamidocinnamic acids to the corresponding α-benzamidophenylpropionic acids.

The method as described by Wheeler and Hoffman gives products in good yield and of excellent purity and, apart from the high cost of the hydriodic acid employed, has only one drawback as a general method. In the synthesis of certain aromatic α-amino-acids, *e.g.* tryptophan, the use of acid reducing agents such as hydriodic acid must be avoided. In such circumstances recourse is had to sodium amalgam. But the use of this reagent, in turn, has its disadvantages. Firstly, a high yield of the reduction product is only obtainable by the use of a very large excess of amalgam. Secondly, some hydrolysis always occurs during the process and the recovery of the resulting amino-acid from the solution, which contains a large quantity of sodium salts, is exceedingly difficult, if not impossible.

It was such practical difficulties as these, encountered during attempts to synthesise derivatives of tryptophan, which led us to investigate whether it was possible to carry out the reduction stage of the Wheeler-Hoffman synthesis by reagents other than those named above.

Amongst the many possibilities which suggested themselves to us was ammonium sulphide. In this connection we had, so far as we knew, no precedent for supposing that hydrogen sulphide would reduce a compound of type I to one of type II, but we were encouraged to attempt the experiment by the observation of Harries and Weiss [1903] that ordinary hydantoin can be hydrolysed to glycine by heating it with ammonium sulphide at 150° for 2 hours. On heating benzalhydantoin in a closed vessel with 16 % ammonium sulphide solution for 72 hours at 100° we obtained a mixture consisting of phenylalanine (50–60 % of theory) and benzylhydantoin (30–40 % of theory). A similar yield of amino-acid was obtained after only 3 hours by carrying out the reaction at 180°. Under similar conditions, benzalthiohydantoin gave partly α-thiocarbamido-β-phenylpropionic acid and partly the corresponding thiohydantoin, the former of which on being boiled with hydrochloric acid is reconverted into the thiohydantoin, whilst the latter compound, as shown by Johnson and Nicolet [1913], can be desulphurised to give benzylhydantoin by treatment with boiling chloroacetic acid.

From such results it was clear that we had found an excellent reducing agent, the use of which would eliminate many of the difficulties attached to the use of hydriodic acid and sodium amalgam. Since however the action of aqueous ammonium sulphide on the unsaturated hydantoin yields a mixture of products, it appeared essential to determine the conditions whereby maximum yields of the reduced hydantoin and of the amino-acid could be obtained.

The problem of obtaining a maximum yield of the reduced hydantoin was solved in the following way. Since certain unsaturated hydantoins were found to be extremely insoluble in aqueous ammonium sulphide even at 100°, an attempt was made to overcome this difficulty by carrying out the reaction at a higher temperature and by adding to the reaction mixture alcohol, pyridine or some such solvent miscible with water. Nevertheless, owing to the solubility factor, the amount of unsaturated hydantoin which could be treated by a given volume of ammonium sulphide solution was much less than the equivalent of the reducing power of the solution. In order therefore to make the method more convenient for the reduction of larger quantities of the more insoluble unsaturated hydantoins the possibility of effecting their reduction by hydrogen sulphide in anhydrous solvents, *e.g.* ethyl alcohol, pyridine *etc.*, was explored. Briefly it may be stated that the maximum yields of reduced hydantoin were obtained by heating the unsaturated hydantoin

(1) at 100° for 48–72 hours in pyridine saturated with hydrogen sulphide at 0°;

(2) at 58° in a mixture of aqueous ammonium sulphide and alcohol for a longer period;

(3) at 100° for 30–35 hours in an alcoholic solution of sodium or barium sulphide, the solution being saturated with hydrogen sulphide at 0° at the beginning of the experiment and again at that temperature after 16 hours.

The yields obtained by such methods was approximately the theoretical.

The optimum conditions for effecting the reduction of the unsaturated hydantoin having been determined, attention was next directed to the problem of converting the reduced hydantoin (II) into the amino-acid (III).

Reduced hydantoins can be hydrolysed by a variety of reagents both acid and alkaline. Lippich [1908] obtained a 92 % yield of leucine by heating its hydantoin for 24 hours with "fuming" hydrochloric acid. Dakin [1920] found that a 70 % yield of hydroxyproline was obtained when its hydantoin was boiled for 12 hours with a large excess of 10 % barium hydroxide solution. From experiments carried out in this laboratory, it appears that the respective times for complete hydrolysis of benzylhydantoin by 50 times its weight of constant boiling hydrochloric, hydrobromic and hydriodic acids are 20–30, 6–7 and 1–2 hours. Whilst these reagents are suitable from many points of view, they cannot, for reasons already given, be generally employed.

As has been mentioned, Harries and Weiss obtained glycine from hydantoin by heating the latter with commercial ammonium sulphide for 2 hours at 150°. These authors however omit to state the yield of amino-acid obtained. Since the use of ammonium hydroxide or ammonium sulphide (the sulphide being present presumably to protect the amino-acid in alkaline solution from atmospheric oxidation) has obvious advantages in the ready removal of the hydrolytic reagent and the isolation of the amino-acid, experiments were undertaken to determine the most suitable conditions for the hydrolysis of hydantoins by such means. From the results obtained, it appears that a suitable strength of reagent is about 6 % ammonium sulphide or 3 % ammonium hydroxide, and that whilst ammonium sulphide gives a practically theoretical yield, ammonium hydroxide under the same conditions gives only a 75–85 % yield of the amino-acid. Another very interesting fact was gleaned from these experiments. During the later stages of the hydrolysis of benzylhydantoin by 6 % ammonium sulphide solution, some colourless crystalline material separated. From its melting-point and other characteristics, this compound appeared to be phenylalanine anhydride. So far as we are aware the formation of this compound under such conditions has not been described before and it is being further investigated.

For purposes of presentation, the experimental work has been divided into the following sections:

(1) The action of aqueous ammonium sulphide at 100° on unsaturated hydantoins.

(2) The action of aqueous ammonium sulphide at 58° on unsaturated hydantoins.

(3) The action of sodium hydrogen sulphide at 100° on unsaturated hydantoins in (*a*) aqueous solution and (*b*) alcoholic solution.

(4) The action of hydrogen sulphide at 100° on unsaturated hydantoins in pyridine solution.

(5) The hydrolysis of reduced hydantoins by aqueous solutions of (*a*) ammonium sulphide and (*b*) ammonium hydroxide.

The successful use of hydrogen sulphide as a reducing agent for the purpose above described is novel and the possibility of the application of the reaction to other unsaturated substances of somewhat similar constitution suggests itself. It has already been found, for example, that hydrogen sulphide will reduce α-acetamidocinnamic acid and benzalcreatinine to phenylalanine and benzylcreatinine respectively. These and other extensions of the method will be discussed in a subsequent paper. Finally, the further possibility of the replacement of hydrogen sulphide by organic sulphides, *e.g.* thiolacetic acid or cysteine in such reactions is being investigated.

EXPERIMENTAL.

1. *The action of aqueous ammonium sulphide at 100° on unsaturated hydantoins.*

Benzylhydantoin and phenylalanine from benzalhydantoin. Benzalhydantoin (6·5 g.) was heated at 100° in a closed vessel for 64 hours with 80 ml. of commercial ammonium sulphide (16 %). The resulting solution was evaporated to dryness and treated with 200 ml. of boiling water and filtered. The filtrate was again evaporated to dryness, taken up in 200 ml. of hot water and re-filtered. The combined insoluble material consisting mainly of sulphur was extracted repeatedly with hot water and filtered. The united filtrates were concentrated until crystals of phenylalanine began to form on the surface. 100 ml. of 95 % alcohol were added, and the phenylalanine was allowed to crystallise out overnight. The amino-acid was collected and recrystallised from dilute alcohol. A second crop was obtained by concentrating the mother-liquor and adding more alcohol. This was collected in its turn and recrystallised. The total yield of amino-acid was 3·1 g. It melted at 263°, and contained 8·40 % N. Erlenmeyer [1893] gives M.P. 263°. $C_9H_{11}O_2N$ requires N 8·48 %.

The mother-liquors from which the phenylalanine separated were concentrated, acidified with hydrochloric acid and boiled for a few minutes. A white crystalline substance separated and this on recrystallisation from dilute alcohol melted at 188°; this was identified by M.P. and mixed M.P. with benzylhydantoin made from phenylalanine and potassium cyanate. On treating the two preparations separately with cold fuming nitric acid and adding cold water 4-benzyl-3-nitrohydantoin was obtained in each case. Both nitrohydantoins melted at 208° after recrystallisation from alcohol, and a mixture of the two melted at the same temperature. The benzylhydantoin obtained amounted to 2·2 g. and contained 14·67 % N. $C_{10}H_{10}O_2N_2$ requires N 14·74 %. These results showed that the reduction of the benzalhydantoin was practically quantitative.

p-*Methoxyphenylalanine and* p-*methoxybenzylhydantoin from* p-*methoxybenzalhydantoin.* In a similar manner to that described above, *p*-methoxybenzalhydantoin (1·0 g.) gave *p*-methoxyphenylalanine (0·5 g.; 50 %) melting at 235° and containing 7·25 % N. $C_{10}H_{13}O_3N$ requires N 7·18 %.

On acidification of the mother-liquor with hydrochloric acid and boiling, the corresponding hydantoin separated on cooling. On recrystallisation it melted at 182·5° and contained 12·64 % N. $C_{11}H_{12}O_3N_2$ requires N 12·73 %. The hydantoin prepared from *p*-methoxyphenylalanine and potassium cyanate melted at 181°, whilst a mixture of the two preparations melted at the same temperature. The yield of the hydantoin was 0·28 g.

Tyrosine from p-*hydroxybenzalhydantoin.* *p*-Hydroxybenzalhydantoin (2·65 g.) [*cf.* Boyd and Robson, 1935] was heated with 30 ml. of ammonium sulphide at 100° for 72 hours. On cooling, the mixture became semisolid owing to separation of the tyrosine. The crystals of amino-acid were collected and the remainder of the amino-acid was isolated as in the previous experiments. After recrystallisation from water and drying, the tyrosine weighed 0·75 g., contained 7·69 % N, and melted at 309° when heated rapidly, 300° when heated slowly. Wheeler and Hoffman [1911] state that the melting-point of synthetic tyrosine is "indefinite" and varies for the same specimen from 295 to 340° according to the rate of heating. $C_9H_{11}O_3N$ requires N 7·74 % The yield was 32 % of the theoretical.

Benzylthiohydantoin and benzylhydantoin from benzalthiohydantoin. Benzalthiohydantoin (2·4 g.) was heated with a mixture of 50 ml. of alcohol and 100 ml. of commercial ammonium sulphide at 100° in a closed vessel for 72 hours. The liquid was evaporated to dryness and the residue was taken up in dilute sodium hydroxide and filtered. The solution was made strongly acid by the addition of dilute hydrochloric acid and boiled for some minutes. The crystalline precipitate which separated on the solution cooling was recrystallised from hot water. It melted at 180°; after a further recrystallisation from water, at 185°. Johnson and Nicolet [1913] quote 185°. It contained 13·86 % N. $C_{10}H_{10}ON_2S$ requires N 13·60 %. It weighed 1·66 g., equivalent to 68 % of the theoretical.

Benzylthiohydantoin (1·0 g.) was boiled for one hour with 10 ml. of 50 % chloroacetic acid. The solution was then diluted with water and cooled. The hydantoin was collected and recrystallised from hot water. It melted at 189° and contained 14·60 % N. The yield was 0·67 g. or 73 % of theory.

p-*Methoxybenzylthiohydantoin and* p-*methoxybenzylhydantoin from* p-*methoxybenzalthiohydantoin.* *p*-Methoxybenzalthiohydantoin (2·0 g.) was heated with 50 ml. of 16 % ammonium sulphide for 72 hours at 100°. The reduced hydantoin was isolated as in the case of benzylthiohydantoin. It weighed 1·24 g., equivalent to 62 % of the theoretical. It melted at 215° and contained 11·73 % N. $C_{11}H_{12}O_2N_2S$ requires N 11·86 %. The preparation of this substance has not been recorded hitherto.

p-Methoxybenzylthiohydantoin (0·6 g.) was boiled with 10 ml. of 50 % chloroacetic acid for 1 hour and the *p*-methoxybenzylhydantoin was isolated as in the case of the benzylhydantoin. It weighed 0·41 g., melted at 182·5° and contained 12·84 % N.

2. *The action of aqueous ammonium sulphide at 58° on unsaturated hydantoins.*

Benzylhydantoin from benzalhydantoin. Benzalhydantoin (2·0 g.) was heated with a mixture of 50 ml. of 16 % ammonium sulphide solution and 50 ml. of alcohol for 240 hours at 58° in a closed bottle. The solution was evaporated to dryness, the residue boiled with 200 ml. of water and the mixture filtered. The insoluble sulphur remaining on the filter was extracted twice with hot water. The combined filtrates were acidified with hydrochloric acid, boiled with a little charcoal and filtered. The filtrate was concentrated and the benzylhydantoin allowed to crystallise out for 3 days. It was collected and washed with a little cold water. The dry hydantoin weighed 1·88 g. The volume of mother-liquor was about 25 ml. and since the solubility of benzylhydantoin is of the order of 1 g. per 1000 ml., it may be assumed that at least 0·03 g. remained in solution. The total yield was therefore 1·91 g. equivalent to 95 % of the theoretical value. The product melted at 187° and contained 14·63 % N. It is probable that a shorter period of heating the benzalhydantoin with the ammonium sulphide would suffice.

A similar experiment in which 50 ml. of ammonium sulphide without alcohol were used gave a yield of 51 % of the theoretical figure after 1 week at 58°. The insolubility of the benzalhydantoin in ammonium sulphide at 58° however was such that it was not completely dissolved until the sixth day. The reduction was therefore retarded by the insolubility of the unreduced substance.

p-*Hydroxybenzylhydantoin from* p-*hydroxybenzalhydantoin.* *p*-Hydroxybenzylhydantoin was prepared in a similar manner to that described for benzylhydantoin, the period of heating being extended to 2 weeks. The product melted at 254° and contained 13·69 % N. The yield was 90 % of the theoretical. $C_{10}H_{10}O_3N_2$ requires N 13·59 %.

p-*Hydroxybenzylthiohydantoin from* p-*hydroxybenzalthiohydantoin.* *p*-Hydroxybenzylthiohydantoin prepared from *p*-hydroxybenzalthiohydantoin as described for benzylhydantoin melted at 209–210°, and contained 12·78 % N. $C_{10}H_{10}O_2N_2S$ requires N 12·62 %. Johnson and Nicolet [1913] quote 211° as the M.P. of a specimen of *p*-hydroxybenzylthiohydantoin made by the action of ammonium thiocyanate and acetic anhydride on tyrosine.

3. *The action of sodium hydrogen sulphide at 100° on unsaturated hydantoins.*

(*a*) *In aqueous solution.*

Benzylhydantoin from benzalhydantoin. Benzalhydantoin (2·0 g.) was treated with the equivalent amount (0·4 g.) of sodium hydroxide in 30 ml. of water. The bottle containing the solution was immersed in ice and the solution saturated with hydrogen sulphide, the hydantoin being precipitated thereby. The bottle was sealed and heated at 100° for 15 hours. It was then cooled, again saturated with hydrogen sulphide and finally re-heated at 100° for a further 16 hours. The solution was then evaporated to dryness *in vacuo*. The residue was treated with hot water and filtered from the insoluble sulphur. The filtrate, made strongly acid by the addition of hydrochloric acid, was boiled for 10 minutes. After cooling and keeping overnight 1·0 g. of pure benzylhydantoin separated. It melted at 188° and contained 14·66 % N. The mother-liquor was concentrated, made neutral to litmus by the addition of sodium hydroxide and boiled with 0·5 g. of potassium cyanate for 30 minutes to re-convert the amino-acid, produced by hydrolysis, into carbamido-acid. The liquid was then made strongly acid with hydrochloric acid and boiled for 10 minutes. A further crop of 0·59 g. of benzylhydantoin separated when the liquid cooled. It melted at 189° and contained 14·60 % N. If allowance be made for the solubility of benzylhydantoin in the 250 ml. of mother-liquor on the assumption that one part dissolves in 1000 ml. of water, the total yield of benzylhydantoin was 1·84 g. or 92 % of the theoretical value. Part of this (32 %) however consisted of amino-acid reconverted into hydantoin. The reduction was therefore practically quantitative.

A second experiment was carried out in which the heating period was only 16 hours. Examination of the resulting product showed that only partial reduction had been effected.

(*b*) *In alcoholic solution.*

Benzylhydantoin from benzalhydantoin. Benzalhydantoin (2·0 g.), sodium hydroxide (5 ml. of 10 % aqueous solution), water (25 ml.) and alcohol (60 ml.) were mixed and saturated with hydrogen sulphide at 0–5°. The mixture was heated in a closed vessel at 100° for 16 hours, re-saturated with hydrogen sulphide at 0–5° and again heated for 44 hours longer. The resulting solution was evaporated to dryness *in vacuo* and the residue taken up in 100 ml. of hot water. The hot solution was filtered and the insoluble sulphur repeatedly extracted with boiling water and filtered. The combined filtrates were acidified strongly with hydrochloric acid, boiled with a little charcoal and filtered hot. The filter was washed twice with hot water. The combined filtrates were concentrated to 150 ml. *in vacuo* and allowed to cool overnight. 1·32 g. of benzylhydantoin, M.P. 188°, were obtained. After addition of 0·15 g. as a correction for the amount of material remaining in solution, the total yield amounted to 1·47 g. or 73 % of the theoretical.

A similar experiment carried out in 90 % alcohol instead of 60 % alcohol gave a total yield, on the same basis, of 1·60 g. of benzylhydantoin, or 78 % of the theoretical.

Further experiments were carried out using in each case 2·0 g. of benzalhydantoin dissolved in 100 ml. of absolute alcohol, to which was added (1) 0·6 g. of sodium hydrogen sulphide (1 mol.) or (2) 0·3 g. of sodium hydrogen sulphide respectively. The cold solution was saturated with hydrogen sulphide, heated for 16 hours at 100°, cooled, re-saturated with hydrogen sulphide and again heated for 16 hours at 100°. The experiment with 1 mol. of sodium hydrogen sulphide yielded 1·5 g. of reduced product, or 75 % of the theoretical. That with 0·5 mol. of sodium hydrogen sulphide yielded 1·62 g. of the required product or 80 % of the theoretical figure.

Finally, an experiment was carried out using 1·8 g. of benzalhydantoin, 2 ml. of 20 % sodium hydroxide solution and 100 ml. of absolute alcohol. The other conditions were the same as in the two preceding experiments. The yield of pure reduced product was here 1·59 g. or 87 % of theory.

It may be noted that solutions of benzylhydantoin which have been saturated at a higher temperature and then kept at room temperature do not attain equilibrium for several days. The solubility figure used above refers to solutions in pure water. The actual yields were probably a little higher than the values given.

p-*Hydroxybenzylhydantoin from* p-*hydroxybenzalhydantoin*. *p*-Hydroxybenzalhydantoin (2·0 g.) was dissolved in sodium hydroxide (2·0 ml. of 20 %) and alcohol (100 ml.). The solution was saturated at 0° with hydrogen sulphide, heated at 100°, cooled, re-saturated with hydrogen sulphide and again heated at 100° for 16 hours. After being cooled, the solution deposited 0·80 g. of pure *p*-hydroxybenzylhydantoin which melted at 256°. Wheeler and Hoffman [1911] quote 257–258°. A further 0·60 g. was obtained in the usual way after removal of sulphur from the solution. The yield was thus 70 % of the theoretical. The material contained 13·62 % N. $C_{10}H_{10}O_3N_2$ requires N 13·59 %.

Experiments carried out with larger proportions of sodium hydrogen sulphide or sodium hydroxide yielded an oily by-product.

4. *The action of hydrogen sulphide at 100° on unsaturated hydantoins in pyridine solution.*

p-*Methoxybenzylhydantoin from* p-*methoxybenzalhydantoin*. *p*-Methoxybenzalhydantoin (2·0 g.) was dissolved in pyridine (20 ml.) to which concentrated ammonia (1 ml.) had been added. The mixture was saturated at 0–5° with hydrogen sulphide and then heated at 110° in a closed vessel for 48 hours. The solution was cooled to 5°, re-saturated with hydrogen sulphide and again heated under the same conditions for a further 18 hours. The solution was evaporated to dryness *in vacuo*, the residue taken up in boiling water and the whole filtered to remove the insoluble sulphur. The latter was boiled out repeatedly with fresh quantities of hot water, the suspension being filtered each time. The combined filtrates were concentrated to 250 ml. and cooled. 1·62 g. of *p*-methoxybenzylhydantoin, melting at 182° and containing 12·80 % N, was thus obtained. On concentrating the mother-liquors a further 0·3 g. of the required material was obtained. The yield amounted to 95 % of the theoretical figure.

Benzylhydantoin from hydantoin and benzaldehyde without intermediate isolation of benzalhydantoin. Benzaldehyde (5·5 g.), hydantoin (4·5 g.), pyridine (10 ml.) and diethylamine (10 drops) were heated to 98° for 42 hours in a closed bottle. The mixture was then cooled, more pyridine (20 ml.) added, and the solution was saturated with hydrogen sulphide at −5°. It was thereafter heated for 66 hours at 98°. The benzylhydantoin was isolated as in the preceding experiments. It weighed 4·1 g. or 48 % of the theoretical.

5. (*a*) *The hydrolysis of reduced hydantoins by aqueous ammonium sulphide.*

Phenylalanine from benzylhydantoin. Benzylhydantoin (2·0 g.) was dissolved in a mixture of 10 ml. of concentrated ammonia (sp. gr. 0·880) and 90 ml. of water. The solution was saturated with hydrogen sulphide at 0°. The vessel containing the resulting mixture was then closed and heated for 5 days at 100°. At the end of this time the solution was clear except for a small quantity of white flocculent matter. It was filtered, the filtrate concentrated until the amino-acid began to separate and finally treated with 50 ml. of alcohol. Pure phenylalanine crystallised out in well-formed plates which were filtered off and washed with dilute alcohol. It weighed 1·4 g., melted at 262° and contained 8·39 % N. A second crop was obtained by concentrating the mother-liquor and treating it again with alcohol. This contained 8·35 % N and weighed 0·3 g. The total yield was, therefore, 1·7 g., which was practically theoretical.

The flocculent material removed from the solution by filtration before isolating the amino-acid melted at 292°, and was evidently phenylalanine anhydride. Phenylalanine anhydride was found by Erlenmeyer and Lipp [1883] to melt at 290–291°. The amount isolated in the above experiment weighed 0·03 g.

5. (*b*) *The hydrolysis of reduced hydantoins by aqueous ammonium hydroxide.*

An exactly similar experiment to the preceding was carried out but omitting the saturation of the solution with hydrogen sulphide. In this case the deposit found in the solution after the period of heating was dark brown in colour indicating that oxidation had taken place to a certain extent. The yield of amino-acid isolated was 1·41 g., equivalent to 80 % of the theoretical. It contained 8·37 % N.

SUMMARY.

Reduction of unsaturated hydantoins, obtained by condensing aromatic aldehydes with ordinary hydantoin and with 2-thio-3-acetylhydantoin respectively, is readily effected quantitatively by heating them at 100° with solutions of sulphides for 24–72 hours. For this purpose aqueous or alcoholic solutions of ammonium sulphide, sodium hydrogen sulphide or sulphides of organic bases may be employed. The accompanying hydrolysis which occurs at 100° in the presence of water may be avoided by using anhydrous or almost anhydrous solutions of ammonium sulphide or sodium hydrogen sulphide in alcohol, or of hydrogen sulphide in pyridine or by heating the unsaturated hydantoin with aqueous ammonium sulphide at a lower temperature (58°) for a longer period (7–14 days). Some alcohol is usually added to the aqueous ammonium sulphide to increase the solubility of the unsaturated hydantoin.

In general a cleaner product is obtained by this method than by those hitherto employed, and it is especially applicable in cases where the use of hydriodic acid or of sodium amalgam is precluded by the instability of other parts of the molecule.

Hydrolysis of the reduced product to the amino-acid may be carried out in conjunction with the reduction process or separately. Dilute solutions of ammonium sulphide give a quantitative yield of pure amino-acid from the reduced hydantoin in 120 hours at 100°. Dilute ammonium hydroxide solutions are almost equally satisfactory but the presence of the sulphide appears to inhibit the darkening (? oxidation) of the solution during the process of hydrolysis.

A small amount of material separates during the course of hydrolysis by ammonium sulphide. This seems to consist of amino-acid anhydride.

LXIV. THE SYNTHESIS OF INDOLE-3-ALDEHYDE AND ITS HOMOLOGUES.

BY WILLIAM JOHN BOYD AND WILLIAM ROBSON.

From the Department of Physiology, University of London King's College.

(*Received February 1st, 1935.*)

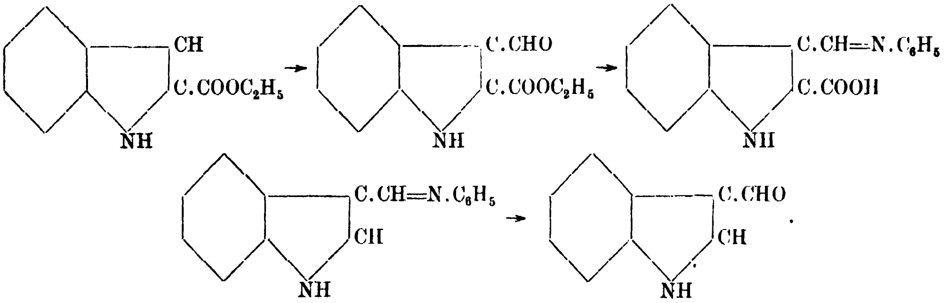
ONE of the many major difficulties encountered in the synthesis of tryptophan is that connected with the preparation of the parent substance, indole-3-aldehyde. Despite the exceedingly poor yields which Ellinger [1906] and Ellinger and Flamand [1908] obtained on synthesising this latter compound from indole, surprisingly few attempts have been made either to improve the yield or to evolve new methods of making it. The only one, indeed, worthy of mention is that of Majima and Kotake [1922] who employed a modified Grignard reaction on indole, using anisole instead of the customary ether as a solvent. The method, whilst it gives a primary yield of aldehyde higher than that obtained by Ellinger, suffers from the drawback that it is not applicable [Robson, 1924] with the same success to other derivatives of indole.

Preliminary experiments having already indicated that the modifications which may be successfully introduced into the Wheeler-Hoffman hydantoin synthesis of phenylalanine and tyrosine [Boyd and Robson, 1935, 1, 2] are applicable with even greater advantage to the synthesis of tryptophan from indole-3-aldehyde, it was decided to re-examine the problem of the preparation of the latter compound and its homologues with the view of making them more readily available.

The investigation followed two lines. The first had for its basis the modification of Ellinger's original method. On repeating the synthesis of indole-3-aldehyde according to that author it was noticeable that at the end of the reaction the resulting mixture still smelled strongly of chloroform. This fact in conjunction with the knowledge that Ellinger recovered unchanged half of the initial indole led to an examination of the quantities of the reacting substances used in the synthesis. It was at once evident that a much better yield of the aldehyde was to be expected if the quantity of hydroxide employed were considerably increased. An actual experiment proved this to be the case, the yield of aldehyde immediately obtainable being raised from the original figure of 9 % to one of 31 % of the figure demanded by theory. In addition, whilst 3-chloroquinoline is present as before in the steam distillate from the reaction mixture, it is accompanied by only insignificant amounts of unchanged indole. The same procedure applied to 2-methylindole and 5-methylindole gave the corresponding aldehydes in yields higher than those previously obtained by Ellinger's method.

In describing the synthesis of 7-methylindole-3-aldehyde, which has not been previously reported, mention must be made of the preparation of 7-methylindole. The first attempt to obtain this compound was made by Raschen [1887] along the lines of Fischer's classical method. For some reason, not apparent from his paper, Raschen did not succeed in decarboxylating the 7-methylindole-2-carboxylic acid. Following much the same procedure as Raschen, Kruber [1926] was able to isolate a small quantity of 7-methylindole and, moreover, evolved a method of isolating it from coal tar. In repeating Kruber's synthesis, the present writers have introduced modifications at certain stages. It has been found, for example, that ring closure is best effected by dissolving the pyruvic acid-*p*-tolylhydrazone in cold alcohol saturated with hydrochloric acid. When the same reaction is attempted with a hot alcoholic solution a second compound in addition to ethyl 7-methylindole-2-carboxylate is formed. Analysis of this substance indicates that it possesses the formula $C_{25}H_{20}O_7N_3$. It contains an amide grouping, the corresponding acid having the formula $C_{25}H_{19}O_8N_2$. Its structure is being further investigated. Kruber's method has been further improved in the last stage. Here, as has been reported previously in other cases, a much higher yield of the indole is obtained by heating the ammonium salt instead of the free carboxylic acid.

The second part of the investigation included several attempts to synthesise indole-3-aldehyde and its homologues on entirely new lines. Of these, only one merits description at the present stage. 2-Carbethoxyindole, by means of the modification of the well-known Gatterman hydrogen cyanide method introduced by Adams and Levine [1923], gave the corresponding 3-aldehyde in excellent yield. The ester aldehyde so obtained was hydrolysed without difficulty to the acid, the sodium salt of which in hot aqueous solution reacted with aniline, the anil thus formed being precipitated on carefully neutralising the cold solution.



Decarboxylation of the latter compound should yield the anil of indole-3-aldehyde. Attempts, however, to carry out this reaction were not altogether satisfactory owing to formation of tar. The best yields were obtained by heating the substance in liquid paraffin at 220° and precipitating the decarboxylated anil from solution therein by the addition of light petroleum. The compound thus obtained gave the required aldehyde on warming with water acidulated with a few drops of acetic acid. In the case of indole-3-aldehyde the yield approximated to 40–50 % but in the case of the 5-methyl and the 7-methyl homologues it was exceedingly poor.

During the course of this part of the investigation an attempt was made to synthesise 2-methylindole-3-aldehyde from 2-methylindole by the Adams-Levine method referred to above. It has already been shown by Barger and Ewins [1917] that on submitting 2-methylindole to the original Gattermann technique, the aldehyde is obtained in very good yield. On applying the method of Adams and Levine, however, we found that the product obtained was by no means homogeneous, but that it consisted of two fractions, one being easily soluble in hot alcohol whilst the other was practically insoluble in that medium. Further examination showed that the soluble fraction consisted of the required 2-methylindole-3-aldehyde and that the insoluble compound was the tri(2-methylindolyl)-

methane, originally obtained by Fischer and Pisbor [1923] by heating a mixture of 2-methylindole and 2-methylindole-3-aldehyde with alcoholic potash.

In reporting this work, the authors have to thank Mr W. R. Boon for valuable help in the preparation of the required 5-methylindole.

EXPERIMENTAL.

Indole-3-aldehyde. Indole (20 g.) was dissolved in a mixture of chloroform (150 ml.) and 96 % alcohol (400 ml.) contained in a 2 l. flask fitted with a rubber stopper carrying a reflux condenser, a stirrer and a dropping funnel. The mixture was kept gently boiling over an electric hot plate and stirred while a solution of potassium hydroxide (250 g.) in water (300 ml.) was gradually dropped in over a period of 4–5 hours. The mixture was boiled for 30 minutes after the last addition of potassium hydroxide. When the contents of the flask had cooled, the potassium chloride was collected on a Büchner funnel and washed with alcohol. The combined filtrate and washings were then steam-distilled, the receiver being changed when the chloroform and most of the alcohol had passed over. The distillation was continued for 30 minutes after the distillate was no longer turbid owing to the presence of 3-chloroquinoline.

The hot aqueous liquid in the flask was decanted from the tarry residue and set aside to cool. The tarry material remaining was dissolved in the minimum quantity of hot alcohol, the alcoholic solution poured into a litre of hot water, the whole again boiled until the tarry globules had coalesced (an action which can be hastened by the addition of a little sodium chloride to the solution) and then filtered through a hot fluted filter-paper. The tar remaining on the filter was extracted yet another time in the same way. Aldehyde separated from all three aqueous solutions. This was filtered off and the combined filtrates amounting to some 2·5–3·0 litres were concentrated to about 300 ml. This concentrated solution on cooling yielded a further crop of aldehyde. The total yield of aldehyde thus obtained amounted to 7·5 g. (31 % of theory). The crude material melted at 194° and after recrystallisation from water at 198° (*cf.* Ellinger and Flamand, 195°). It contained 9·57 % N. C_9H_7NO requires N 9·66 %.

2-Methylindole-3-aldehyde. 2-Methylindole (13 g.) gave, by the above method 8 g. of 2-methylindole-3-aldehyde (51 % of theory).

5-Methylindole-3-aldehyde. By the same procedure, 20 g. of 5-methylindole yielded 6·5 g. of 5-methylindole-3-aldehyde (27 % of theory).

Pyruvic acid-o-tolylhydrazone. *o*-Toluidine (107 g.) was slowly added to a litre of hydrochloric acid (sp. gr. 1·16), cooled to 0°. A semi-crystalline mass of the hydrochloride separated out. Sodium nitrite (69 g.) dissolved in 150 ml. of water was slowly added, the temperature being maintained at zero by means of a freezing mixture. Stannous chloride (580 g.) dissolved in 500 ml. of hydrochloric acid and cooled to zero was next added. A white precipitate separated out. The mixture was left overnight in a cool place and next day the white precipitate was filtered off and well pressed. It was then shaken with 600 ml. of 25 % sodium hydroxide solution and 800 ml. of ether, and the ethereal layer was separated. The extraction with ether was repeated three times and the combined extracts were washed with water and then shaken with a slight excess of 1 % hydrochloric acid. The aqueous layer was separated and the ether was again washed twice with 100 ml. of dilute acid. To the combined acid solutions a solution of pyruvic acid in water equivalent to the *o*-tolylhydrazine present was added slowly with stirring. The yellow crystalline hydrazone began to separate at once and finally the mixture became semi-solid. It was filtered by suction on a Büchner funnel, and the solid was washed with a little water, air-dried and crystallised from hot 80 % alcohol. It melted at 157° (Raschen gives 158°). Yield 82·2 % of the theoretical.

2-Carbethoxy-7-methylindole. The pyruvic acid-*o*-tolylhydrazone (60 g.) was dissolved in cold absolute alcohol (500 ml.) which had been previously saturated with dry hydrogen chloride. The solution was kept at room temperature overnight and then poured into 5 litres of cold water. After standing overnight the precipitated material had become hard and was collected and dried at 100°. The brown amorphous product weighed 58 g. It was distilled at atmospheric pressure in a current of superheated steam and yielded 27 g. of light yellow 2-carbethoxy-7-methylindole which was somewhat impure as it melted below 100°. After crystallisation from hot 80 % alcohol it gave 15 g. of pure ester (M.P. 128°). The material in the mother-liquor was precipitated by the addition of water, collected, dried and extracted with hot light petroleum. In this way a further 3 g. of pure ester was obtained. The yield of pure ester from 60 g. of the pyruvic acid-*o*-tolylhydrazone was thus 18g. or 28 % of the theoretical yield. On decarboxylation of the impure uncrystallisable material, however, pure 7-methylindole corresponding to a further 8 % was obtained, making the total yield of ester 36 % of the theoretical value.

When the ester of the pyruvic acid-*o*-tolylhydrazone was used instead of the acid, no improvement in yield or purity of 2-carbethoxy-7-methylindole was found. The hydrazone ester was prepared by dissolving 50 g. of the hydrazone acid in 500 ml. of absolute alcohol, adding 25 ml. of concentrated sulphuric acid and heating the mixture under reflux for 30 minutes. The mixture was then poured into several litres of water, the precipitate which formed was collected and crystallised from 80 % alcohol. The yield was practically theoretical. The product melted at 61° (Raschen gives 61°, Kruber 62°).

When the solution of the pyruvic acid-*o*-tolylhydrazone in absolute alcohol previously saturated with hydrogen chloride was kept overnight and then heated on the water-bath for an hour before being poured into water, no improvement in yield or purity was obtained.

When pyruvic acid-*o*-tolylhydrazone was dissolved in absolute alcohol and the solution was then saturated with dry hydrogen chloride the yield was much less, and another crystalline substance was formed in considerable quantity. This appears to be an amide of high molecular weight. It was formed under the following conditions. *o*-Tolylhydrazone of pyruvic acid (80 g.) was dissolved in absolute alcohol (500 ml.) and dry hydrogen chloride was passed in. After a time the flask was cooled to prevent the alcohol from boiling away, and the saturation of the alcohol was completed. The solution was kept at room temperature overnight, and next day a white crystalline deposit was found at the bottom of the flask. This substance, of which about 5 g. were present, was very insoluble in ether, benzene, petroleum, cold alcohol and cold water. It was recrystallised from hot water and then melted with decomposition at 283° and evolved ammonia on being warmed with dilute sodium hydroxide. On acidifying the alkaline solution with hydrochloric or sulphuric acid, an acidic substance was precipitated which melted after recrystallisation from water at 235°. It was more soluble in water than the parent substance and dissolved in sodium bicarbonate solution with evolution of carbon dioxide.

Elementary analysis of these substances showed them to be an amide and the corresponding acid of compositions corresponding respectively to the formulae $C_{25}H_{20}O_7N_3$ and $C_{25}H_{19}O_8N_2$. (Found for amide: C, 63·9; H, 4·0; N, 8·83 %. For acid: C, 63·6; H, 4·0; N, 5·9, 6·0 %.)

The substances did not give a coloration with Ehrlich's reagent or with glyoxylic acid and concentrated sulphuric acid.

7-Methylindole-2-carboxylic acid. The corresponding ester was hydrolysed by boiling under a reflux with 6 % alcoholic KOH for 30 minutes. The alcoholic solution was then poured into water, the alcohol distilled off and the solution acidified. The 7-methylindole-2-carboxylic acid which separated was filtered off and recrystallised from dilute alcohol. It formed fine needles melting at 173°. Raschen gives 171° and Kruber 170°. The yield was quantitative. The substance contained 7·94 %N. $C_{10}H_9O_2N$ requires N 8·00 %.

7-Methylindole. Although Raschen failed originally to obtain the indole by melting 7-methylindole-2-carboxylic acid, Kruber obtained it in this way. In the present case the ammonium salt was used. The acid was dissolved in dilute ammonium hydroxide and the solution evaporated to dryness on the water-bath. The dry ammonium salt was transferred to a small distilling flask and carefully heated in a metal-bath to 240° at which temperature it melted and evolved ammonium carbonate which condensed in the side tube of the flask and was expelled by warming. On further heating the indole distilled as a water-clear liquid which solidified to a white mass. The yield was 62 % of the theoretical. Crystallisation of the indole from alcohol gave white plates melting at 78°. After recrystallisation from light petroleum, it melted at 82°. Since Kruber has reported a melting-point of 85°, the product was twice recrystallised from light petroleum and the melting-point redetermined. It was still 82°. After careful sublimation of the product in a test-tube, it was still the same. Commercial 7-methylindole from coal-tar also melted at 82° before and after recrystallisation from light petroleum. A mixture of the synthetic and coal-tar products also melted at 82°. (Found: C, 82·54; H, 6·98 %. C_9H_9N requires C, 82·39; H, 6·92 %.)

The picrate, prepared by adding aqueous picric acid solution to a hot saturated aqueous solution of the indole, separated as the solution cooled as a crimson precipitate. It crystallised from light petroleum in fine needles, which melted at 172° (*cf.* Kruber, 175°).

In working up impure 7-methylindole-2-carboxylic ester which could not be purified by crystallisation it was found convenient to convert it into crude ammonium salt and to decarboxylate it as already described. The indole was then readily recovered reasonably pure by steam distillation. It melted at 78° on recrystallisation from alcohol.

7-Methylindole-3-aldehyde. This substance was prepared in exactly the same way as indole-3-aldehyde. The yield from 20 g. of 7-methylindole was 7–8 g. It crystallised in gritty prisms of a sandy colour or in plates and melted at 202°. It contained 8·89 % N. $C_{10}H_9ON$ requires N 8·81 %.

3-Chloro-8-methylquinoline. This substance, which has not been described hitherto, was obtained in the steam distillate of the reaction mixture obtained in the Tiemann-Reimer preparation of 7-methylindole-3-aldehyde. Since there was little unchanged 7-methylindole present, the chloromethylquinoline crystallised out from the aqueous distillate. The yield from 20 g. of 7-methylindole was 5·0 g. It crystallised in long needles from dilute alcohol melting at 55°. Found 19·79 % Cl. $C_{10}H_8NCl$ requires Cl 20·00 %.

2-Carbethoxyindole-3-aldehyde. 2-Carbethoxyindole (19 g.), zinc cyanide (17 g.) and 300 ml. of ether which had been distilled over sodium were placed in a flask fitted with (*a*) an inlet tube dipping below the surface of the ether, (*b*) an outlet tube connected through a sulphuric acid trap to the outside air and (*c*) an efficient stirrer. Dry hydrogen chloride was passed into the ether for

3 hours, the reaction flask being kept cold by an ice-bath. After 2 hours, the ice-bath was removed and one of warm water substituted so that the ether just boiled. After a further 30 minutes the reaction was considered complete. The 2-carbethoxyindoleiminochloride was deposited as a yellowish white substance on the sides of the flask. Next morning the ether was decanted off, and the inside of the flask and its solid contents were washed with ether. The imino-compound was then boiled with water and the aldehyde which separated was filtered off and crystallised from dilute alcohol. 15 g. of pure product melting at 187° (188–189° after recrystallisation from chloroform) were obtained. A further crop of 3 g. of crude product was isolated from the mother-liquor. 3·5 g. of unchanged carbethoxyindole were recovered from the ether. The 2-carbethoxyindole-3-aldehyde contained 6·49 % N. $C_{12}H_{11}O_3N$ requires N 6·45 %.

2-Carboxyindole-3-aldehyde anil. 3·0 g. of indole-3-aldehyde-2-carboxylic ester were warmed with 1·5 equiv. of dilute alcoholic sodium hydroxide for 15 minutes. 1·4 g. of aniline were added to the hot solution with stirring. The liquid was cooled and carefully neutralised to Congo red with dilute hydrochloric acid, whereupon the acid anil was precipitated. The yield of anil was practically quantitative. It melted at 239° (raised to 244–245° on recrystallisation from dilute alcohol). It crystallised in yellow needles and contained 10·52 % N. $C_{16}H_{12}O_2N_2$ requires N 10·61 %.

Indole-3-aldehyde anil. 1·5 g. of indolealdehyde-2-carboxylic acid anil were suspended in 15 ml. of medicinal paraffin and heated to 210°. Gas was evolved and the substance gradually passed into solution. After evolution of gas had ceased, the addition of light petroleum to the solution precipitated the decarboxylated product. This was filtered off, washed with light petroleum and recrystallised from chloroform and finally from light petroleum. It melted at 123° and contained 12·61 % N. $C_{15}H_{12}N_2$ requires N 12·73 %. A certain amount of tar was formed, but the yield was estimated at approximately 50 % of the theoretical.

0·5 g. of ordinary indole-3-aldehyde was heated with 0·7 g. of aniline in a test-tube. The product was crystallised from alcohol and recrystallised from 50 % alcohol. It melted at 122·5°. Majima and Kotake [1925] quote 126–127° as the melting-point of the product made by a different method.

Treatment of the anil with a very slight excess of dilute acetic acid sufficed to liberate the aldehyde.

2-Carbethoxy-7-methylindole-3-aldehyde. The preparation of this substance from 2-carbethoxy-7-methylindole followed exactly the preparation of 2-carbethoxyindole-3-aldehyde as described above. The yield was similar, but a small quantity of another product was obtained which was less soluble in alcohol. This has not been further investigated. After recrystallisation from alcohol the product melted at 189°, and contained 6·09 % N. $C_{13}H_{13}O_3N$ requires N 6·04 %.

2-Carboxy-7-methylindole-3-aldehyde anil. This substance was prepared from the ester-aldehyde (or from the acid-aldehyde) as described for the anil of 2-carboxyindole-3-aldehyde. It melted at 255° with decomposition. The yield was reduced by the formation of an insoluble yellow compound which melted at 245°, and could not be decomposed with acid to regenerate the aldehyde.

7-Methylindole-3-aldehyde anil. The preparation of this substance from the preceding compound by decarboxylation followed closely that of the anil of indole-3-aldehyde. It was also formed by fusing 7-methylindole-3-aldehyde and aniline together as described for the lower homologue. Both preparations melted at 128° and gave the aldehyde on treatment with very slight excess of acetic acid. The anil contained 11·82 % N. $C_{16}H_{14}N_2$ requires N 11·97 %.

2-Methylindole-3-aldehyde (*by the modified Gattermann method*). A mixture of 2-methylindole (15 g.), zinc cyanide (17 g.) and 150 ml. of dry ether was treated with dry hydrochloric acid gas (*cf.* the preparation of 2-carbethoxyindole-3-aldehyde above) first for 2·5 hours at 0° and finally for 30 minutes at 40°. The highly pigmented mass which had separated during the reaction was filtered off, washed several times with ether and then warmed with hot water. Gradually an almost colourless crystalline mass began to separate. After standing some time, this was filtered off and washed several times with water and dried. The dry product was triturated with hot alcohol which dissolved only a fraction of it. While still hot, the mixture was filtered and water was added to the filtrate until crystallisation commenced. When the mixture was cold, the crystals were filtered off and dried. They weighed 3·5 g. They had M.P. 201° (Barger and Ewins give 202–203°) and contained 8·9 % N. This fraction of the product was therefore 2-methylindole-3-aldehyde.

For purposes of purification, the alcohol-insoluble fraction of the product was dissolved in pyridine and reprecipitated with benzene, and was thus obtained almost colourless. M.P. 319°. It contained 10·62 % N. $C_{28}H_{25}N_3$ requires N 10·4 %. These characteristics showed that this fraction was undoubtedly the tri-(methylindolyl)methane obtained originally by Fischer and Pisbor [1923]. Approximately 10 g. of it were obtained by the above procedure.

SUMMARY.

Ellinger's original method of synthesising indole-3-aldehyde has been modified so that an increased yield of the product is obtained in one operation and the necessity of recovering unchanged indole is avoided. Similarly improved yields of 2-methylindole- and 5-methylindole-3-aldehyde have also been obtained by the modified method. Modification of the synthesis of 7-methylindole has led to increased yields of that substance; moreover, the synthesis of 7-methyl-3-aldehyde, which has not been recorded previously, is described. Details are given of an alternative method of synthesising indole-3-aldehyde.

Part of the work described above was done during the tenure of a Berridge Scholarship awarded to one of us (W. J. B.) by the Delegacy of the University of London King's College. The cost of the materials used was defrayed partly from a grant from the Royal Society to one of us (W. R.).

LXV. THE EFFECT OF ASCORBIC ACID ON EXPERIMENTAL GOITRE.

By ALLAN WILLIAM SPENCE and ERIC FRANK SCOWEN[1].

From the Dunn Laboratories, St Bartholomew's Hospital, London.

(*Received January 15th, 1935.*)

The experiments of Marine and his collaborators [Marine *et al.*, 1933] show that the development of simple goitre in rabbits, fed on a diet consisting chiefly of cabbage, can be prevented by the feeding of certain fresh plants and indicate that the plants in question contain an antigoitrigenic substance other than iodine. The authors suggest that the substance may be identical with hexuronic acid isolated by Szent-Györgyi [1928] from cabbage, orange juice and suprarenal cortex. They state however that iodine cannot be entirely excluded as a contributory antigoitrigenic factor in these experiments, and that final proof must await the production of thyroid involution by the use of a pure iodine-free preparation of hexuronic acid. The purpose of this paper is to show that in our experience hexuronic acid (ascorbic acid) has no involuting effect on thyroid hyperplasia produced in rabbits by means of cabbage feeding or on that produced in guinea-pigs by daily intraperitoneal injections of acid extract of anterior pituitary. Further, it will be seen that there is no definite evidence that a deficiency of ascorbic acid over a prolonged period has a goitrigenic action in guinea-pigs.

EXPERIMENTAL.

The effect of ascorbic acid on simple thyroid hyperplasia produced by cabbage feeding. The production of simple thyroid hyperplasia in rabbits fed on a diet consisting chiefly of cabbage was observed by Chesney *et al.* [1928], and confirmed by Marine *et al.* [1929] in the United States, by McCarrison [1931] in India and by Spence *et al.* [1933] in England. In the present experiment considerable thyroid enlargement and marked hyperplasia were produced in a batch of eight rabbits, aged 3 months and weighing 960–1537 g., by feeding them for one month on fresh cabbage in amounts equivalent to 75 Cals/kg. of body weight. The diet was supplemented with 35 g. of rolled oats three times weekly. The condition of the thyroid glands was observed surgically. The animals then continued with their cabbage diet, but two received daily by mouth 5 mg. and two 20 mg. of pure ascorbic acid, freshly dissolved in boiled distilled water. The remaining four served as controls. At the end of 20 days of this treatment the thyroids were again inspected surgically and also microscopically. The glands of two of those which had received ascorbic acid were perhaps slightly less hyperplastic than on the previous occasion, but this might well have been due to some diminution in the potency of the cabbage, as one of the controls had similarly regressed and two had not increased in size (Table I).

By the same means marked thyroid hyperplasia was produced in a second batch of eight rabbits, aged 3 months and weighing about 1500 g. The animals continued with their cabbage diet, but four of them received daily by mouth 50 mg. of ascorbic acid. The remaining four as controls received no medication.

---

[1] Baly Research Scholar.

At the end of 3 weeks there was no diminution in the size of the thyroid glands, and histologically all showed marked hyperplasia with no evidence of involution (Table I).

The effect of ascorbic acid on thyroid hyperplasia produced by anterior pituitary extract. Twenty guinea-pigs, ten males and ten females, weighing 200–300 g., were fed on a non-goitrigenic diet containing fresh lettuce three times weekly. They were divided into two groups in which the sexes were equally distributed. Both groups received daily intraperitoneal injections of 1 ml. of acid extract of Organon's anterior pituitary powder, prepared after the method of Loeb and Bassett [Scowen and Spence, 1934]. In one group, however, five received in addition 25 mg. and five 50 mg. of ascorbic acid daily subcutaneously. The administration of ascorbic acid was started 4 days before treatment with anterior pituitary extract was begun. It has been shown by numerous observers, including Aron [1929; 1930], Collip [1933] and Loeb and Friedman [1931], that the initial hyperplasia produced by anterior pituitary extract regresses and involutes to the colloid state in spite of continued administration. In some cases the hyperplasia may reach its maximum in one or two weeks. So that this regression should not be a complicating factor and vitiate the results, the animals were sacrificed after receiving anterior pituitary for 7–8 days. The thyroid glands of both groups, *i.e.* those which received ascorbic acid and those which did not, all showed macroscopically marked hyperaemia and histologically marked hyperplasia. There was no significant difference in the weights of the suprarenals in either group (Table II).

The effect of a diet deficient in ascorbic acid on the thyroid gland of guinea-pigs. Should ascorbic acid be an antigoitrigenic substance, a deficiency of it might

be expected to bring about hyperplasia of the thyroid gland in a considerable percentage of animals. To test this hypothesis we examined the thyroid glands of guinea-pigs which were maintained on scorbutic diets as suggested by Dr S. S. Zilva of the Lister Institute, where he kindly carried out the experiments for us. Twenty-four guinea-pigs weighing 200–300 g. were fed on a scorbutic diet consisting of a daily ration of 15–20 g. of a mixture of 1 part by volume of crushed oats, 2 parts by volume of bran and about 40 ml. of reconstituted dried milk, autoclaved at 120°. They were divided into three groups. The first group consisting of six animals was fed on this diet for 22 days, and at the end of this period all were in a condition of acute scurvy. The second group consisting of twelve guinea-pigs received the diet for periods varying from 26 to 44 days, and was maintained in a condition of chronic scurvy by the daily administration of ascorbic acid in doses varying from 0·25 to 0·5 mg., the amount being regulated by the animal's weight and daily condition. The third group of six guinea-pigs received the diet for 44 days, but each animal was fully protected against scurvy by a daily dose of 5 mg. of ascorbic acid. At the end of their respective periods the animals were sacrificed. The thyroids of the six guinea-pigs with acute scurvy were normal, both macroscopically and microscopically. The thyroids of the six guinea-pigs which were fully protected against scurvy were also normal. Of the twelve animals suffering from chronic scurvy, one showed marked, one moderate and three slight hyperplasia. There was no definite enlargement of the glands (Table III).

CONCLUSION.

In view of the antigoitrigenic effect of plant juices the consideration of the part played by vitamin C (ascorbic acid) in the aetiology of simple goitre is important. Contradictory results have been obtained in studying the effect on the thyroid gland of vitamin C deficiency. McCarrison [1919–20] found that guinea-pigs fed on a scorbutic diet consisting of crushed oats and autoclaved milk and deficient in essential salts developed thyroid enlargement, mainly as a result of congestion and haemorrhage. He does not state whether hyperplasia was present. In later experiments he found no thyroid enlargement in rats fed on a synthetic diet deficient in vitamin C but complete in other respects [McCarrison, 1930]. Harris and Smith [1928], on the other hand, observed a slight degree of thyroid hyperplasia in guinea-pigs in which experimental scurvy had been produced by means of a diet of alfalfa meal, wheat flour, oats and water.

In the experiment described above it has been seen that in acute scurvy there was no evidence of thyroid hyperplasia, but that in twelve guinea-pigs with chronic scurvy thyroid hyperplasia was present in a fairly marked degree in two and in a slight degree in three animals. We feel that this finding occurred in too small a percentage to have any definite significance. It has also been shown that the daily administration of large doses of ascorbic acid does not prevent the occurrence of thyroid hyperplasia in guinea-pigs receiving injections of anterior pituitary extract containing thyrotropic hormone, a finding which is not in agreement with the conclusions of Marine *et al.* [1934]. Neither has ascorbic acid any involuting effect on the hyperplastic goitres produced in rabbits by means of cabbage, which itself is rich in vitamin C. We are consequently of the opinion that ascorbic acid cannot be regarded as an antigoitrigenic substance.

SUMMARY.

1. The administration of ascorbic acid in daily doses of 5, 20 and 50 mg. for 3 weeks did not cause involution of hyperplastic thyroids produced in rabbits by means of cabbage.
2. The administration of ascorbic acid in daily doses of 25 and 50 mg. for 12 days did not prevent the occurrence or diminish the degree of thyroid hyperplasia in guinea-pigs which received at the same time 8 daily injections of thyrotropic hormone of the anterior pituitary.
3. In six guinea-pigs with acute scurvy, there was no evidence of thyroid hyperplasia; in twelve guinea-pigs with chronic scurvy there were varying degrees of hyperplasia in five animals, but there was no significant thyroid enlargement.
4. It is concluded that ascorbic acid is not an antigoitrigenic substance.

We wish to thank Dr A. Macbeth, of the Organon Laboratories, for supplies of anterior pituitary powder.

One of us (A. W. S.) is indebted to the Medical Research Council for personal and expenses grants.

LXVI. A STILL FOR CONCENTRATION UNDER REDUCED PRESSURE.

By COLIN JOHN OWEN RHONABWI MORRIS.

From the Biochemical Department, Lister Institute, London.

(*Received January 20th, 1935.*)

In the course of work with protein hydrolysates, it was necessary to concentrate large volumes of acid liquids at a fairly low temperature. The acidity of the solutions to be concentrated precluded the use of metal parts in the apparatus, and the solutions were prone to froth during concentration under reduced pressure in a simple still.

The apparatus to be described obviated these difficulties. Fig. 1 shows the layout of the still. The distillation vessels consist of two 2 l. long-necked flasks A_1, A_2 (only one of these is shown in the figure), connected by the short tubes B_1, B_2, to the arms C_1, C_2, of the stillhead D. The arms C_1, C_2, are of 18 mm. internal diameter and permit the free flow of the vapour to the enlarged upper portion of the tube D. This is provided with an external water-jacket E, and an internal cooler F, which extends to the bottom of the receiver G. F is located centrally in D by three glass projections (not shown). The receiver G is cooled externally by the overflow water from F which is distributed over its surface by the tubes H. In order to empty the receiver without dismantling the apparatus, it is provided with two tubes K_1, K_2, connected by a two-way tap to the water-pump. During normal distillation, the pump communicates with K_2, but when it is desired to empty the receiver, the pressure in the system is

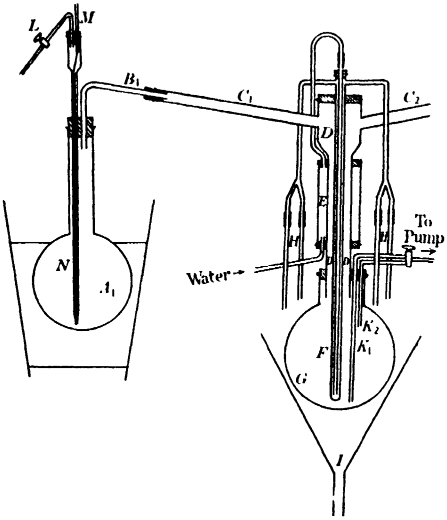

Fig. 1.

increased slightly and the tap turned to communicate with K_1; the contents of G can then be sucked over into a suitable receiver placed between the pump and the still.

With foaming liquids, a modified air-leak has been found very useful. The liquid to be concentrated enters continuously at L and is mixed with air from the very fine capillary M. The foam passes down the tube N, which is drawn out somewhat at its lower end. It is found that this device prevents both bumping and excessive foaming in the distillation flasks. In the case of a non-foaming liquid, an ordinary air-leak can be used, and the feed L then passes directly into the distillation flask A.

The distillation flasks and the condensing system are clamped independently, and the rubber sleeves between B and C permit small relative movements. The condensing system is also supported on the funnel I by three cork blocks (not shown).

The distillation flasks are heated in baths consisting of buckets heated by gas-rings. The large volume of liquid makes loss by evaporation unimportant at the low temperatures used.

The advantages of the still are as follows:

(1) It is cheap and simple to construct and operate.

(2) Owing to the free passage afforded to the vapour and to the fact that it is cooled somewhat before it passes through the more constricted parts of the system, the efficiency is high. At a water-bath temperature of 50–55° and a pressure of 12 mm. it has a capacity of $1\frac{1}{2}$–2 l. per hour, depending on the liquid being concentrated.

(3) The central cooler minimises re-evaporation of the condensed liquid and the establishment of back-pressure.

(4) The liquid to be distilled can enter and the condensate can be removed from the system without a large increase in pressure.

(5) Frothing is minimised.

LXVII. THE INFLUENCE OF ANIMAL TISSUES ON THE OXIDATION OF ASCORBIC ACID.

BY COLIN ASHLEY MAWSON.

From the John Burford Carlill Laboratories, Westminster Hospital Medical School, S.W. 1.

(*Received January 30th, 1935.*)

IT has usually been considered that ascorbic acid cannot be kept under aerobic conditions except in the solid form unless in relatively strongly acid solution. Green [1933] suggested that under the conditions of p_H and oxygenation of living tissues the existence therein of reduced ascorbic acid might be explained by the presence of some anti-oxidative mechanism. St Huszák [1933] showed that a substance occurred in the suprarenal medulla which prevented the reduction of silver nitrate by the ascorbic acid of suprarenal medulla and cortex. This protective substance was precipitated by lead acetate. Further work by de Caro [1934] and by de Caro and Giani [1934] which appeared during the course of this investigation led to the conclusion that in most animal tissues a protective mechanism existed of the kind postulated by Green. This work showed that ascorbic acid in phosphate buffer (p_H 7·5) would remain unoxidised in presence of air for several hours if mixed with small amounts of liver, muscle, blood, ovary, nerve or suprarenal gland from normal or scorbutic guinea-pigs. The protective material could be extracted by phosphate buffers, trichloroacetic acid or alcohol and was not precipitated by lead acetate or mercury. Although extracts deprived of reduced glutathione by mercury treatment still possessed protective power, de Caro and Giani considered that traces of oxidised glutathione had escaped precipitation and would account for the protection, but they pointed out that in this case the substance responsible differed from that observed by St Huszák, which was precipitated by lead acetate.

In the present paper it has been shown that although no protective mechanism exists in the lemon apart from the acidity of the juice, small traces of animal tissues or tissue extracts will prevent the oxidation of ascorbic acid in $M/30$ phosphate buffer at p_H 7·4 when incubated at 37°. This protective effect is most powerful in the presence of whole tissues, but extracts filtered through Bechhold collodion membranes (0·7 μ pores) still contain the protective mechanism. Active extracts have been made from the liver, spleen, brain and muscle of rats.

The protective effect of tissues can be closely imitated by cysteine, cystine, H_2S and glutathione. Extracts treated with mercuric acetate retain only about 1/100 of their original activity and at the same time lose most of their glutathione, but by heating liver extract for one hour in a boiling water-bath the protective activity can be reduced to about 1/10 of its original value without any change in the glutathione content. Addition of iodoacetate has no effect on protection by liver extract and only slightly reduces protection by glutathione when present in excess. Quantitative experiments showed that far more glutathione, as the pure substance, was necessary to prevent the oxidation of ascorbic acid than could be found in extracts giving optimum protection, and dialysed extracts containing practically no reduced glutathione had exactly the same protective power as undialysed extracts. The various pure substances used did not give as high a degree of protection as liver extract, the presence of which, at optimum concentration, would usually preserve 90 % of the original concentration of ascorbic acid for an hour at 37° in $M/30$ phosphate (p_H 7·4).

Ascorbic acid is comparatively stable at 37° if dissolved in water twice redistilled from a glass apparatus, but the addition of minute traces of copper caused rapid oxidation. Ferrous and ferric ions catalysed the oxidation to a less extent, while mixtures of iron and copper caused oxidation to take place more rapidly than addition of either metal alone. It is considered likely that the rapid oxidation of ascorbic acid solutions made from ordinary laboratory distilled water is due to contamination with traces of copper and iron.

Copper in fairly high concentration catalysed the aerobic oxidation of glutathione, but iron had no appreciable effect, confirming the results of Pirie [1931]. Addition of iron to liver extracts did not reduce their power to protect ascorbic acid from oxidation until a concentration of 10^{-3} mg. per ml. was reached, and iron had little effect on the protective power of glutathione. A reduction in the protective power of glutathione was effected by 4×10^{-4} mg. Cu per ml., but that of liver extract containing the same amount of glutathione was only reduced by copper concentrations greater than 2×10^{-3} mg. per ml. The amounts of free copper and iron in the serum, and especially in the liver, are so large that without some anti-oxidative mechanism the oxidation of ascorbic acid would be very rapid indeed. Tompsett [1934] gives the copper content of blood serum as 2×10^{-3} mg. per ml. and Fowweather [1934] states that the iron content of serum is about $1{\cdot}6 \times 10^{-3}$ mg. per ml. At the copper concentration of serum a 0·005 % solution of ascorbic acid in glass-distilled water was almost completely oxidised in one hour without the addition of any iron at all.

It has not been found possible to decide upon the nature of the undialysable part of the protective mechanism, but several results suggest that in the fresh extract the effect is due to several substances, some of which can be removed by dialysis and some precipitated by mercury or trichloroacetic acid or by boiling, but whichever of these processes is used there is always sufficient of the protective mechanism left behind to be easily detectable. It seems unlikely that the protective effect can be wholly due to the same substance or group of substances in each case.

EXPERIMENTAL.

Ascorbic acid has been estimated by titration with 0·01 % 2:6-dichlorophenolindophenol [Harris and Ray, 1933] in 4 % trichloroacetic acid solution. Glutathione has been estimated in 4 % trichloroacetic acid solutions containing ascorbic acid by oxidation of the ascorbic acid with the dye, addition of starch and titration with $N/500$ iodine. Using mixtures of glutathione and ascorbic acid, it was found that these substances could be accurately estimated by this method.

Where tissues or tissue extracts containing "ascorbic acid" or glutathione have been used, appropriate corrections have been applied. Unless otherwise stated, reagents and extracts have been made up with water distilled through a tinned copper coil with a solid tin nozzle and this has been referred to as "ordinary" distilled water. All metallic salt solutions have been made up in glass-distilled water.

In an attempt to decide whether the reducing substance which occurs in normal animal tissues was identical with that of tumour tissue [Boyland, 1933], and whether these substances were indeed ascorbic acid, an investigation was made of the effect of exposure to a temperature of 37° on the reducing values of various tissues. It was found that whether the tissue were whole or minced, alone or in presence of phosphate ($M/30$, p_H 7·4), or with phosphate + glucose, the amount of reducing substance remained unchanged, at any rate for periods up to 4 hours at 37° (Table I). These results confirm a recent observation by Guha and Ghosh [1934] on normal rat tissues.

Table I. *"Ascorbic acid" in tissues incubated at 37°.*

Tissue 1 g. minced	Duration of incubation mins.	ml. dye	mg. "ascorbic acid" per g.

Blank on reagents: 0·19 ml. dye, 0·10 ml. iodine.

The instability of ascorbic acid in air at p_H 7·4 is well known, so it seemed doubtful whether the reducing substance could really be ascorbic acid. In order to check this point ascorbic acid solution (B.D.H. commercial) was kept at 37° with and without minced rat liver tissue in presence of $M/30$ phosphate, p_H 7·4. Although the ascorbic acid without additions had almost completely disappeared in half an hour at 37°, the same amount of ascorbic acid added to 0·5 g. minced liver was not oxidised at all after 2 hours. Even after 24 hours a large proportion still remained, though autolytic changes probably made the estimations in the latter case somewhat unreliable (Table II, Fig. 1).

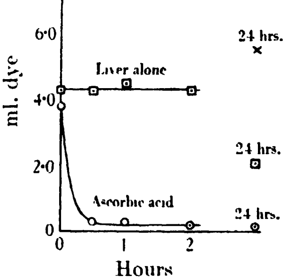

Fig. 1. Stabilisation of ascorbic acid by minced liver.

In this experiment, and in subsequent experiments of a similar nature, the iodine titre obtained subsequent to oxidation with 2:6-dichlorophenolindophenol has been assumed to represent glutathione, and it is evident that under the conditions of this experiment the glutathione content of the incubated tissue remained constant at 37° for at least 2 hours whether added ascorbic acid were present or not.

The stability of the reducing substance of liver, and the exact similarity of behaviour of ascorbic acid added to liver, are in such marked contrast to the rapid disappearance of ascorbic acid in absence of added tissue that this experiment tends to confirm the view that these substances are identical. The stability of the reducing substance (subsequently referred to as "ascorbic acid") is not confined to short periods of incubation at 37°, for if an animal was killed and kept at 4° for 24 hours, or if 5 % trichloroacetic acid extracts of the tissues were kept under similar conditions, the amount of "ascorbic acid" present did not decrease to any great extent.

Since tissues maintained their "ascorbic acid" content equally well whether minced or whole, the behaviour of extracts and suspensions was investigated. In these and subsequent experiments rat liver was generally used because of the ease with which it could be ground up and the large amount available in each animal, but similar results were obtained with other tissues. The suspensions were made by grinding the tissue with $M/30$ phosphate, p_H 7·5, and the extracts by centrifuging such suspensions for 15 minutes at 3000 r.p.m., pouring off, and re-centrifuging the supernatant liquid for the same time.

Both "ascorbic acid" and glutathione disappeared more rapidly in extracts than in suspensions, and both were more stable in the more concentrated preparations. In each case the "ascorbic acid" and glutathione occurring naturally in these preparations were estimated; no additions were made (Table III). The "ascorbic acid" in liver extracts and suspensions is more stable than the glutathione, but the decrease in amount of these substances during incubation does to some extent run a parallel course. A comparison was therefore made between the protective properties of rat liver extract and those of B.D.H. glutathione. In both cases an optimum concentration could be determined at which the maximum anti-oxidative effect was operative and the curves showing the variation of the protective effect with glutathione concentration were very similar in general appearance (Table IV, Fig. 2). In a series of ten experiments with centrifuged liver extracts the amount of liver necessary to give optimum protection varied considerably (from 0·13 mg. per ml. of ascorbic acid solution to 1·70 mg. per ml.), the mean value being 0·6 mg. per ml. The latter amount of rat liver would contain about $1{\cdot}5 \times 10^{-3}$ mg. glutathione, but the actual amount of reduced glutathione in the extracts was only of the order of 5×10^{-4} mg per ml. owing to the rapid oxidation of dilute solutions of liver glutathione.

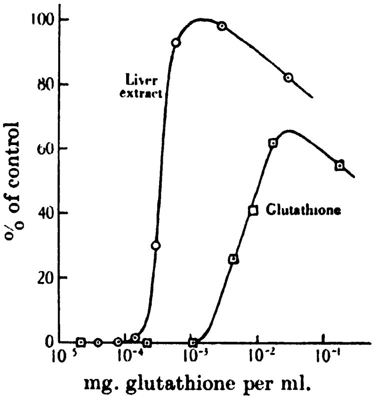

Fig. 2. Stabilisation of ascorbic acid by liver extract and glutathione.

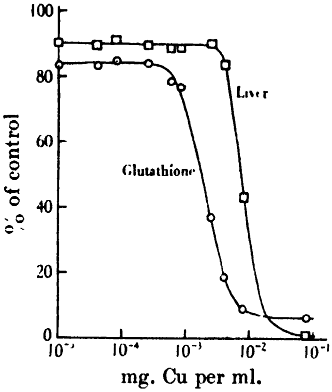

Fig. 3. Stabilisation of ascorbic acid by liver extract and glutathione, inhibition by copper.

The amount of B.D.H. glutathione necessary to give optimum protection was of the order of $3{\cdot}3 \times 10^{-2}$ mg. per ml. At the optimum liver concentration the protection afforded during 1 hour at 37° was usually about 90 %, but the protection given by glutathione seldom rose above 75 %. Nevertheless some of the pure glutathione might have been oxidised before addition to the ascorbic acid, although the glutathione and ascorbic acid solutions were both made in air-free phosphate and the tubes set up as rapidly as possible. Dr E. Boyland suggested that the commercial glutathione might contain traces of copper which

might act as a positive catalyst in the oxidation of ascorbic acid. Investigation of this suggestion led to several interesting results.

A rat liver extract was prepared so as to contain 0·10 mg. liver glutathione per ml., and the protective effect of this material against oxidation of added ascorbic acid was compared with that of a solution containing 0·10 mg. B.D.H. glutathione per ml. Various amounts of copper sulphate were added to each, and the mixtures incubated for 1 hour at 37° in a total volume of 5 ml. $M/30$ phosphate p_H 7·4, containing 0·5 mg. ascorbic acid (Table V, Fig. 3). The addition of copper has very similar inhibitory effects upon the protective properties of liver and glutathione, but the suppression of the protective effect of glutathione commences at a copper concentration of 4×10^{-4} mg. per ml., whereas in the case of liver extract containing the same amount of glutathione a copper concentration of $2{\cdot}3 \times 10^{-3}$ mg. per ml. is necessary. At the latter concentration the protection by glutathione is inhibited to the extent of 50 %.

A somewhat similar experiment was done using ferrous sulphate, in which the glutathione and liver concentrations were so arranged as to have equal anti-oxidative effects, and under these conditions ferrous sulphate had little effect on protection by glutathione but at concentrations higher than 10^{-3} mg. Fe^{++} per ml. the protection by liver was considerably decreased (Table VI).

Table VI. *Effect of Fe^{++} on anti-oxidative powers of liver extract and glutathione.*

2 ml. extract (1 part in 1000) or 2 ml. B.D.H. glutathione (0·05 mg. per ml.) for 1 hour at 37° with 2 ml. ascorbic acid. Unincubated control 4·17 ml. dye.

ml. dye with G.SH	3·53	3·62	3·54	3·44	2·72	3·53

These experiments suggested the possibility that the disappearance of ascorbic acid in aqueous solution might be connected with catalysis by heavy metals, and a preliminary experiment showed that ascorbic acid was remarkably stable in solution in water which had been twice re-distilled from an all-glass apparatus. Table VII gives the rates of oxidation in glass-distilled, ordinary distilled and London tap-water. The ordinary distilled water, which has been used throughout these experiments unless otherwise stated, was prepared by means of a tinned copper coil with a solid tin nozzle. It is quite evident from these results that something is present in ordinary distilled water and in tap-water which very greatly accelerates oxidation of ascorbic acid.

Table VII. *Oxidation of ascorbic acid in various types of water.*

3·7 mg. ascorbic acid in 20 ml. glass-distilled water. 1 ml. incubated with 4 ml. tap, ordinary distilled or glass-distilled water. Blanks on reagents subtracted.

Duration of incubation (mins.)		0	4	6	10	20	40
ml. dye	London tap-water	2·85	1·05	0·77	0·19	0·05	0·05

	Glass-distilled water	3·38	3·39	3·76	2·95	2·74	2·40

The amount of copper which must be added to glass-distilled water in order to cause an appreciable increase in the rate of oxidation of ascorbic acid is less than 2×10^{-6} mg. Cu per ml. (Table VIII (*a*)). 2×10^{-4} mg. Fe^{++} or Fe^{+++} have a similar effect, but even at higher concentrations of iron the catalytic effect of this metal is not so great as that of copper. If copper and iron are present

together, however, the catalytic effect is greater than that due to either metal alone (Table VIII (*b*), (*c*) and (*d*)). Fe^{++} has no effect on the rate of aerobic oxidation of glutathione, which is, however, increased by copper at concentrations greater than 6×10^{-4} mg. per ml. (Table VIII (*a*) and (*b*)). Addition of tin has no effect on the aerobic oxidation of either ascorbic acid or glutathione.

Since serum contains about 2×10^{-3} mg. Cu per ml. [Tompsett, 1934] and $1·6\times10^{-3}$ mg. Fe per ml. [Fowweather, 1934] it is evident that the relative stability of ascorbic acid in tissues cannot be explained by absence of a metallic catalyst, and we must look for a special protective mechanism. De Caro and Giani [1934] stated that cysteine and cystine both had effects similar to that of glutathione in the protection of ascorbic acid, and this has been confirmed. It has also been found that very minute traces of H_2S have a similar effect (Table IX). From the results with cysteine and cystine it seemed probable that the sulphydryl group played no part in the phenomenon, and this conclusion was supported by the observation that the protective power of liver was unaffected

Table IX. *Prevention of aerobic oxidation of ascorbic acid by cysteine, cystine and H_2S.*

0·1 mg. glutathione is equivalent to 0·06 mg. iodoacetic acid.

It was found that if liver extract was kept in a boiling water-bath for one hour with the tube loosely corked its glutathione content remained practically unchanged but its protective power was reduced to one-tenth of normal. If reducing substances were removed from the extract by mercury precipitation [Emmerie and Van Eekelen, 1934] the glutathione content was considerably reduced and the protective power became only 1/100 that of untreated extract (Table XI). Trichloroacetic acid extracts of liver retained a large proportion of the protective properties of the untreated tissue.

Table XI. *Effect of boiling and mercury treatment on anti-oxidative properties of liver extract.*

	Mercury-treated	96	59	1·5	0	0·01
	Untreated	83	95	99	0	0·07

The evidence presented up to this point tends to suggest that, although the effect of glutathione on the stability of ascorbic acid is very similar to that of liver extract, the effect of liver cannot wholly be accounted for by its glutathione content. Nor can any possible cysteine or cystine present be responsible as the amount necessary would be far too large. Since mannitol in minute traces is known to inhibit the aerobic oxidation of sulphite [Bigelow, 1898] this substance was tried, but neither mannitol nor inositol had any inhibitory effect on the aerobic oxidation of ascorbic acid. Indeed it seemed likely that the properties of liver extract depended upon the combined protective effect of traces of several reducing substances, until an experiment was carried out on the protective powers of dialysed and undialysed liver extracts. Suspensions of liver tissue in phosphate or distilled water were dialysed in collodion sacs or by means of cellophane membranes kindly supplied by the Cellophane Co., Ltd. During dialysis the liquid within the dialyser was stirred by means of a fine stream of nitrogen. Dialysis was continued for 3½–4½ hours against running tap-water, and then for one hour against 100 volumes of glass-distilled water. The suspension so obtained was centrifuged and was usually found to contain no detectable iodine-reducing substances. These extracts, however, retained unimpaired their power to prevent the aerobic oxidation of ascorbic acid. The dialysed extracts were compared with extracts which had been kept in stoppered tubes in the dialysis bath and which, though they usually lost a considerable proportion of their reduced glutathione, always retained a comparatively large amount of this substance. The facts that cysteine and cystine possess protective powers of the same order of magnitude and that glutathione loses little of this property in presence of iodoacetate suggest that a change from reduced to oxidised glutathione would have little effect on the protective power of this compound. In a series of ten experiments with dialysed materials, not all of which were quite free from reduced glutathione, no difference could be found between the protective powers of dialysed and undialysed extracts. The protocol of one experiment is given in Table XII.

Table XII. *Effect of dialysis on protective power of liver extract.*

1/10 extract dialysed 4½ hours in tap-water and 1 hour in glass-distilled water. Ascorbic acid in $M/30$ phosphate (p_H 7·5) made up with ordinary distilled water. 5 ml. dialysed extract required 0·12 ml. dye and 0·13 ml. $N/500$ iodine. 5 ml. undialysed extract required 2·09 ml. dye and 0·63 ml. iodine.

Blanks: 0·15 ml. dye; 0·13 ml. iodine.

1 ml. dye ≡ 0·050 mg. ascorbic acid. 1 ml. iodine ≡ 0·60 mg. glutathione.

2 ml. liver extract + 2 ml. ascorbic acid solution.

It was of interest to find whether any protective mechanism existed in vegetable material similar to that found in animal tissues, and for this purpose 10 ml. of lemon juice were brought to p_H 7·5 by addition of 5 ml. of dilute ammonia. 10 ml. of untreated juice were diluted to 15 ml. and 5 ml. of each sample diluted to 50 ml. with $M/30$ phosphate, p_H 7·5. 5 ml. portions were incubated at 37°, and it was found that the ascorbic acid in the neutralised material disappeared at the same rate as ascorbic acid in phosphate solution, while that in the diluted juice which had not been treated with ammonia was relatively stable. The p_H of the un-neutralised juice was less than 3·6 (Table XIII).

Table XIII. *Incubation of lemon juice.*

Blanks on reagents subtracted.

	% of control	79	62	42	11	0·9	0·5	1·0

It is evident, therefore, that the stability of ascorbic acid in the lemon is entirely due to the low p_H of the juice and not to any protective mechanism such as that found in animal tissues.

Discussion.

Although it has not been found possible to identify all the constituents of the mechanism which prevents the spontaneous oxidation of ascorbic acid in the animal body, it has been shown that glutathione is probably one of the factors involved. De Caro and Giani [1934] concluded that glutathione was the substance which caused stabilisation, but it cannot be wholly responsible for the phenomenon since liver extracts from which glutathione has been removed by prolonged dialysis retain the protective properties of fresh extract. The protective properties of boiled liver extract and extract which has been treated with trichloroacetic acid are likely to be due to their glutathione content, but the main part of the protective mechanism is of an undialysable nature. Although certain sulphydryl compounds when present in small traces have the property of preventing the oxidation of ascorbic acid, their effectiveness in this direction does not necessarily lie in the —SH group. De Caro and Giani found considerable differences in the protective properties of cysteine and cystine, although the curves were along the same general lines, but we found that equal amounts of these compounds had practically equal protective powers over wide ranges of concentration. This might be explained by a condition of equilibrium between cysteine and cystine, but this is made less likely by the fact that iodoacetate only slightly inhibits the protective properties of glutathione even when present in more than equimolecular proportions. Dickens [1933] has shown that iodoacetic acid condenses with sulphydryl compounds to give substances of the type $RS.CH_2.COOH$.

It is likely that a chain of protective mechanisms of a similar kind will be found to occur in animal tissues. Abderhalden [1934] states that tyrosine, 3:4-dihydroxyphenylalanine, and more especially adrenaline, are stabilised against oxidation by traces of ascorbic acid, and in a private communication Dr Heard states that work done in Toronto confirms Abderhalden's results.

The instability of aerobic solutions of ascorbic acid can be explained by the presence of small traces of copper and iron, which act as very powerful catalysts in the oxidation of ascorbic acid. The protective properties of tissue extracts and of the pure compounds investigated are probably due to their inhibition of metallic catalysts, which are present in body fluids in such a concentration that without a protective mechanism of some kind ascorbic acid could never exist in them at all.

The stability of the reducing substance of tumour tissue when in contact with tissue and the fact that its concentration in tissue is neither increased nor decreased by periods of incubation with or without glucose or phosphate are in such close agreement with the similar properties of ascorbic acid as strongly to suggest that these substances are identical. Before this can be stated with confidence, however, more biological and chemical work is necessary.

SUMMARY.

1. The ascorbic acid-like reducing substances of normal and tumour tissue are unaltered in amount by incubation of whole or minced tissue with or without phosphate or glucose for periods up to 4 hours at 37°.

2. Small amounts of animal tissues or tissue extracts prevent the aerobic oxidation of ascorbic acid solutions.

3. Glutathione, cysteine, cystine and H_2S prevent the aerobic oxidation of ascorbic acid, but protection by tissue extracts cannot wholly be explained by these facts.

4. Dialysed tissue extracts retain their anti-oxidative properties in full. These properties are also present, in reduced amount, in extracts which have been boiled or precipitated with mercuric acetate or trichloroacetic acid.

5. Ascorbic acid is relatively stable in glass-distilled water. Copper, and to a less extent iron, and especially mixtures of these two metals act as positive catalysts in the aerobic oxidation of ascorbic acid.

6. Lemon juice contains no protective mechanism other than the low p_H.

I wish to express my gratitude to Dr E. Fraenkel and Dr R. J. V. Pulvertaft for their interest in this work and to Dr Pulvertaft for assistance in revision of the manuscript.

LXVIII. THE INFLUENCE OF ALKALI CATIONS ON THE FERMENTATION CAPACITY OF YEAST.

By ARTHUR LASNITZKI[1] AND EMERICH SZÖRÉNYI.

From the Biochemical Laboratory of the Cancer Research Institute at the University of Berlin.

(*Received December 30th, 1934.*)

In a recently published communication [Lasnitzki and Szörényi, 1934] experiments on the influence of different cations on the growth of yeast cells were described. They showed that growth, under the experimental conditions used, was greatly increased by potassium and rubidium, and very little, if at all, by lithium, while sodium and caesium had an intermediate action. The influence of these five alkali cations thus agreed with their position in the Hofmeister series. A growth-promoting influence was also found for magnesium, while calcium, under the same conditions, had hardly any action.

We have been occupied with a second parallel series of investigations on the influence of alkali cations on the fermentation capacity of yeast. The object of these researches was to find out whether the energy metabolism of yeast cells, which must be considered as a necessary condition of growth, is increased by alkali cations and whether a similar order of action may be found in this case as in the activation of growth. It is these investigations which form the subject of this paper.

The influence of alkali salts on alcoholic fermentation has, like their influence on growth of yeast, up to the present time not been very systematically investigated. Harden [1917] found when using washed acetone-yeast and dried yeast that the activation of glucose fermentation in a medium containing phosphate by pyruvic acid or acetaldehyde only took place in the presence of potassium (or ammonium) and not at all or at the most to a slight degree in the presence of sodium. On the other hand Harden and Henley [1921], in confirmation of corresponding investigations of Meyerhof [1918], found that a surplus of potassium phosphate in the medium inhibited the fermentation of glucose and fructose by (unwashed) acetone-yeast or yeast-juice, and that other alkali salts (sodium and potassium sulphate, sodium and potassium chloride) in a high concentration acted in a similar manner. There is a doubt, however, whether the effects obtained can be ascribed to the cations. Contrary to the above authors the following workers used living yeast cells. Boas [1921] tested the action of lithium, sodium, potassium and ammonium nitrates (0·1 and 0·2 *M*) on the fermentation of sucrose by a suspension of brewer's yeast in pure water. The addition of the salts, with the exception of lithium nitrate, led to an increase of fermentation intensity, which, however, as a rule was near the limit of experimental error, and in no case was the increase more than 30 %. Also the difference in the action of the individual alkali salts was but little evident. Speakman *et al.* [1928] investigated the influence of sodium chloride on fermentation by brewer's yeast and found that weak concentrations somewhat accelerated whilst stronger concentrations inhibited. Since, however, the yeast cells under the experimental conditions used (wort as medium, and long duration of experiments) grew considerably the results were evidently not very clear. Finally Lindahl [1933; 1934], who worked under conditions similar to those of Boas, found that the fermentation of glucose by brewer's yeast was inhibited by lithium chloride, the amount of this inhibition being increased as the concentration of the salt was augmented, while the addition of potassium at the same time to a certain extent modified this inhibition. These results agreed with the findings in corresponding experiments upon the respiration of fertilised eggs of sea-urchins. Lindahl further stated that the oxidation of glucose and the dephosphorylation of hexosediphosphoric acid was inhibited by lithium chloride while the oxidation of glycerophosphoric acid and ethyl alcohol was accelerated.

---

METHODS.

Alcoholic fermentation was measured by estimating the amount of carbon dioxide developed, Warburg's [1926] manometric method being used. The culture medium was similar to that used in our growth experiments, but in order to exclude the effect of respiration, fermentation was carried out under anaerobic conditions.

We proceeded as follows. 10 to 30 mg. of fresh baker's yeast was accurately weighed and shaken for about 10 minutes with 10 to 20 ml. of "suspension fluid". The suspension fluid had a similar composition to that used in the growth experiments. 0·1 g. diammonium hydrogen phosphate, 0·03 g. magnesium sulphate ($MgSO_4, 7H_2O$), 7·5 g. glucose, 0·75 g. asparagine, 0·15 g. tartaric acid, distilled water to 100 ml. The homogeneous cell suspension was centrifuged at a high speed for 5 minutes, the supernatant fluid poured off and the sediment diluted with suspension fluid so that the quantity of cells per ml. corresponded to 0·5–1·5 (usually 1·0) mg. of fresh yeast. 2 ml. of the suspension (kept constantly shaken) were measured into medium sized metabolism troughs (in one experiment 1 ml. in smaller troughs also). 1 ml. of "addition solution" (or 0·5 ml. respectively) was then added, and as control the same volume of distilled water. The addition solutions were 0·03 *M* solutions of lithium, sodium, potassium, rubidium and caesium chlorides. Having mixed these with the cell suspension in the proportion of 2:1, we had as in the growth experiments an alkali chloride concentration of 0·01 *M*. As regards the hydrogen ion concentration (p_H of the control medium about 3·1), it was probably near the upper limit of the zone which allows an optimum fermentation by living yeast. Before beginning the experiment the medium was saturated with nitrogen. The temperature employed was as a rule 21°, but in some cases a little higher. The readings were mostly made at intervals of 15 minutes. The time between the addition of the alkali chlorides and the first reading was about 1 to 1½ hours.

The experimental conditions in the fermentation experiments differed in three respects from those of the growth experiments: (1) much smaller quantity of cells; (2) shorter duration of experiments; (3) anaerobic conditions instead of the aerobic (or partial anaerobic) conditions in the growth experiments.

RESULTS.

Our results are expressed by the "fermentation quotient" which is defined as

$$Q_{CO_2} = \frac{\text{carbon dioxide developed, in } \mu l \text{ (0°, 760 mm. Hg)}}{\text{mg. yeast}^1 \times \text{time (in hours)}}.$$

The quotient is calculated to within 0·5.

The individual experiments which will now be considered are divided into three groups. In Exps. 1 to 3 (Table I) the influence of sodium and potassium

[1] Here as fresh yeast.

* Mean of two parallel estimations.

chlorides, acting for varying time periods, was examined. The fermentation intensity tended to alter during the observation time. With the exception of one control estimation of Exp. 1, in which there was a small decrease, this change consisted of a more or less distinct increase, apparently up to constant values. For comparison we will therefore consider, where possible, only those time intervals in which the fermentation intensity in all parts of the experiment was practically constant. It is to be noted that, compared with the figures of the corresponding control estimations, the addition of sodium chloride to the medium gives a definite increase of the fermentation intensity, while the addition of potassium chloride gives a still higher increase.

In Exps. 4 to 8 (Table II), again for varying time periods, the actions of sodium, potassium, rubidium and caesium chlorides were compared. Here the fermentation intensity as a rule increased during the observation time, but it appeared that the addition of potassium or rubidium chloride tended to bring it more rapidly nearer to a constant value. In one of the control estimations of Exp. 4 only did the fermentation intensity decrease until it gradually approximated to the value of the other control. For comparison those periods in which the fermentation intensity was not sufficiently constant in all parts of the experiment are again excluded. We see that all four alkali chlorides increase the fermentation intensity. Potassium and rubidium chlorides have always the same effect, and that of sodium chloride is always weaker than either. The position of caesium chloride is, on the other hand, variable. While in three experiments its influence is as strong, or nearly as strong, as that of potassium and rubidium chlorides, in two experiments it is weaker than that of sodium chloride. In one of these the increase obtained is near, if not within, the experimental error.

Table II.

Exp. no.	Date (1932)	Temperature	Duration (mins.)	Q_{CO_2}					Time interval (mins.)
					Addition of				
				Control	NaCl	KCl	RbCl	CsCl

* Mean of two parallel estimations.

Lastly in Exps. 9 to 11 (Table III) we investigated the influence of lithium chloride, comparing it with that of potassium chloride. In Exps. 9 and 10 we also again investigated the effect of caesium chloride and in 11 that of sodium chloride. In Exp. 11 we tested in addition the effect of ammonium chloride. It may be noted that there was a striking decrease of the fermentation intensity in one control estimation of Exp. 9. Gradually the values became comparable with those of the other control in which there was only a slight decrease. Otherwise the fermentation intensity tended to increase or, notably in the tests with potassium chloride, to remain fairly constant. For comparison we have again selected only the time intervals above specified. As we see, the action of lithium chloride is in two experiments within the experimental error. The same can be said as regards ammonium chloride. In the third experiment with lithium chloride the effect is larger, due to the low value of the corresponding control; nevertheless the position of lithium chloride relatively to potassium chloride remains unaltered. Caesium chloride acts similarly to, or a little more strongly than, the latter. Sodium chloride stands in Exp. 11 approximately between lithium and potassium chloride. This is also shown especially clearly in Fig. 1, in which the whole course of fermentation in the individual tests of this experiment (with the exception of that with ammonium chloride) is given.

Table III.

* Mean of two parallel estimations.

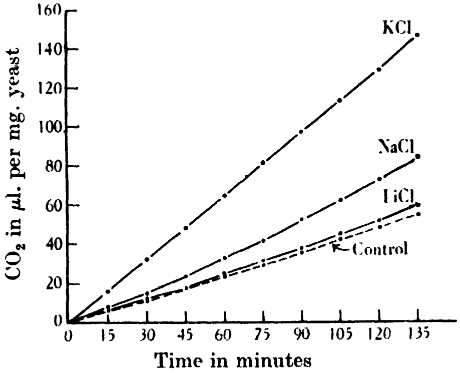

Fig. 1. Influence of 0·01 *M* lithium, sodium and potassium chlorides on fermentation of baker's yeast at 21°.

The observation that the fermentation intensity tended to increase during the course of experiments, together with the fact that in media containing potassium or rubidium chloride it was either fairly constant or showed a comparatively slight rise, indicates that when not completely activated the induction period of the fermentation was delayed, the time utilised in preparing the experiment having been insufficient to enable the fermentation intensity to reach a constant value. On the other hand the fermentation decrease, sometimes observed in the control, requires a different explanation.

The mean increase in fermentation intensity by the addition of potassium chloride, the effect of which was tested in eleven experiments, was about 150 %. In order to find the mean position in which the other alkali chlorides stand in relation to potassium chloride we cannot compare the mean values one with another, in view of the very unequal number of estimations made. For this purpose we have chosen rather the "relative mean increase" which we may define as

$$\frac{\text{mean increase by alkali chloride}}{\text{mean increase in the corresponding tests with potassium chloride}} \times 150.$$

We, in this way, obtain the following figures:

Relative mean increase in fermentation intensity by

LiCl	NaCl	RbCl	CsCl
about 20 %	about 80 %	about 150 %	about 100 %

While rubidium chloride acts as strongly as potassium chloride the mean action of sodium and caesium chlorides is only about one-half to two-thirds as large. Lithium chloride acts very feebly, if at all. It is evident that these differences must be ascribed to the influence of the cations, the chlorine ion being a common constituent. As regards the individual figures there was considerable variation in the increase of fermentation by the addition of each alkali chloride, but meanwhile we are unable to give a definite explanation for this. However large the variation may be, it will be noted that there is in each individual experiment a similar order of action of the alkali chlorides as shown by the relative mean values. The only exception to this rule is caesium chloride.

DISCUSSION.

The object of our researches was to show whether alkali cations can augment the fermentation capacity of yeast and whether there is a parallelism between the influence on fermentation and that on growth. We have seen that our results confirmed our anticipations. The potassium ion greatly increases fermentation. Rubidium acts similarly, while lithium, on the contrary, either only increases it a little or not at all. Sodium and caesium have intermediate effects. Thus it is found that the order of action is similar both for growth and fermentation, and this supports strongly the theory that increase of growth occurs as a result of an acceleration of energy metabolism. Complementary researches on the influence upon respiration appear therefore to be necessary. One must be guarded, however, about drawing conclusions as regards caesium. Its mean effect on fermentation is slightly stronger than that of sodium while the relation is rather the reverse as regards the amount of growth activation. On the other hand caesium was the only alkali cation of which the relations to potassium were not similar in all fermentation experiments. Further investigations are needed in order to explain the irregular action of caesium.

Among the five alkali cations tested potassium is probably the only one which is of importance for the life of the yeast cell under normal conditions, the sodium content of yeast being apparently very small. Potassium may thus be considered as a natural activator of yeast fermentation (and very likely of the whole energy metabolism). In view of this fact the very important question arises as to whether the observed activation of fermentation is in effect the result of the addition of different alkali cations to the potassium originally present in the yeast cell, or whether the original potassium content was lessened by our preliminary manipulation, and the subsequent addition of alkali cations compensated in a varying degree for this deficit. A satisfactory answer to this question can only be given by making ash analyses. Meanwhile we may be permitted to draw attention to the following point. The ordinary method of preparing fermentation experiments consists in washing the yeast with distilled or tap water in order to free it from adhering substances. On electrostatic grounds, under this condition a large outward diffusion of potassium is only possible if the surface of the yeast cell is permeable to cations and anions to a similar degree. That this is not so, and that the potassium content of yeast is therefore only slightly or not at all lessened has been shown by Genaud [1929]. He found that the potassium and likewise the chlorine content of wine and baker's yeast was hardly changed by washing with distilled water. If the yeast cells were, however, washed in 0·01 *M* ammonium chloride solution (with a p_H of 7·0) potassium and calcium ions came out of the yeast into the medium from which an approximately equivalent quantity of ammonium ions disappeared. The chlorine content of the yeast here also remained approximately constant.[1] Thus it is probable that the surface of the yeast cell is permeable with ease to cations but with difficulty to anions. The outward diffusion of cations must therefore be more rapid in an electrolytic medium than in the practically electrolyte-free water, for in the former an interchange of the cations takes place. But, in our investigations the yeast was washed with a relatively large amount of suspension fluid, rich in ammonium and hydrogen ions. The condition for a more rapid outward diffusion of potassium was thus present, and it is probably for this reason that we obtained, by the subsequent addition of alkali cations, a significantly greater increase of fermentation intensity than had Boas who, before commencing his experiments, only washed his yeast in distilled water.[2] Meanwhile it is questionable whether, with a single and short washing as carried out by us, there is a very significant diminution in the potassium content of the yeast. It is important that this point should be investigated, and especially also to find out whether any fermentation at all is possible in the complete or almost complete absence of potassium.

When we consider that the potassium content of yeast cells suspended in water is relatively high and that it can only be diminished by the addition of another kind of cation we must assume that the inhibitory effect of lithium, which Lindahl observed in his researches, was indirect. It may be that a certain part of the intracellular potassium is replaced by the almost inert lithium. It remains for further researches to show whether this conception is correct, and whether in addition to the indirect action there may not be a direct inhibiting influence of lithium, at least when in a high concentration.

If, as appears probable, potassium is a natural activator of alcoholic fermentation it will be interesting to try and find out at what stage of the glucose disintegration the potassium works. This can be done by the investigation of partial reactions; lines formerly worked along by Harden, and recently also by Lindahl.

APPENDIX: THE INFLUENCE OF MAGNESIUM.

We also investigated the influence of magnesium in three further experiments, using methods similar to those already described. The suspension fluid contained, as in the corresponding growth experiments, 0·015 *M* potassium chloride, and was free from magnesium. Also, as before, magnesium was added as magnesium sulphate and magnesium chloride. Further parallel estimations were made with the addition of sodium sulphate in order to test the influence of the SO_4 ions. The concentration of the addition solutions was 0·06 *M*. After mixing with the yeast suspension in the proportion of 2:1 the concentration of the added salts was therefore 0·02 *M*, 2½ times as high as the concentration of magnesium sulphate in the former experiments. The concentration of potassium chloride was as before 0·01 *M*. In two experiments each estimation was duplicated.

---

[1] Similar results were obtained with magnesium by Lohmann [1931] and by Euler and his collaborators [1931] during the course of their experiments on the activation of alcoholic fermentation by magnesium. These authors, however, worked with dried yeast.

[2] However, in comparing our results with those of Boas we must also remember the differences in the conditions of the media during the fermentation experiments themselves, especially the higher concentration of the salts added by him.

Of the three experiments, the duration of which was between 60 and 120 min., two showed no influence of magnesium. In the third there was an increase in fermentation intensity of about 30 % for both magnesium salts, while sodium sulphate was without influence. Thus it appears that in the given conditions magnesium exerts little or no action on fermentation.

According to the researches of Lohmann [1931] and Euler *et al.* [1931] magnesium is an activator of alcoholic fermentation as well as of lactic acid formation in the animal tissue. It represents the inorganic part of the "co-enzyme system". Thus we cannot conclude from our result that the magnesium ion is without essential importance for the fermentation capacity of yeast. The best explanation for the indifference of magnesium in our experiments would appear to be that the intracellular magnesium was not sufficiently washed away by our technique, so that even in the control medium the activating amount of magnesium was at a maximum. The fact that magnesium ions, in consequence of their lower mobility, diffuse more slowly out of the cells than do potassium ions may account for this. On the other hand there is in our investigations the remarkable difference between the lack of dependence of the fermentation on the presence of magnesium and the activating effect of the latter in the growth experiments made under similar conditions as to media. Perhaps this difference can be ascribed chiefly to a subsequent outward diffusion of a large amount of magnesium, due to the longer duration of the growth experiments, in spite of the fact that otherwise the conditions for diffusion were less favourable.

SUMMARY.

In the present investigations we have tested the influence of alkali cations on the alcoholic fermentation of baker's yeast. The fermentation was carried out under anaerobic conditions. Our results show that the alkali cations on the whole facilitate fermentation. Individually, however, their actions are very different, as was the case in the growth experiments previously described. For instance, with potassium chloride there is a mean increase of about 150 %. Rubidium acts as strongly as potassium. On the contrary the effect of lithium is slight or zero. Sodium stands between lithium and potassium while the position of caesium is somewhat doubtful. Although in five experiments its influence was about as strong as that of potassium, in two experiments it was perceptibly weaker than that of sodium. If one leaves caesium out of account for the moment, the results of both series of investigations show a clear parallelism between growth and fermentation activation. This parallelism indicates that the activation of growth is to be attributed to an increase of the fermentation capacity (or very likely of the whole energy metabolism) of the yeast cell. In some experiments (with the addition of potassium to the medium) the influence of magnesium was also tested. Its action proved to be very slight or zero. This is explained on the grounds that the intracellular magnesium was not sufficiently washed away during the preparation of the yeast.

LXIX. STUDIES IN THE METABOLISM OF PROTOZOA.

I. THE NITROGENOUS METABOLISM AND RESPIRATION OF *BODO CAUDATUS*.

By NORMAN RISBOROUGH LAWRIE[1].

From the Sir William Dunn Institute of Biochemistry, Cambridge, and the Bonnett Memorial Laboratory, Addenbrooke's Hospital, Cambridge.

(*Received January 10th, 1935.*)

I. NITROGENOUS METABOLISM.

The nitrogenous metabolism of the protozoa has hitherto been much more extensively studied from the anabolic than from the catabolic aspect. This is probably due to the fact that information regarding nitrogenous food requirements is likely to facilitate culture of the protozoa, whilst the search for metabolic end-products is greatly hampered by the complexity of the cultural media which it is usually necessary to employ. A discussion of this difficulty and of the methods used in this work to minimise its effects is given later in this paper.

For a review of the nutritional requirements of the protozoa and many original contributions to this subject the reader is referred to the monograph by Lwoff [1932] and to the review of the rôle of bacteria in the nutrition of protozoa by Luck *et al.* [1931].

Griffiths [1888] stated that *Amoeba sphaerococcus*, *Vorticella* sp. and *Paramoecium bursaria* contained uric acid in their contractile vacuoles. His evidence consisted of positive murexide tests obtained upon the organisms in bulk and a flaky precipitate observable in their contractile vacuoles when the organisms were treated with alcohol. Adolph [1922] concluded that *Phagocata* and *Paramoecium* did not produce urea. Howland [1924] repeated the tests used by Griffiths with the organisms *Centropyxis* and *Amoeba verrucosa* and obtained negative results. Using the very sensitive Benedict's uric acid reagent, however, he obtained a positive reaction for uric acid in cultures of *Paramoecium* and *Amoeba*.

Weatherby [1927] concluded that *Paramoecium* produces urea, but his findings were not consistently positive using the urease test, nor was he able to demonstrate the presence of urea by the xanthydrol test. Injection of Nessler's reagent failed to show the presence of ammonia in the contractile vacuole, but the limit of sensitivity of the test under these conditions is not made clear. The same worker [Weatherby, 1929] studied the production of ammonia in suspensions of protozoa washed by decantation and suspended in salt solution. His results are summarised as follows:

Organism	Ammonia	Urea	Uric acid	Creatine	Creatinine
Paramoecium	0	+	0	0	0
Spirostomum	0	+	0	0	0
Didinium	+	0	?	0	0

---

[1] Beit Memorial Research Fellow.

He found that many culture media gave a positive test for uric acid with Benedict's reagent. In the case of the *Didinium* cultures the production of ammonia was shown to vary with the food supplied to the organism.

EXPERIMENTAL.

The types of cultures of protozoa available for metabolic studies may be considered under the following three headings:

Type A. Double cultures, containing one species of protozoan and one or more species of bacterium, both protozoa and bacteria growing and multiplying actively in a medium nutrient for the bacteria.

Type B. Cultures containing one species of protozoan feeding upon live bacteria suspended in some non-nutrient medium in which the bacterial growth and multiplication is minimum.

Type C. Bacteriologically sterile cultures of protozoa.

A culture of type A would give a large metabolic turnover corresponding to very active growth and division, but on account of the extreme difficulty of separating bacterial from protozoal effects in such a culture it was not considered advisable to attempt any metabolic studies upon a culture of this type.

A culture of type B represents a compromise between types A and C. The cultures of *Bodo* used in the experiments described below belong to this type. They have the advantage of providing high rates of metabolic activity, of growth and of division, whilst the effects due to the bacteria alone can be determined with sufficient accuracy for many studies.

A culture of type C is by far the most satisfactory for metabolic studies provided sufficiently active growth and division can be obtained. Metabolic studies of cultures of this type will be presented in future communications. In the case of a very few protozoa growth takes place upon killed bacteria, and such cultures belong to this type C.

The culture of Bodo caudatus.

The culture of *Bodo caudatus* was carried out by methods almost identical with those used by Robertson [1932]. The method may be outlined as follows.

The food supply consists of a suspension of bacteria in either sterile distilled water or a simple inorganic salt solution according to the particular experiment in hand. The salt solutions were sterilised by autoclaving at 110° for 20 minutes.

The bacterium was the predominant organism in the primary cultures which were isolated from a macerating tank. It is Gram-negative, asporogenous, motile, and rod-shaped, slightly pleomorphic and produces a slight yellow colour when grown on agar slopes. The bacterium is almost inert towards the sugars and slightly proteolytic. It has been repeatedly purified by replating.

The density of the bacterial suspension is so chosen that the final concentration of bacteria in the inoculated culture shall give an opacity matching the "opacity 3" of the "Wellcome" standard opacity tubes.

This food supply is then inoculated with a measured quantity of a previous culture, the size of the inoculum being so chosen that the new culture starts with approximately 300 bodos per 1 μl. Measured samples, usually 6 ml., of cultures prepared in this way are transferred to sterile Petri dishes and kept in an incubator at 25°.

In order to estimate the number of bodos in a culture dish the contents are transferred to a test-tube and thoroughly mixed. 0·5 ml. is then transferred into 2 ml. of a saturated solution of mercuric chloride in 1·5 % aqueous acetic acid. This fixed and diluted suspension is then counted in Thoma-Zeiss or Fuchs-Rosenthal counting chambers in the usual way. Before all volumetric measurements involved in the above procedure the suspension of organisms is very thoroughly mixed by means of Pasteur pipettes.

All glassware which is used in the manipulation of these cultures is sterilised by baking at 120° for 30 minutes.

BIOCHEMICAL FINDINGS.

The total nitrogen present in a culture prepared as above with a bacterial suspension of "opacity 3" density was found to be approximately 10 mg. of ammonia-nitrogen per 100 ml. of culture. In order therefore to study fluctuations in a fraction of this total nitrogen it was essential to use a delicate method of estimation. This consideration largely determined the use of the following methods.

Estimation of the ammonia content of the cultures.

The culture was first deproteinised with "colloidal iron" (B.D.H.). To 4 ml. of the culture in a 15 ml. centrifuge-tube was added 0·3 ml. of "colloidal iron." After mixing the contents of the tube thoroughly one drop of a saturated solution of potassium sulphate was added to complete the precipitation of the iron. The preparation could now stand for 24 hours if necessary without alteration of its ammonia content. Otherwise, the preparation was centrifuged at once, for 10 minutes at 3000 r.p.m. Alternatively, the precipitate could be filtered off. 2 ml. of the perfectly clear supernatant fluid were then transferred to a test-tube, and 5 ml. of a 0·1 % solution of gum ghatti in water saturated with thymol was added. After mixing by inversion, 1 ml. of Nessler's reagent was added. A series of standards was simultaneously prepared and nesslerised. The tubes were matched, after standing for 20 minutes, in a Klett-Bio or Bausch and Lomb colorimeter, using a heavy blue screen over the eyepiece. The value for the ammonia-nitrogen per 100 ml. of culture thus obtained was multiplied by 1·08 to correct for the dilution with "colloidal iron." Duplicate estimations carried out by this method agreed within 5 % and usually within 3 %. Recovery of ammonia added as ammonium sulphate was satisfactory as the following example shows:

Bacterial suspension washed free from ammonia and ammonium sulphate added to give a concentration of	2·00 mg. ammonia-N/100 ml.
Ammonia found by estimation	1·97 ,,
Loss	1·5 %

Total nitrogen was estimated by a micro-Kjeldahl incineration and aeration of the ammonia formed into standard acid. This receiving acid was then neutralised and nesslerised. Standard ammonium sulphate solutions were aerated in exactly the same way.

Nitrogen partition in the cultures.

It was necessary at the outset of these experiments to determine to what extent ammonia formation accounted for the whole of the end-products of the nitrogenous metabolism of *Bodo*. The fraction "non-protein-nitrogen other than ammonia-nitrogen" was therefore estimated at the time of inoculation and after

24 hours' growth of two strains of *Bodo*, cultured simultaneously and fed upon the same stock of bacterial suspension. The results are tabulated below.

	Non-protein-nitrogen other than ammonia-nitrogen mg. per 100 ml. of culture	
	(*a*) At the start of the culture	(*b*) After 24 hours' growth
Bacterial suspension 58	0·65	0·36
Bodo culture N 58	0·72	0·83
Bodo culture R 56	0·82	0·62
Bacterial suspension 59	0·57	0·42
Bodo culture N 59	0·96	0·89
Bodo culture R 57	1·02	0·80
Bacterial suspension 60	0·49	0·37
Bodo culture N 60	0·68	0·58
Bodo culture R 58	0·51	1·09

A consideration of these figures led to the conclusion that the non-protein-nitrogen other than ammonia-nitrogen was probably largely derived from the food supply and did not show variations which could be correlated with the growth and multiplication of *Bodo*.

No urea could be demonstrated in the deproteinised filtrates from cultures by the xanthydrol test or by treatment with urease preparations. No uric acid could be demonstrated in these filtrates by means of Benedict's uric acid reagent [Benedict and Franke, 1922]. Neither urea-nitrogen nor uric acid-nitrogen can then be present in these filtrates to a greater extent than 3 % of the total non-protein-nitrogen formed. The cultures showed no urease activity.

Production of ammonia during the development of the cultures.

In order to follow the production of ammonia throughout the life of the culture a stock of bacterial suspension of standard opacity 3 containing about 300 bodos per μl. was prepared in a large boiling-tube. After thorough mixing, this culture was distributed throughout a series of Petri dishes, 6 ml. of culture being measured into each dish. The cultures were incubated at 25° and representative dishes removed at appropriate intervals for counting of bodos and estimation of ammonia.

The bacterial suspension itself produces ammonia at a slow and approximately constant rate. It was only considered necessary therefore to measure the ammonia contents of the controls in these experiments at the start and end of the period of observation.

The relation of ammonia production to the development of the cultures was then studied by means of a series of daily subcultures carried out under conditions as nearly constant as practicable. Thus the transfer was so calculated each day as to produce a population of 300 bodos per μl. in the new culture. Each culture was allowed to grow for the same length of time, 22 hours, before being subcultured. The handling of the cultures and exposure to room temperature which this involved were kept as constant as possible, and 22 hours of each culture's life were spent in the incubator at 25°. The bacterial food supply was prepared freshly each day from 24-hour old cultures on agar slopes, and it contained approximately 10 mg. of total nitrogen per 100 ml. After a few days' subculture under these conditions the cultures settled down to a steady rate of development, so that the extent to which they had to be diluted in making a new subculture tended to a constant figure (about × 20). Several Petri dishes were then set up from a common stock and dishes withdrawn for counting of bodos and estimation of ammonia at suitable intervals. The results of four such successive subcultures are shown in Fig. 1, in which the ammonia production of cultures and controls is shown. The dilution figures used in preparing cultures N 50 to N 53 were 23, 21, 20 and 23 respectively. These figures are indicative of the degree of reproducibility of the rate of multiplication of the bodos.

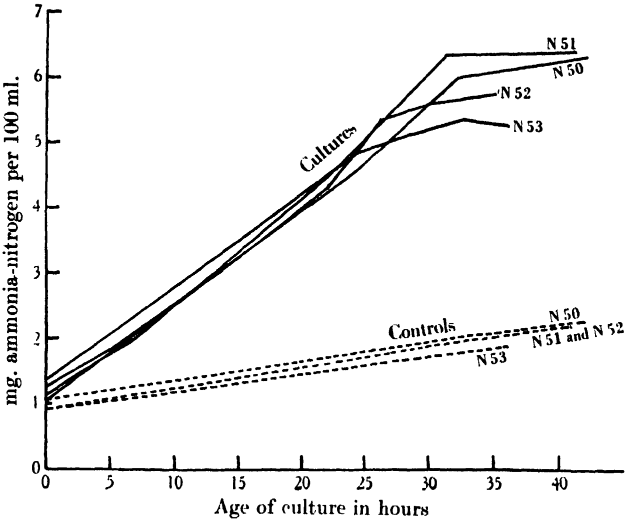

Fig. 1.

The following are the main features brought out by this figure:

(*a*) The contribution of the bacterial suspension alone is only a small fraction of the total ammonia produced.

(*b*) The total ammonia-nitrogen produced by the cultures less that produced by the corresponding controls was 3·9, 4·0, 3·7 and 3·0 mg. per 100 ml., *i.e.* an average of 3·7 mg. or 37 % of the total nitrogen in the culture.

(*c*) The bodos were multiplying rapidly until about the 24th hour, when their rate of multiplication fell off. About this time too encystation often appeared in the cultures. Thus the rapid formation of ammonia is associated with the period of rapid multiplication of the bodos rather than with the period just before the onset of encystation.

A similar and more complete set of curves was then obtained during experiments carried out in collaboration with Dr Robertson. Different strains of *Bodo* were used, grown, however, under conditions almost identical with those described above. The controls were obtained by a different procedure. A portion of the freshly prepared culture was set aside at 40° for a constant period of 2 hours. This treatment sufficed to kill all the bodos but left the bacteria alive. This killed bodo culture was then set up in Petri dishes in exactly the same way as the live culture. It is to be noted that every element in the culture is here represented in the control with the exception of the live bodos. This control is of course somewhat exaggerating the bacterial effect as all the bodos in the new control are here available for food supply for the bacteria, whilst the bacteria are not themselves being consumed as in the live bodo cultures.

In interpreting the figures for the ammonia contents of the cultures the ammonia gained by the control was deducted from the total ammonia present in the live culture to get a corrected curve of ammonia production for the live culture. From this corrected curve of ammonia production the rate of ammonia production was calculated for each period between two observations. Fig. 2 shows how this rate of ammonia production and the number of bodos present vary with age in the case of three representative cultures.

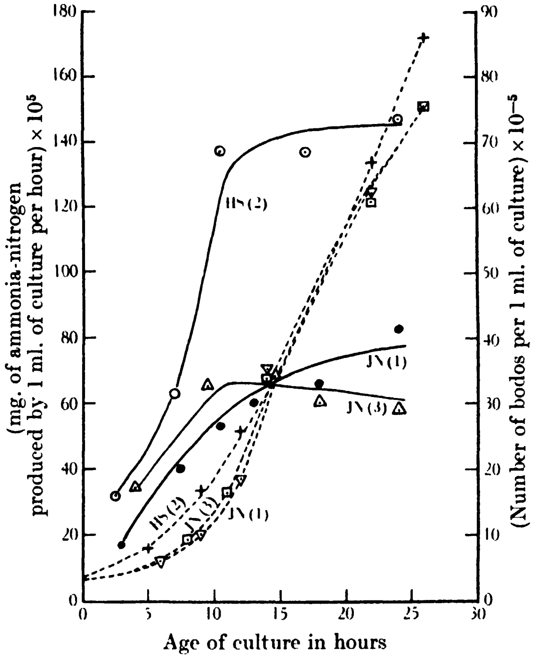

Fig. 2. Rate of ammonia production by: culture HS(2) o—o; culture JN(1) •—•; culture JN(3) ▵—▵. Number of bodos: culture HS(2) ×---×; culture JN(1) ▿---▿; culture JN(3) ▫---▫.

Considering first the curves of rates of ammonia production, it is seen that the initial rate of ammonia production is more than doubled by the time the culture is 8–10 hours old and thereafter remains steady or increases relatively slowly till the end of the period studied. It is at just this period when the rate of ammonia production ceases to increase rapidly that the bodos pass out of their period of lag in multiplication and enter upon a period of very rapid increase in numbers which is maintained to the end of the period studied. Thus from about the 8th to 10th hour onwards a roughly steady rate of ammonia production is being maintained by a rapidly increasing number of bodos, or in other words the rate of ammonia production per bodo falls steadily and rapidly from the 8th to 10th hours onwards until about the 26th hour of growth.

In the case of measurements of ammonia production made during the early hours of the culture's development the figures are small differences between relatively large quantities, and it would not therefore be justifiable to attempt to draw any more precise conclusion than that during this period the rate of ammonia production is very markedly low in comparison with the steady rate which is established later.

The possible significance of this feature of nitrogenous metabolism will be discussed at the end of this paper in relation with curves of oxygen uptake and certain morphological data.

II. RESPIRATION.

A number of more or less quantitative experiments have been carried out to determine what oxygen tension is most favourable for the development of various protozoa. Such experiments involve observation of the migration of protozoa in cultures into oxygen-rich or oxygen-poor localities and of the influence of altered oxygen tension upon the behaviour and viability of cultures. These experiments have indicated a pronounced sensitivity of protozoa to the oxygen tension of their environment. The work of Fox [1920–21] is particularly to be noted in this connection. Fox worked with a culture of *Bodo sulcatus* obtained from 6-day old infusions of grass. Square cover glasses were mounted over microscope slides and samples of the cultures run in between the cover glasses and slides. The preparations were kept in moist chambers and periodically examined under the microscope. At first the bodos were uniformly distributed, but after a time, varying from a few minutes to a day, they collected in the centre of the cell. Subsequently an area free from bodos appeared in the middle of the clump, and the ring of bodos thus formed expanded till it took up a position at a uniform distance from the edge of the cover slip. Finally these migrations were reversed and the bodos again clumped in the centre of the cell. The influence of bubbles of air and other gases, of solid particles, of de-oxygenating reagents and increased oxygen tension upon their behaviour was studied. The conclusion was drawn that *B. sulcatus* is very sensitive to changes in the oxygen tension around the optimum oxygen tension for its development and migrates to the region of optimum oxygen tension.

In connection with experiments to be described in this paper it is of particular interest to note that Fox has occasion to refer to the possibility of a change in the optimum oxygen tension occurring during development of the culture. Such a change might explain the migration of the bodos from the edge of the cell to the centre on allowing the cultures to stand in the moist chamber, and also, to a certain degree, the shape of the ring of bodos as viewed in vertical section.

Soule [1924] studied the respiration of *Trypanosoma lewisi* and *Leishmania tropica* grown on a blood-broth-agar medium. When his cultures were supplied with 100 ml. of air *Leishmania* used all the oxygen in 144 hours, whilst the trypanosomes required twice that time to consume all the oxygen. When the cultures were supplied with 2 litres of air the rates of oxygen consumption and carbon dioxide output were approximately equal for both species of protozoa. Excess of oxygen or anaerobiosis inhibited growth. Carbon dioxide was toxic in concentrations of over 20 %. The respiratory quotient for *Leishmania* measured from the time of inoculation to the seventh day of growth was 0·84, and that for the trypanosomes 0·74. It was suggested that much base was produced to account for the carbon dioxide retained in the culture. No counts were made. Degeneration was always present at the end of the experiments.

Fenyvessy and Reiner [1924] showed that cultures of trypanosomes gave a vigorous oxygen uptake and carbon dioxide output when studied by means of the Barcroft differential manometer. Their work was continued [1928] with the Warburg respirometer, and a washed suspension of trypanosomes in Ringer's solution containing glucose was used. The gaseous exchange was observed for periods of about 20 minutes. The glucose was decomposed by both oxidation and "glycolysis"; the latter being greatest during anaerobiosis. The very interesting observation was made that neither germanin nor potassium cyanide inhibited either process when added to the suspension in any concentration up to 0·1 %. This finding is the more remarkable in that germanin is toxic to trypanosomes in their vertebrate host. If the p_H of the system is lowered "glycolysis" is increased at the expense of oxidation and *vice versa*. These workers found aerobic and anaerobic "glycolysis" to proceed at the same rate. The rate of oxygen uptake per 10^8 organisms per hour varied from 3·7 to 7·5 μl., and it is very interesting to note that in experiments to be described immediately the same number of the very much smaller organism *Bodo caudatus* consumed 350 μl. of oxygen in the same time. In the case of the trypanosomes the organisms were in a medium which was non-nutrient for them, whilst the bodos were metabolising foodstuffs, growing and multiplying very actively.

EXPERIMENTAL.

The oxygen uptake of cultures of *B. caudatus* was measured by means of the Barcroft differential manometer. The cultures were prepared in bulk in boiling-tubes as described earlier in this paper. Control material was prepared by heating a portion of these newly inoculated cultures to 40° for 2 hours, which process kills the bodos but not the bacteria. 5 ml. of live culture were measured

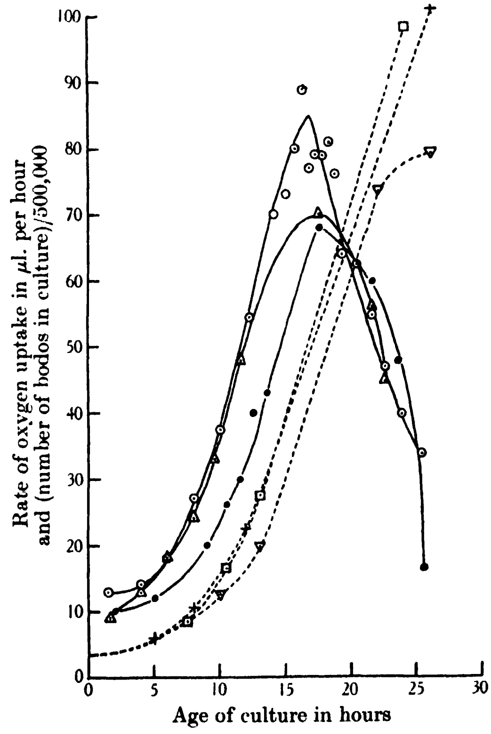

Fig. 3. Rate of oxygen uptake by: culture JN(1) •—•; culture JN(3) △—△; culture JN(7) ○—○; Number of bodos: culture JN(1) ▽---▽; culture JN(3) □---□; culture JN(7) ×---×.

into the right-hand cups of four differential manometers and 5 ml. of killed bodo control material into the left-hand cups. The water-bath was maintained at a temperature of 25°. At intervals throughout the next 24 hours cups were removed, the contents analysed for ammonia and the numbers of bodos per μl. counted. The manometer cups were cleaned particularly scrupulously but were not sterilised, since the bodo culture is not likely to provide a medium which would allow of significant bacterial growth within the period of these experiments. The oxygen uptake of the control was of course automatically allowed for by the differential character of the apparatus. The results of three experiments of this type are shown graphically in Fig. 3. In this figure the rate of oxygen uptake per hour for the whole culture and the number of bodos in the culture are plotted against the age of the culture in hours.

It is seen that a most pronounced change occurs in the relationship between the rate of oxygen uptake and numbers of bodos present about the 16th to 18th hours. Up to this time the two curves have run almost parallel, implying that the rate of oxygen uptake is directly proportional to the number of bodos present throughout this period. Between the 16th and 18th hours the rate of oxygen uptake reaches a sharp peak value and then starts to fall rapidly. This occurs despite the fact that the number of bodos in the culture is still increasing. After the 16th to 18th hour, however, the generation time is always increasing; its minimum value having occurred between the 8th and 16th hours of development of the culture. By the 22nd to 24th hours the rate of oxygen uptake has fallen to about one-half of its peak value, although there are then nearly twice as many bodos in the culture as there were at the time of most rapid oxygen uptake. Very good confirmation of the earlier parts of these curves, up to the peak value, was obtained in the study of another strain of *Bodo*. With this strain, however, the experiments were not carried on sufficiently long to follow the curve after the 18th hour.

Variations in size of Bodo caudatus.

It is to be noted that the size of the bodos varies greatly at different ages of the culture, so that the curves of the numbers present give only a limited picture of the morphological development of the culture. Dr Robertson has kindly placed at my disposal a large series of unpublished measurements of individual bodos at various ages of the cultures. In Fig. 4 the data giving the area distribution curves for the typical cultures HN (2) and HN (13) are summarised. In these curves a decrease in the proportion of large bodos present is indicated by a flattening of the curve, and a decrease in the average size of the bodos present is indicated by a shift of the curve as a whole towards the left. As a matter of convenience area × 4 is plotted instead of the actual area. These measurements were obtained by tracing the outline of bodos by means of the camera lucida. Hence the area measured is that projected by the bodo upon the plane surface upon which it is lying and not the actual surface area. It is clear from this figure that the proportion of small bodos increases very greatly between the 11th or 12th and the 22nd hours. Thus there are from three to four times as many bodos of 50 units size at 22 hours' growth as there were at any previously measured period. Moreover, there are hardly any bodos bigger than 100 units at 22 hours although at previously measured periods such large individuals were numerous.

It is during this period when multiplication is outpacing individual growth that the marked peak in the rate of oxygen uptake by the culture occurs (Fig. 3). It must be borne in mind that during this period (the 12th to 22nd hours) no dead bodos are appearing in the cultures, encystation is not occurring and motility does not appear to be in the least diminished. It would appear then that during this period some form of anaerobiosis is supplying the energy requirements of the organisms to an increasing extent. The occurrence of this biochemical change during a period of pronounced morphological change must be noted, although any correlation between these two types of change is not at present apparent. If anaerobiosis did indeed play an important part in the metabolism of cultures of *B. caudatus* during their later phases, it would be reasonable to expect their optimum oxygen tension to be lower in these later phases. The work of Fox [1920–21], quoted above, may indicate such an effect in the case of *B. sulcatus*, although it must be emphasised that Fox was able to account for his results without assuming any change in the optimum oxygen tension for *B. sulcatus*.

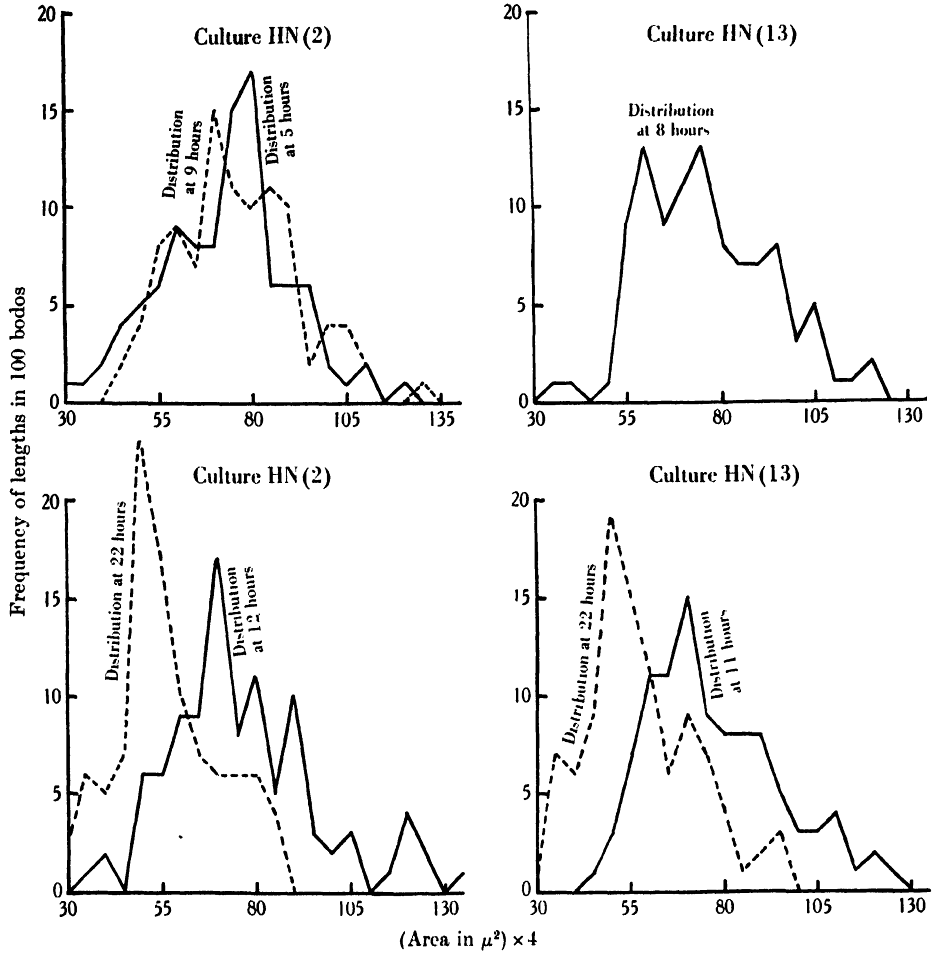

Fig. 4.

The development of the culture may be divided into two phases with respect to the three aspects for which data are here presented. In the case of nitrogenous metabolism, as studied by ammonia production, there is an early period of relatively great activity, when the rate of ammonia production runs roughly parallel with the increase in the numbers of bodos in the culture. This period lasts till about the 8th hour of growth. The second phase then commences, and during this period the rapid increase in numbers of bodos is no longer paralleled by an increase in the rate of ammonia production, which becomes steady or shows only relatively slow increase. The motility of the organisms is maintained during this second phase and no death or encystation is seen. A probable inference from these observations would be that during the early development of the culture, taking place in the presence of abundant food supply and in a low concentration of growth products, nitrogenous foodstuffs are preferentially metabolised, whilst during the later life of the culture, when metabolic products are accumulating and food supplies decreasing, the food requirements of the organism are met by the preferential metabolism of non-nitrogenous food materials.

The two phases brought out by the curve of rate of oxygen uptake have already been discussed and their time relationship to the morphological changes noted.

SUMMARY.

Data are presented for the production of ammonia, consumption of oxygen, rate of multiplication and growth of the protozoan *Bodo caudatus*. The metabolic significance of these findings is discussed.

I wish to express my thanks to Sir F. G. Hopkins for his interest in this work and to Dr M. Robertson both for her generous advice and hospitality at the Lister Institute of Preventive Medicine and for providing me with the strains of *Bodo caudatus* used in this work. I have also to thank Dr Robertson for permission to quote certain of her unpublished data.

LXX. THE COMPONENT GLYCERIDES OF HEN BODY FATS.

By THOMAS PERCY HILDITCH
and WILLIAM JOHN STAINSBY.

From the Department of Industrial Chemistry, University of Liverpool.

(*Received January 18th, 1935.*)

The methods which were recently employed in the study of the glyceride structure of a pig depôt fat [Hilditch and Stainsby, 1935] have been applied to hen body fats, the component fatty acids of which were discussed by Hilditch *et al.* [1934]. For this purpose the material (abdominal and gizzard fats) which had been left over from the last-mentioned work was utilised, since the full analysis of the total component fatty acids of a fat is essential for the study of its component glycerides. The quantity of fat thus remaining at our disposal was not very large, but by using both abdominal and gizzard fats (the component acids of which (*cf.* Table I) were almost identical) it proved possible:

(i) to ascertain the proportion and nature of fully-saturated glycerides present in the original fat;

(ii) to carry out fractional crystallisation of a specimen of completely hydrogenated hen body fat;

(iii) to make a complete analysis of a specimen of the fat after it had been hydrogenated to a point (iodine value 14·6) at which (by analogy with pig depôt fat) it was expected that all dipalmito-glycerides would have passed into the fully-saturated portion; and to carry out fractional crystallisation of the fully-saturated glycerides present in this partially hydrogenated fat.

The results obtained show that, although the fatty acids present in hen body fats are, in many respects, not dissimilar from those of an animal such as the pig, the composition of the mixed glycerides is quite different. The glycerides are much more heterogeneous in character: tri-C_{18}-glycerides and dipalmito-mono-C_{18}-glycerides are present in much greater quantities than in pig depôt fat, with a corresponding diminution in the amount of monopalmito-di-C_{18}-glycerides.

The glyceride structure of bird fats is referred to by Amberger and Bromig [1921] and Bömer [1922], both of whom submitted goose body fat to fractional crystallisation. Amberger and Bromig detected dipalmitostearin, oleodipalmitin, palmitodiolein and possibly triolein, whilst Bömer suggested that the fat probably contained about 45 % triolein, 30 % palmitodiolein, 5 % dioleostearin, 3–4 % of dipalmitostearin and a very small amount of palmitodistearin.

EXPERIMENTAL.

The abdominal and gizzard fats employed were from the batch of 24 Light Sussex hens, which Mr Halnan and Dr Cruickshank of the Cambridge School of Agriculture had kindly placed at our disposal. The diet of the fowls and the general characteristics of the fats were described in the earlier paper [Hilditch *et al.*, 1934, p. 787], while the component acids of the fats are, for reference, again quoted below (Table I). The chief features of the component acids include the palmitic acid content (27 %—a characteristic proportion for a land animal fat), low stearic and high linoleic acid contents and the presence of 8 % of the unsaturated palmitoleic ($\Delta^{9:10}$-hexadecenoic) acid.

Table I. *Component fatty acids of depôt fats from 24 Light Sussex hens (aged 7 months).*

	Weight percentages		Molar percentages	
Acid	Abdominal	Gizzard	Abdominal	Gizzard
Myristic	0·1	0·1	0·1	0·1
Palmitic	25·6	25·3	27·3	26·9
Stearic	7·0	7·1	6·7	6·8
Palmitoleic	7·0	7·6	7·6	8·2
Oleic	38·4	36·6	37·1	35·4
Linoleic	21·3	22·8	20·7	22·2
C_{20-22} unsaturated	0·6	0·5	0·5	0·4

Fully-saturated glycerides of the hen depôt fat.

These formed only a small proportion (2·5 %) of the whole fat. In this respect the fat is comparable with rat, rabbit or the more unsaturated varieties of pig depôt fats, which also contain only small quantities of stearic acid, in addition to the more or less constant amount (25–30 %) of palmitic acid.

The gizzard fat (189 g.) was oxidised in acetone solution with powdered potassium permanganate, the unchanged neutral products of oxidation were resubmitted to similar oxidation until they possessed a negligible iodine value. Fully-saturated glycerides (6·8 g.) were thus isolated in a somewhat impure condition (iodine value 0·8, acid value 19·0 and including 0·32 g. of unsaponifiable matter).[1] After applying a correction for the unsaponifiable matter and acidic compounds (calculated as azelaodipalmitin) present in the crude fully-saturated glycerides, the content of the latter in the fat was calculated to be 2·5 %. Their mixed fatty acids (M.P. 59°) had a mean molecular weight of 260·3, corresponding with a mixture of about 85 % palmitic and 15 % stearic acids; the glycerides, after several crystallisations from ether, melted at 60°, and evidently consisted mainly of tripalmitin with some palmitostearins.

Estimation of tri-C_{18}-glycerides in the hen depôt fat.

(*i*) *Fractional crystallisation of the completely hydrogenated abdominal fat.* After hydrogenation to as low an iodine value as possible (1·5), the fat (77·7 g.) was submitted to systematic fractional crystallisation from ether. Six crystallisations in all were performed, the volumes of ether employed varying from 10 to 30 ml./g. of glycerides crystallised. Table II shows the weights and analytical characteristics of the fractions finally obtained, given in increasing order of solubility.

Assuming that fraction A (M.P. 68°) is a mixture of tristearin (sap. equiv. 296·7) and palmitodistearin (sap. equiv. 287·3), the fat (77·7 g.) contained 21·4 g. of tristearin, corresponding to a molar content of 27 % of tri-C_{18}-glycerides in the whole fat. If all the glyceride unsaturation in fractions E, F, G is credited to oleodistearin, a further 3 % of tri-C_{18}-glycerides must be added; for reasons which will appear later however it is quite possible that, in this particular hydrogenated fat, any residual unsaturation is due as much to oleodipalmitin as to oleodistearin.

---

[1] Part of the unsaponifiable matter (0·14 g.) was a yellow crystalline material, M.P. 120°, which was insoluble in ether.

Table II. *Fractional crystallisation of completely hydrogenated (abdominal) hen fat.*

(77·7 g., I.V. 1·5.)

		Glycerides		Corresponding acids (freed from unsap.)	
No.	g.	Sap. equiv.	I.V.	Sap. equiv.	I.V.
A	42·1	292·0	—	—	—
B	2·7	287·2	—	—	—
C	6·3	284·3	—	—	—
D	4·4	282·3	—	—	—
E	6·3	279·8	2·6	267·3	2·5
F	9·2	279·4	1·0	266·7	1·1
G	6·7	287·7	9·5	268·9	8·7

If fractions B to G are similarly dealt with, on the basis of the observed equivalents, as binary mixtures of palmitodistearin and dipalmitostearin, or dipalmitostearin and tripalmitin, the original fat appears to have contained about 40 % of mono-C_{16}-di-C_{18}-glycerides, 29 % of di-C_{16}-mono-C_{18}-glycerides and 1 % of tripalmitin. In presence of more than small amounts of dipalmitostearin however the quantitative separation of the latter from monopalmitodistearin and tripalmitin becomes uncertain, and it is probably better to derive the composition of these groups from the total amounts of C_{16} and C_{18} acids present in the original fat, after deducting (*a*) the C_{18} acids determined as tristearin (in fraction A) and (*b*) the palmitic acid present as tripalmitin in the fully-saturated glycerides of the original fat.

On the latter basis, the results of the fractional crystallisation of the completely hydrogenated fat indicate the following approximate molar composition of the original glycerides: tri-C_{18}, 28–29 %; mono-C_{16}-di-C_{18}, 41 %; di-C_{16}-mono-C_{18}, 28–29 %, and tripalmitin, 2 %.

(ii) *Examination of a partially hydrogenated abdominal fat* (*I.V. 14·6*). Lack of material compelled us to confine our investigation to a single partially hydrogenated fat, instead of studying a series of these fats as in our previous work on the pig depôt fats [1934]. The abdominal fat (100 g.) was hydrogenated until its iodine value was reduced to 14·6. The product (84·4 g.), after oxidation with potassium permanganate in acetone, yielded 50·7 g. of crude fully-saturated glycerides (I.V. 0·6). Subsequent purification of the latter (50·0 g.) gave the following products: (*a*) almost pure fully-saturated glycerides, 47·2 g. (acid value 0·2, sap. equiv., 285·6); (*b*) less pure fully-saturated glycerides, 1·9 g. (acid value 8·2); and (*c*) acidic products of oxidation, 0·9 g. (acid value 130·0). The content of fully-saturated glycerides was therefore 58·8 % (wt.) or 58·5 % (mol.).

Fractionation of the methyl esters (27·2 g.) from the purified glycerides (*a*) showed that the component acids present were:

	% (wt.)	% (mol.)
Palmitic	32·8	35·1
Stearic	67·2	64·9

The general structure of the partially hydrogenated fat was thus as shown in Table III. Here however it is not possible, in the present instance, to differentiate between the saturated and unsaturated acids of the respective C_{16}- and C_{18}-series, because the shortage of material also prevented a separate analysis of the component acids of the whole fat. The latter can readily be derived by calculation from the iodine value of the fat and the corresponding figures for the original fat (Table I), but, the individual amounts of palmitoleic and of oleic acids remaining unhydrogenated being undetermined, it is only possible to give the total molar contents of the C_{16} and C_{18} acids in each group. Since we are only concerned, for the moment, with the relative proportions of C_{16} and C_{18} acids in the mixed saturated-unsaturated glycerides, this information is sufficient for the purpose.

Table III. *Component acids (mols.) in the fully-saturated and non-fully-saturated parts of the hydrogenated hen fat of* I.V. *14·6.*

	Whole fat	Fully-saturated	Mixed saturated-unsaturated glycerides (by difference)
Mols.	100	58·5	41·5
Myristic	0·1	—	0·1
C_{16} (Palmitic + palmitoleic)	34·9	20·5	14·4
C_{18} (Stearic + oleic)	64·5	38·0	26·5
C_{20-22}	0·5	—	0·5

If, as in other fats which have been studied, the remaining mixed saturated-unsaturated components were at this stage only tri-C_{18}-glycerides with di-C_{18}-glycerides containing only one C_{16} (or other) radical, the 15 equivalents of non-C_{18} acids present in the mixed part would require, in order to form mono-C_{16}-di-C_{18}-glycerides, more C_{18} acids (30 equivalents) than are actually present. In other words, di-C_{16}-glycerides must still be present in quantity in the mixed saturated-unsaturated part of the hydrogenated fat at present under discussion.

This support of the evidence given by the fractional crystallisation ((i) above) of the completely hydrogenated fat received additional confirmation when the purified fully-saturated glycerides (*a*) (14·27 g.) from the partially hydrogenated fat were systematically crystallised from ether into the fractions summarised in Table IV.

Table IV. *Fractional crystallisation of purified fully-saturated glycerides (a) from the hydrogenated hen fat of* I.V. *14·6.*

		Glycerides		Corresponding acids (freed from unsap.)	
No.	g.	Sap. equiv.	I.V.	Sap. equiv.	I.V.
A	4·82	291·9	—	—	—
B	3·75	286·2	—	—	—
C	3·30	283·6	0·7	271·0	0·7
D	2·40	282·5	2·1	269·8	2·2

Estimated as in the former case (*cf.* Table II, *et seq.*) these figures show that the molar composition of these fully-saturated glycerides was approximately 16 % tristearin, 65 % palmitodistearin, 14 % dipalmitostearin and 3 % tripalmitin (with 2 % of residual unsaturated glycerides, which might be either oleodipalmitin or oleodistearin). Since these fully-saturated components amounted to 58·5 % of the hydrogenated fat of iodine value 14·6, the proportions of the various glycerides present in the latter fat as a whole were respectively about 10 % tristearin, 38 % palmitodistearin and 8·5 % dipalmitostearin (with 2 % tripalmitin).

DISCUSSION.

Although, as we have already seen, the presence of palmitoleic acid, in addition to oleic and linoleic acids, in combination in the hen depôt fats complicates the interpretation of the experimental data, the latter afford a fair amount of information with regard to the component glycerides present and also give rise to certain suggestive inferences.

The very minor amounts of fully-saturated components in the original fat are, as already mentioned, quite in keeping with what has been observed in other animal fats of similar total palmitic and stearic acid contents. The non-fully-saturated glycerides however are sharply differentiated from other animal depôt fats which we have studied, in that they contain far more tri-C_{18} (unsaturated) glycerides and especially di-C_{16}-mono-C_{18} glycerides, with proportionately less monopalmito-di-C_{18}-glycerides than in other cases.

In considering the foregoing data, we would next direct attention to the following points:

(i) *The monopalmitodistearin produced by hydrogenation of hen fat.* If we compare the proportions of the various fully-saturated derivatives present in the completely and the partially hydrogenated hen fats, it is clear that palmitodistearin has been formed from palmitodi-"oleins" far more rapidly and completely than the dipalmitostearin results from its precursors:

Table V.

Mols. present (per 100 mols. of fat) of:	Completely hydrogenated fat	Partially hydrogenated fat
Tristearin	28–29	10
Monopalmitodistearin	41	38
Dipalmitomonostearin	28–29	8·5
Tripalmitin	2	2

The relative ease with which the monopalmito-derivatives pass into palmitodistearin is exactly parallel with the behaviour observed in pig depôt and other fats, and it is reasonable to assume that the same glycerides are concerned in each case, *i.e.* hydrogenation of β-monopalmitodi-"oleins" to β-palmitodistearin. If this view be accepted, it also follows that palmitoleic acid is not present to any appreciable extent in the form of monopalmitoleo-di-C_{18}-glycerides.

(ii) *Inferences regarding the dipalmitostearins produced by hydrogenation of the hen fat.* During hydrogenation, the monopalmitodistearin is not only produced much more rapidly than dipalmitostearin and tristearin, but the (slower) rates of production of each of the two latter glycerides are closely similar (*cf.* Table V): this naturally suggests a single cause for the relatively slow conversion into fully-saturated glycerides in the cases of both dipalmitostearin and tristearin. It was mentioned in our previous communication [1935] that, pending the results of configurational studies directed towards establishing the mechanism of such preferential hydrogenation, we incline to the view, as a working hypothesis, that the observed differences may be connected with relative difficulty of hydrogenation of an oleic radical in the β-, as compared with that of one in an α-position. In the present case, on this hypothesis, it follows that the unsaturated precursors of dipalmitostearin (as well as of tristearin) will contain an unsaturated acyl radical attached to the β-carbon atom of the glycerol molecule.

If this be so, any palmitic radicals originally present as such in these di-C_{16}-glycerides must have been attached to α-glyceryl carbon atoms. There remains however a further consequence of these arguments: if the mono-C_{16}-glycerides (*v. supra*) are wholly or for the most part β-monopalmitodi-"oleins", the 8 % of palmitoleic acid present in the original fat must be assigned to the di-C_{16}-glycerides now under consideration. The latter would then, for the most part, be formulated as either α-palmito-β-oleo-α'-palmitolein or α-palmito-β-palmitoleo-α'-olein. It is of some interest that the palmitoleic acid content of the whole fat (8 % mol.) would suffice to give 24 % (mol.) of these glycerides, as compared with the observed total content (p. 601) of 28–29 % of di-C_{16}-glycerides.

It is also interesting to note that, in glycerides of this type, palmitoleic acid would be acting as an individual and independently of any other fatty acid. In other words, the glyceride structure formulated seems to preclude the view that palmitic and palmitoleic acids might be regarded as interconvertible, by means of desaturation or saturation.

(iii) *Distribution of the stearic acid (7 mols. %) present in the original fat.* Apart from the insignificant amount of stearic acid combined as palmitostearins in the 2·5 % of fully-saturated glycerides, all of this acid must be in the form of mixed saturated-unsaturated glycerides. It may be present (*a*) as α-stearodi-"olein", (*b*) as β-palmitostearo-"olein", or (*c*) possibly as α-palmito-β-palmitoleo-α'-stearin. If it were present exclusively in any one of these forms, the quantity of the respective mixed glyceride would be about 20 % (mol.) of the whole fat.

There is naturally no evidence from our experimental data as to the precise mode of combination of this stearic acid. It might be confined to one isomeride; perhaps more probably, it may be distributed amongst the different types. In the summary of component glycerides (Table VI) the three possibilities can therefore merely be indicated without offering any precise solution.

Table VI. *Approximate general composition of the glycerides of hen depôt fat.*

General type		% (mol.)
Fully-saturated	Mainly tripalmitin with small amounts of palmitostearins	2
Tri-C_{18}-glycerides	Tri-unsaturated (oleo-linoleins), but may include up to 20 % (mol.) of α-stearodi-"olein"	28–29
(β-) Monopalmitodi-C_{18}-glycerides	β-Monopalmitodi-"oleins", but may include up to 20 % (mol.) of β-monopalmitostearo-"olein"	41
Di-C_{16}-mono-C_{18}-glycerides	Probably α-palmito-"oleo"-palmitoleins, but might include up to 20 % (mol.) of α-palmito-β-palmitoleo-α'-stearin	28–29

The terms "olein" or "oleo"- indicate that linoleic as well as oleic radicals are concerned in these cases.

SUMMARY.

1. The chief component glycerides of the hen body fat studied are about 40 % (mol.) of monopalmitodi-"oleins", with nearly 30 % (mol.) each of mainly unsaturated tri-C_{18}-glycerides and of di-C_{16}-mono-C_{18}-glycerides. Fully-saturated glycerides (mainly tripalmitin) only form about 2 % of the fat. The proportion of stearic acid (*ca.* 7 %) combined in the fat may be present in the form of monostearo-glycerides in either of the three main groups; the combined amount of such monostearo-unsaturated glycerides will approximate to 20 % (mol.) of the fat. The individual distribution in the mixed glycerides of oleic and linoleic acids (present respectively to the extent of about 36 % and 21 % of the total com-

ponent acids) cannot be given, since the glyceride structure has been deduced mainly from study of the hen fat after partial or complete hydrogenation.

2. The 40 % of monopalmito-glycerides are almost certainly present in the form of β-palmitodi-"oleins" (or, to some extent, β-palmito-stearo-"oleins"). Consideration of the structure of the hydrogenated fats leads to the conclusions that the di-C_{16}-glycerides consist largely of α-palmito-derivatives, and that the 8 % of palmitoleic acid in hen fat is also probably mainly present in this group. The di-C_{16}-glycerides, on this basis, may be α-palmito-β-palmitoleo-α′-"olein", α-palmito-β-"oleo"-α′-palmitolein, α-palmito-β-palmitoleo-α′-stearin, or a mixture of these.

3. The hen body fats are differentiated from the corresponding fats of pigs, sheep, cows and some other animals by their unusually large proportions of tri-C_{18}-(unsaturated)-glycerides and, especially, of the mixed semi-unsaturated di-C_{16}-mono-C_{18}-glycerides. The result is a more heterogeneous mixture of mixed triglycerides than in fats of the lard type. This is reflected in the physical consistency of the fats. A pig fat of similar mean unsaturation and not very different palmitic, stearic, oleic and linoleic acid contents forms a thin, semi-solid, almost homogeneous paste at atmospheric temperature; but the hen body fats separate into two well-marked phases—a clear liquid fat with a lower layer of solid glycerides (so-called "stearin").

Grateful acknowledgment is made of a grant from the Department of Scientific and Industrial Research in aid of this investigation.

LXXI. STUDIES IN THE BIOCHEMISTRY OF MICRO-ORGANISMS.

XLII. THE METABOLIC PRODUCTS OF *ASPERGILLUS TERREUS* THOM. A NEW MOULD METABOLIC PRODUCT—TERREIN.

BY HAROLD RAISTRICK AND GEORGE SMITH.

From the Division of Biochemistry, London School of Hygiene and Tropical Medicine, University of London.

(*Received January 15th, 1935.*)

THE name *Aspergillus terreus* is used by Thom and Church [1918; 1926] to cover a series of strains which have a number of well-marked morphological features in common, but which show a certain amount of variation in colour and type of growth. The conidial colour may range from pale cinnamon to fairly deep brown; the texture of the surface growth may vary from smooth velvety to definitely floccose, whilst the reverse of the colony and the agar may vary in colour from pale or bright yellow to fairly dark brown. Thom and Church state that *A. terreus* is common in soil and decaying vegetable matter throughout the United States, but has not been received by them from any European source. Smith [1928] found this organism as a latent infection of cotton yarns, occurring fairly often on American cottons and very frequently on all types of Egyptian cottons; also as a cause of serious damage to exported cloths, particularly dhooties.

The present communication is an account of experiments which have been carried out with five strains of *A. terreus*, obtained from different sources and covering approximately the range of variation shown by different strains in the series. When grown at 24° on the well-known Czapek-Dox solution with 5 % of glucose as the sole source of carbon, two of the strains, No. 45 and Ac 100, produce in the solution a new mould metabolic product which we have named *terrein* ($C_8H_{10}O_3$, M.P. 127°).[1] The yield of terrein appears to reach a maximum when the sugar in solution has been reduced to approximately 1 %. Succinic acid has also been identified as a metabolic product of No. 45, but is formed in small amounts only. From the metabolism solutions of the remaining three strains (No. 3, No. 37 and Ac 24) no terrein has been isolated but only small amounts of oxalic acid, succinic acid or both. The strain Ac 100 is of special interest since it produces, in addition to the new product terrein, appreciable quantities of citrinin, a substance hitherto believed to be formed only by *Penicillium citrinum* Thom [Hetherington and Raistrick, 1931]. The other four strains also give rise to fairly large amounts of substances which, like citrinin, are precipitated by acidification of the metabolism solutions. From none of these acid precipitates has any citrinin been obtained and so far no other substance has been isolated in a state of purity.

---

[1] At a meeting of the Biochemical Society held at Oxford on May 5th, 1934, a paper was read in which this substance was described as "terreic acid" [Raistrick and Smith, 1934]. It has since been found that a highly purified sample has p_H 6·8 in 1 % aqueous solution, and work on the constitution of terrein, at present in progress, has shown that the substance does not contain a true acidic group. Hence the change of name.

Thom and Church [1918] state "With the accumulation of material however, we find ourselves with a series of related strains (of *A. terreus*) rather than a single organism....Whether some of them may ultimately be separated as varieties, upon physiological grounds, is not determined". We suggest that if as the result of future research the *A. terreus* series be subdivided into a number of named species, the production of terrein when grown on Czapek-Dox glucose medium at 24° be diagnostic for one of these named species.

EXPERIMENTAL.

The organisms.

Relevant details of the five strains of *A. terreus* used in this investigation are given in Table I.

Table I.

Catalogue no.	Source	Isolated by	Cultures on Czapek-Dox agar: Surface colour	Reverse colour	Texture
No. 3	Mildewed cloth	G. Smith 1926	Cinnamon	Deep yellow	Smooth velvety
No. 37	Egyptian cotton	G. Smith 1926	Cinnamon	Greenish yellow	Smooth velvety
No. 45	American cotton	G. Smith 1926	Brownish	Brown	Slightly floccose
Ac 21	British National Collection of Type Cultures No. 981	Thom and Church (Washington 144)	Brownish	Deep brown	Slightly floccose
Ac 100	F. T. Brooks, Cambridge	Hansford. Identified by Miss Church	Brown	Deep brown	Definitely floccose

Cultural conditions.

The culture medium used throughout was the well-known Czapek-Dox solution containing: glucose, 50 g.; $NaNO_3$, 2·0 g.; KH_2PO_4, 1·0 g.; KCl, 0·5 g.; $MgSO_4, 7H_2O$, 0·5 g.; $FeSO_4, 7H_2O$, 0·01 g.; distilled water, 1000 ml. Cultures were grown in conical flasks of 1 litre capacity, each containing 350 ml. of medium, and sown, after sterilisation, from cultures on Czapek-Dox agar slopes approximately 2 weeks old, one slope being used to sow 4 flasks. The temperature of incubation was 24°.

The course of metabolism.

Twenty flasks of medium were sown with each of the 5 strains, and single flasks were taken for analysis at intervals of 3 or 4 days. The experiment was continued for 35 days, by which time metabolism appeared to be complete in all cases. The examination included measurement of p_H colorimetrically, estimation of apparent residual glucose by polarimeter, estimation of bromine absorption

Table II.

R.S.P., % apparent residual sugar determined by polarimeter. B.A., bromine absorption in mg. Br per ml. Initial p_H, 4·1; initial glucose, 5·17 %; initial bromine absorption, 0·08 mg. Br per ml.

by Koppeschaar's method [1876] and observation of the effect of adding $FeCl_3$ solution. After 2 weeks' incubation the reactions of the metabolism solutions with various metallic salts were tested. The results of the analyses are given in Table II.

With the strains No. 45, Ac 24 and Ac 100 the metabolism solution gradually became coloured an intense reddish brown. Estimation of p_H was thereby rendered difficult and, in the later stages of incubation, with Ac 24 and Ac 100 was quite impossible. For estimation of residual glucose the solutions from No. 45 and Ac 100 could be cleared by addition of a few drops of HCl and filtration. With Ac 24, however, this treatment did not appreciably lighten the colour and the figures are therefore only approximate.

The figures show that with all the strains there was some irregularity in growth, so that single flasks, though selected to be as representative of the whole as possible, could not be regarded as averages of a whole batch. With No. 3, No. 37, No. 45 and Ac 100 the appearance of the cultures was reasonably uniform. Ac 24 however showed great irregularity. In some flasks the solution remained yellow for a long time and the mycelium was thick, gelatinous and non-sporing. In others the solution quickly became intense brown, with the mycelium thinner, brittle and sporing freely.

The metabolism solutions of No. 3 and No. 37 did not at any stage give an appreciable reaction with $FeCl_3$. With No. 45, Ac 24 and Ac 100, $FeCl_3$ intensified the brown colour of the solutions and, with Ac 100 after 17 days, gave a precipitate. After 13 days' incubation solutions from all the strains reduced $AgNO_3$ rapidly in the cold, gave slight brownish precipitates with $HgCl_2$, $CuSO_4$ and uranium acetate, and heavy precipitates with neutral or basic lead acetate. Acidification gave precipitates in all cases, greatest in amount with No. 45 and Ac 100, and increasing with continued incubation.

Large-scale experiments.

For isolation and identification of products of metabolism each strain was grown in batches of 100 flasks. When the glucose was reduced to the desired figure (about 1 %) as determined by testing single pilot flasks, the combined metabolism solution was poured off and filtered. The mycelium was scraped out of the flasks, well pressed and washed and the filtered squeezings and washings added to the main filtrate. The whole was made slightly acid to Congo red by cautious addition of strong HCl (about 100 ml.) and the precipitate allowed to settle. The clear supernatant liquid was decanted, the residual precipitate filtered, well washed and dried *in vacuo* (fraction I). The supernatant liquid and filtrate were combined and evaporated *in vacuo*, with a bath temperature not exceeding 50°, to approximately 750 ml. Usually a further quantity of flocculent precipitate separated during evaporation, also a certain amount of black tar (fraction II) which has not been further examined. The concentrate was centrifuged (filtration was impracticable) until almost clear and the precipitate added to fraction I. The aqueous solution was exhaustively extracted with equal volumes of ether, 20 to 30 extractions being usually necessary. On evaporation the ether extracts gave fraction III. Only small amounts of syrupy material were obtained by subsequent extraction with $CHCl_3$.

Strain No. 3. Fraction I was a brown powder, weighing 29·4 g. from which no crystalline material has yet been obtained. The ether extracts, fraction III, gave on evaporation small amounts of crystals (1·34 g.) which were identified as oxalic acid by M.P., mixed M.P. and the usual chemical tests. Further evaporation of the ether mother-liquor gave only small amounts of reddish gum.

Strain No. 37. Fraction I was a bright yellow powder weighing 30 g. Extraction with ether gave thick syrups from which no crystalline material has been obtained. Ether extracts, fraction III, gave traces of oxalic acid and appreciable quantities of succinic acid, identified by analysis, M.P. and mixed M.P., amounting in one experiment to 8·5 g.

Strain No. 45. Fraction I was a buff-coloured powder, the weight of which in six successive experiments is given in Table III. It was extracted in a Soxhlet apparatus with several successive lots of ether until nothing further was dissolved, this requiring about 24 hours in all. The extracts, which were dark brown in colour, deposited on standing hard crusts of microcrystalline material which were filtered off and well washed with ether. Evaporation of the mother-liquors gave further amounts of apparently identical material, and was repeated until nothing but a thick, almost black syrup remained. The solid isolated was yellowish buff in colour and had M.P. 193–196° (decomp.). No satisfactory method of purification and no reliable criteria of purity have yet been found.

The ether extracts (30 extractions with an equal volume of ether were carried out) containing fraction III, on evaporation to small volume deposited long needles of crude terrein (fraction III*a*). The first ten ether extracts were combined. They were dark-coloured but gave clean, pale-coloured crystals, whilst extracts 11–30, which were also combined, were much paler but gave brownish crystals mixed with small amounts of sticky syrup. The ether mother-liquors were further evaporated, those from extracts 11–30 giving further small amounts of crude terrein (fraction III*a*), whilst those from extracts 1–10 gave crystals which softened at 115°, became red at 145–150° and finally melted about 170° (fraction III*b*). The crude terrein constituting fraction III*a*, M.P. 124–126°, was recrystallised from ether, in which it is only sparingly soluble, until of constant M.P., 127°. The pure material forms fine colourless needles, which are very difficult to free from the last traces of colour. Fraction III*b* was obviously a mixture, and was shown to consist of terrein (which is readily detected in mixtures on account of its reddening at 145–150°) and succinic acid.

In order to prove the presence of the latter, the mixture was dissolved in a minimum of water and excess of neutral lead acetate added. The precipitate was filtered off, well washed, suspended in water and decomposed by passing H_2S. The PbS was filtered off and the clear aqueous solution evaporated to dryness. The crystalline residue had M.P. 184°, unchanged on mixing with authentic succinic acid. This method does not give a complete separation, although it does result in the isolation of pure succinic acid, since lead succinate is not quantitatively precipitated unless the solution is first neutralised, and neutralisation is undesirable because of the instability of terrein. Terrein, still somewhat impure, was recovered by extraction of the lead acetate mother-liquors with ether.

The yields of products from six batches of Strain No. 45, each of 100 flasks, are given in Table III.

Table III.

Batch no.	Days' incubation	R.S.P. %	Crude precipitate (g.) Fraction I	Pure terrein (g.)	Mixture of terrein and succinic acid (g.)
1	29	0·4	46	8·5	2·76
2	33	0·2	52	9·3	0·31
3	26	0·7	38	13·1	3·70
4	27	0·5	38	13·0	0·54
5	26	0·38	80·5	4·5	1·64
6	23	0·9	31	17·3	2·05

Strain Ac 24. The acid precipitate (fraction I) was a brown powder, weight 22·9 g. The only crystalline product so far obtained from the ether extracts (fraction III) was succinic acid, 2·8 g. from 100 flasks.

Strain Ac 100. The acid precipitate, fraction I, was a yellowish green powder, weight 57·5 g. Extraction with ether gave a dirty yellow, micro-crystalline powder which melted at 170°, and decomposed in a manner characteristic of citrinin. Recrystallised from absolute alcohol it was obtained as long golden yellow needles, M.P. 173° (decomp.), mixed M.P. with an authentic sample of citrinin from *P. citrinum* Thom, 172° (decomp.). In absolute alcohol solution ($c = 0{\cdot}92$), $[\alpha]^{23^\circ}_{5461} - 43{\cdot}1^\circ$. (Hetherington and Raistrick [1931] give for citrinin $[\alpha]_{5461} - 41{\cdot}7^\circ$, $-43{\cdot}9^\circ$.) Titration in aqueous suspension gave equiv. wt. 245, and in alcoholic solution 254. Estimation of molecular weight by depression of F.P. of dioxan gave 259. (Found (Schoeller): C, 62·36, 62·25; H, 5·59, 5·68 %. $C_{13}H_{14}O_5$ requires C, 62·37; H, 5·64 %. Mol. wt. 250.) A solution of the sodium salt gave on addition of $FeCl_3$ a heavy buff-coloured precipitate, soluble in excess of the reagent to give the clear deep iodine-brown solution characteristic of citrinin.

The statement by Hetherington and Raistrick [1931] that citrinin was apparently produced only by *Penicillium citrinum* Thom and was to be regarded as diagnostic for this organism, was based on the fact that no other of the hundreds of moulds tested at that time gave the typical reaction given by *P. citrinum* when $FeCl_3$ is added to the metabolism solution. Although the strain of *A. terreus* Ac 100 was actually one of the strains examined by Hetherington and Raistrick it is not surprising that citrinin was not detected by its colour reaction with $FeCl_3$, since this is almost entirely masked by the intense colour of the untreated metabolism solution and by simultaneous reactions between $FeCl_3$ and other metabolic products.

Because of the importance of this outstanding exception, the only one encountered in 13 years' work, it seemed desirable to repeat the experiment with *A. terreus* Ac 100 after rigorously re-checking the purity of our cultures. To this end the culture which was used as the starting point for the first 100-flask experiment with Ac 100 was plated out and showed no sign of contamination. Further, single spore cultures were made and these were used to sow the flasks in a second experiment. Citrinin was again obtained. There can thus be no doubt that citrinin is a metabolic product of at least one authentic strain of *A. terreus* Thom.

The yield of citrinin could not be estimated accurately since, as shown by Hetherington and Raistrick, it cannot be recovered quantitatively from very impure crude samples. In the first experiment 5·5 g. of pure material were obtained. In the second experiment, in which the crude acid precipitate was much darker in colour, only 3·5 g. were isolated.

Ether extracts of the metabolism solution, fraction III, gave crude terrein on evaporation. It was purified by recrystallisation from ether until practically colourless and of sharp and constant M.P. In the first experiment referred to above, final glucose 0·50 %, 4·8 g. of pure terrein were obtained. In the second experiment referred to above, final glucose 1 %, 6·1 g. of pure terrein were obtained. No succinic acid was isolated in either experiment.

General properties of terrein.

The substance crystallises from ether or acetone in colourless needles, M.P. 127°. The melt resets instantly on cooling and melts again at the same temperature. On heating to higher temperatures it begins to turn yellow at 145°, without any other visible change. The colour deepens as the temperature rises, becoming deep red at about 175°, and if held for some time at this temperature the melt does not solidify on cooling.

(Found (Schoeller): sample *ex* ether, C, 62·37, 62·33; H, 6·59, 6·53 %; OCH_3, nil; N, nil. Sample *ex* acetone, C, 62·33; H, 6·46 %. $C_8H_{10}O_3$ requires C, 62·31; H, 6·54 %.)

Mol. wt., by depression of F.P. of dioxan = 157·5. $C_8H_{10}O_3$ requires 154·1.

Optical rotation. In 1 % solution in water $[\alpha]_{5461}^{20^\circ} + 185^\circ$, $[\alpha]_{5790}^{20^\circ} + 168{\cdot}5^\circ$. In 2 % aqueous solution $[\alpha]_{5461}^{21^\circ} + 183{\cdot}4^\circ$, $[\alpha]_{5790}^{21^\circ} + 167{\cdot}2^\circ$.

Active hydrogen (Roth). In anisole at 28°, 1·60, 1·67 atoms; at 95°, 1·85, 1·84 atoms; in pyridine at 28°, 2·06 atoms of active hydrogen.

Solubilities at room temperature were estimated approximately by adding the desired solvent from a micro-burette to 0·1 g. of finely powdered substance and shaking vigorously until solution was just complete. Solubilities, as g. substance in 100 ml. of solvent are: water, 11·9; alcohol, 10·5; acetone, 5·75; chloroform, 0·75; ether, 0·32; benzene, 0·02; light petroleum, nil.

Reactions. A 1 % aqueous solution is neutral to litmus and has p_H 6·8. Addition of NaOH turns the solution first yellow, then brown and finally dark brown on standing. The neutral aqueous solution gives no reactions with salts of Ag, Ca, Ba, Hg″, Cu″, Fe‴, U, Ni or Pb. Fehling's solution is reduced instantly in the cold, bromine is rapidly absorbed without giving a precipitate, acid $KMnO_4$ is instantly decolorised, and Brady's reagent (2:4-dinitrophenylhydrazine in 2*N* HCl) produces a turbidity almost immediately and gives a bright red precipitate on standing overnight. An alkaline solution of terrein reduces $AgNO_3$ rapidly in the cold, reduces iodine instantly and immediately discharges the colour of alkaline phenolphthalein. The constitution of this interesting substance will be the subject of a future communication.

SUMMARY.

1. Five strains belonging to the group species *Aspergillus terreus* Thom have been grown at 24° on Czapek-Dox solution with glucose as sole source of carbon, and their metabolic products have been examined.
2. Two of the five strains give rise to a new mould metabolic product *terrein*, $C_8H_{10}O_3$, M.P. 127°, the isolation and properties of which are described.
3. One of these strains produces, in addition to terrein, citrinin, $C_{13}H_{14}O_5$, the crystalline yellow colouring matter which has previously been obtained only as a metabolic product of *Penicillium citrinum* Thom.
4. Of the three strains that do not produce terrein, one gives succinic acid, one oxalic acid, while the third strain gives a mixture of these two acids.

Our best thanks are due to Dr A. E. Oxford who kindly carried out for us determinations of the molecular weights of terrein and citrinin.

This work has been rendered possible by a grant to one of us (G.S.) from the Research Council of Imperial Chemical Industries, Ltd., to whom we tender our best thanks.

LXXII. POLYSACCHARIDES SYNTHESISED BY MICRO-ORGANISMS.

I. THE MOLECULAR STRUCTURE OF MANNOCAROLOSE PRODUCED FROM GLUCOSE BY *PENICILLIUM CHARLESII* G. SMITH.

BY WALTER NORMAN HAWORTH, HAROLD RAISTRICK AND MAURICE STACEY.[1]

From The Chemical Laboratories, University of Birmingham and the Division of Biochemistry, London School of Hygiene and Tropical Medicine, University of London.

(*Received January 15th, 1935.*)

IT has recently been shown that, using glucose as the sole source of carbon, a number of hitherto undescribed metabolic products are formed when *Penicillium Charlesii* G. Smith is grown on Czapek-Dox solution of the sugar [Clutterbuck *et al.*, 1934]. Among the products are two new polysaccharides one of which consists only of mannose residues and the other of galactose residues. In addition, six hitherto unknown organic acids are found. The present communication describes the investigation of the molecular constitution of the polymannose to which is given the name *mannocarolose*. This is a white, amorphous, hygroscopic powder, $[\alpha]_{5780} + 66^\circ$, readily soluble in water and forming an acetate which is soluble only in organic solvents. Repeated fractional precipitation of the polysaccharide and removal of ash by electrodialysis yielded a product which was essentially homogeneous and on hydrolysis this gave a yield of 97 % of mannose, isolated as the phenylhydrazone. The molecular weight of the acetate was calculated by the use of the Staudinger factor from the viscosity measurements and corresponded to 9 mannose units in the molecule. This value is in agreement with that determined by the estimation of the mean iodine number. The same value is also found by a direct determination or gravimetric assay of the end group of the methylated polysaccharide. The latter yielded, on hydrolysis, 13·4 % of tetramethyl-methylmannoside which corresponds to a chain length of 8–9 mannose units. It is of considerable interest to record the general agreement of all three methods of determining the molecular size of the polymannose.

The precise form in which mannose is combined in the polysaccharide whether as pyranose or furanose, and also the particular mode of linking of adjacent units of the hexose were investigated in the following way. Methylated mannocarolose was completely hydrolysed, the hydrolysis products converted into the glycosides, and a quantitative analysis of the products revealed the presence of 75 % of a trimethyl-methylmannoside (I), 13·4 % of tetramethyl-methylmannoside, together with another fraction (10 %) which was identified as mainly a dimethyl-methylmannoside. On complete methylation and hydrolysis, the trimethyl- and dimethyl-mannosides yielded 2:3:4:6-tetramethylmannopyranose (III) which was characterised as its crystalline anilide.

---

[1] Beit Memorial Research Fellow.

The trimethylmannose fraction was identified as a crystalline 2:3:4-trimethylmannopyranose (II), M.P. 102–103°, $[\alpha]_{5780}^{21^\circ}+7^\circ$ (equilibrium value) which is now described for the first time. The positions of the methyl groups were determined and the experimental evidence for the allocation of the 2:3:4-positions is here given. The trimethyl sugar gave, on oxidation, 2:3:4-trimethylmannopyranolactone (IV) which was distilled; its hydrolysis curve in aqueous solution and the rate of lactonisation of the corresponding acid were characteristic of a δ-lactone of the mannose series. It gave on further methylation a quantitative yield of tetramethylmannopyranolactone characterised as its crystalline phenylhydrazide. It was evident therefore that the hydroxyl group at position 4 in the trimethyl-sugar must have been methylated. This was shown conclusively by the degradative oxidation of the trimethylmannonolactone (IV) with nitric acid, which yielded *d*-arabotrimethoxyglutaric acid (V) and *i*-dimethoxysuccinic acid (VI) both of which were characterised as their crystalline methylamides [Goodyear and Haworth, 1927]. The isolation of the former of these products proves that the methylated positions in the trimethylmannose

must be at hydroxyls 2, 3, 4; that position 5 must be engaged in ring-formation; and that the terminal position 6 is to be represented as a free hydroxyl group liberated from the methylated polysaccharide by fission during hydrolysis. It is evident therefore that mannocarolose is constituted by the linking of mannopyranose units at positions 1 and 6 and that the form of mutual linking of successive units of mannose characterises the structure of the polysaccharide. This mode of union of hexose units differs fundamentally from that found in starch and cellulose in which the glucose residues are united at positions 1 and 4.

In the original hydrolysis of methylated mannocarolose it was noted that about 10 % consisted of a dimethyl-sugar which on glycoside formation was identified as 2:3-dimethyl-methylmannoside in the following way. It yielded on further methylation 2:3:4:6-tetramethyl-methylmannopyranoside identified by hydrolysis and isolation of the crystalline anilide. The 2:3-dimethylmannose gave on oxidation a γ-lactone which was further degraded by oxidation with nitric acid and yielded only crystalline *i*-dimethoxysuccinic acid, characterised also as its crystalline methylamide.

In the hydrolysis products of methylated mannocarolose this 2:3-dimethylmannose occurs to the extent of 10 % corresponding very nearly with the amount of the 2:3:4:6-tetramethylmannose which was isolated as the non-reducing terminal group. It should be noted that the polysaccharide reduces alkaline hypoiodite and gives an iodine number corresponding to the presence of one reducing group in the chain length of 9 mannose residues. The formulation can hardly be represented therefore by a continuous loop with a tetramethylmannose projection as a side-chain. The absence of reduction to Fehling's solution is in contrast to the hypoiodite reaction. The occurrence of one dimethyl residue of the 9 which otherwise have their quota of methyl groups in the methylated polysaccharide may be significant in other directions, but at the moment we incline to the view that inasmuch as it is not possible to ensure complete homogeneity of methylated mannocarolose by a procedure corresponding to that of crystallisation it seems inevitable that any not quite completely methylated portion may account for the occurrence of this quantity of dimethylmannose. The formulation (A) is subject to this modification, and although the stereochemical form is represented as that of α-mannose it should be clearly understood that this is not based on anything more definite at the moment than the comparatively high dextrorotation (+66°) of the polysaccharide.

EXPERIMENTAL.

The crude mixture of mannocarolose and galactocarolose (*i.e.* the polygalactose) was prepared by the method described by Clutterbuck *et al.* [1934]. The yields and properties of batches on Czapek-Dox medium and on Raulin-Thom medium were consistent with those previously described. Moreover by the method of fractionation it was shown that the crude polysaccharide mixture obtained from the Czapek-Dox medium contained mannocarolose and galactocarolose identical in properties with, but different in amount from, those obtained from Raulin-Thom medium as was previously suggested [Clutterbuck *et al.*, 1934, p. 103]. About equal amounts of mannocarolose and galactocarolose were isolated from the polysaccharide mixture from the Czapek-Dox medium, whereas with the Raulin-Thom medium the proportions were 30 % and 70 % respectively.

A sample of mannocarolose, prepared as previously described, was subjected to rigorous purification to attain homogeneity. The last portions (1 %) of ash were difficult to remove by alcohol precipitations, but all traces were removed by electrodialysis during 18 hours. The product had the following properties: it was a white hygroscopic powder, $[\alpha]^{21^\circ}_{5780} + 66^\circ$ (*c*, 3·3) in water. (Found: C, 44·8; H, 6·8 %. $(C_6H_{10}O_5)_x$ requires C, 44·4; H, 6·2 %.) Its solution was neutral to litmus and did not reduce Fehling's solution. After acid hydrolysis it gave mannosephenylhydrazone in 97 % yield and crystalline *d*-mannose in 84 % yield. The latter compound was crystallised from glacial acetic acid and the mother-liquors yielded mannosephenylhydrazone (12 %). Mean iodine number [Bergmann and Machemer, 1930], 14·3, corresponding to a molecular weight of 1400.

Mannocarolose acetate.

Mannocarolose (20 g.) was acetylated as previously described [Clutterbuck *et al.*, 1934]. The mannocarolose acetate (OAc, 46·1 %) was a fine white powder, easily soluble in chloroform and acetone, slightly soluble in ethyl alcohol and insoluble in methyl alcohol, ether and light petroleum. It was separated into four fractions by the graded addition of light petroleum to a 25 % chloroform solution. Each fraction showed identical properties. M.P. 150–160°; $[\alpha]^{20°}_{5780}+53°$ in acetone (*c*, 1·6), $[\alpha]^{20°}_{5780}+66°$ in chloroform (*c*, 0·84). Ash, 0·07 %. (Found: C, 50·1; H, 5·8; OAc, 46·0 %. $(C_{12}H_{16}O_8)_x$ requires C, 50·0; H, 5·6; OAc, 44·8 %.) The mean iodine number was 8·0, corresponding to a molecular weight of 2500.

Viscosity measurements were carried out on each fraction and the values obtained were identical. The molecular weight calculated by the use of the Staudinger factor from the viscosity measurements was 2584, corresponding to 9 mannose units in the molecule, a value which supports that calculated from the mean iodine number of the original polysaccharide and similar to that determined by the gravimetric assay of the end-group of the methylated polysaccharide.

Methylated mannocarolose.

(1) *By direct methylation of mannocarolose.* In a typical experiment mannocarolose (5 g.) was dissolved in water (20 ml.) and methylated in the usual manner by the gradual addition of sodium hydroxide and dimethyl sulphate during 5 hours. After 30 minutes acetone (100 ml.) was added. The temperature was maintained at 35–40° during the addition of the reagents, after which it was raised to 80–90° until all the acetone was removed (30 minutes).

Partly methylated mannocarolose was obtained as a light brown gum on the surface of the hot solution, and it redissolved on cooling. The temperature was raised and the methylated material was separated and dissolved in chloroform. The solution was dried over anhydrous magnesium sulphate and cleared by centrifuging. The chloroform was removed by distillation and the resulting thin syrup poured into light petroleum (B.P. 40–50°). The methylated product (5 g.) was precipitated as a fine cream-coloured powder. $[\alpha]^{20°}_{5780}+80°$ in chloroform (*c*, 1·0). (Found: OMe, 36·2 %.)

The product (5 g.) was re-methylated in acetone solution (50 ml.) at 40° with dimethyl sulphate and sodium hydroxide over a period of 2 hours. Before raising the temperature to 90° for the final heating the excess alkali was carefully neutralised and the solution diluted, since it was observed that the product was appreciably soluble in hot alkali. The methylated product separated as a brown gum and was fractionally precipitated as before from chloroform solution giving a light-brown powder (yield 5·4 g.). $[\alpha]^{20°}_{5780}+96°$ in chloroform (*c*, 1·2). (Found: OMe, 41·0 %.)

The product (5 g.) was now dissolved in methyl iodide (50 ml.) containing dry methyl alcohol (2 ml.), and re-methylated by heating gently for 4 hours with silver oxide (10 g.) which was added in 2 g. lots. The product was extracted with boiling chloroform, which was removed by distillation. On pouring the residual thin syrup into light petroleum (B.P. 40–50°) the methylated compound was precipitated as a light brown gum, prolonged trituration of which with renewed amounts of light petroleum (B.P. 40–50°) converted it into a cream-coloured powder. M.P. 95–100°. Yield 5·4 g. $[\alpha]^{21°}_{5780}+102°$ (*c*, 1·4) in chloroform. (Found: OMe, 44·4 %.) Further methylation by either method failed to alter the methoxyl content or the specific rotation.

(2) *By methylation of mannocarolose acetate.* Mannocarolose acetate (15 g.) was dissolved in acetone (200 ml.) and methylated at 45° by the simultaneous addition of dimethyl sulphate (140 ml.) and 30 % sodium hydroxide (290 ml.) in the usual manner. Acetone was added from time to time to retain the methylated product in solution. After the addition of the reagents (90 minutes) the temperature was raised to 80° for 30 minutes. The excess alkali was neutralised with dilute sulphuric acid and the cold solution poured slowly into ethyl alcohol (1·5 l.) and kept overnight. The separated sodium sulphate was filtered off and extracted with alcohol. The combined alcoholic solution and extracts were concentrated *in vacuo* to a viscid syrup which was dissolved in water (20 ml.) and re-methylated with dimethyl sulphate (100 ml.) and 30 % sodium hydroxide (210 ml.) in the presence of acetone at 35–40°. The product was isolated as previously described as a fine light brown powder. Yield, 10 g. $[\alpha]^{18°}_{5780}+80°$ (*c*, 2·0) in chloroform. (Found: OMe, 36·1 %.)

The above product was re-methylated twice with silver oxide and methyl iodide and the resulting almost completely methylated mannocarolose was obtained in the form of a cream-coloured powder. Yield, 10·5 g. M.P. 95–100°; $[\alpha]^{18°}_{5780}+102°$ in chloroform (*c*, 2·0). (Found: OMe, 44·2 %.) It was observed that the specific rotations of the partially methylated fractions gave a good indication of their methoxyl contents.

Fractionation of methylated mannocarolose.

The different preparations of methylated mannocarolose having $[\alpha]^{21°}_{5780}+102°$ in chloroform and methoxyl content, 44·4 %, were mixed (20 g.) and separated into three fractions as follows. The combined material (20 g.) was boiled for 20 minutes with ether (200 ml.), which was decanted, and then for a further 10 minutes with fresh ether (200 ml.). A gummy residue (A) remained undissolved. To the mixed ether solutions was added light petroleum (B.P. 40–50°), (400 ml.) with vigorous stirring. An oily precipitate (B) separated and the clear mother-liquor was decanted after standing for an hour. Evaporation of the solvent left a gummy residue (C). Each fraction was obtained as a cream-coloured powder by trituration with light petroleum (B.P. 40–50°) and had the following properties:

Fraction	Yield (g.)	% OMe	$[\alpha]^{20°}_{5780}$ in chloroform	Apparent mol. wt. by viscosity	Mol. wt. (Rast)
A	6·2	44·3	+102°	1960	2010
B	9·8	44·5	+102·5°	1960	1926
C	3·8	44·1	+101°	1960	2000

These results indicate that fully methylated mannocarolose prepared either by method 1 or 2 is fairly homogeneous. This compound was readily soluble in cold water, acetone, chloroform, methyl and ethyl alcohols, slightly soluble in ether and insoluble in hot water and light petroleum. (Found: C, 53·1; H, 7·8; OMe, 44·4 %. $(C_9H_{16}O_5)_x$ requires C, 52·9; H, 7·9; OMe, 45·6 %.)

Hydrolysis of methylated mannocarolose.

Methylated mannocarolose is comparatively stable towards acid. It was unaffected by 8 % methyl alcoholic hydrogen chloride even after boiling for several hours, but was completely hydrolysed by fuming hydrochloric acid at 15° in 4 days, the specific rotation $[\alpha]_{5780}^{15^\circ}$ changing from $+71^\circ$ to $+5{\cdot}2^\circ$ (c, 1·0). 15·3 g. were hydrolysed in fuming HCl (150 ml.) at 15° for 4 days. There was considerable darkening in colour of the solution towards the end of the reaction. The excess acid was removed by aeration and the residual solution completely neutralised by the addition of barium carbonate. The solution was filtered after the addition of a little charcoal and the filtrate and washings made up to 500 ml. This colourless solution was extracted 8 times with chloroform (250 ml. each time). The combined chloroform extracts were dried over anhydrous magnesium sulphate, filtered and the chloroform removed by distillation, giving 3·1 g. of a viscid pale yellow syrup which was strongly reducing to Fehling's solution. $[\alpha]_{5780}^{15}+28{\cdot}6^\circ$ in methyl alcohol (c, 3·1). This syrup was converted into the methylmannoside by boiling with 3 % methyl alcoholic HCl for 12 hours, the product being isolated in the usual manner. Yield, 3·1 g. of a mobile non-reducing syrup (fraction a), $n_D^{16\cdot5}$, 1·4597; OMe, 56·4 %.

The chloroform-extracted aqueous solution was concentrated *in vacuo* at 40° to 100 ml. and then poured into 90 % ethyl alcohol (1 l.) and filtered. The alcoholic filtrate was evaporated to dryness and the residue extracted eight times with chloroform. This chloroform solution was combined with a chloroform extract of the solid barium chloride which had been collected by the above filtration and yielded on evaporation 12 g. of a colourless viscid syrup, n_D^{17}, 1·4740; $[\alpha]_{5780}^{18^\circ}+30^\circ$ (in MeOH). This syrup was converted into the methylmannosides in the usual manner. There were thus obtained 12 g. of a non-reducing colourless mobile liquid (fraction b), $n_D^{16\cdot5^\circ}$, 1·4640. (Found: OMe, 51·91 %.)

Further prolonged extraction with chloroform of the alcohol and barium chloride residues gave fraction c (0·8 g.) as a very viscid syrup, $[\alpha]_{5780}^{20}+27^\circ$ in methyl alcohol (c, 1·5), which was also converted into the methylmannoside. Yield, 0·8 g., n_D^{16}, 1·4735. (Found: OMe, 42·5 %.)

Fractional distillation of the methylated mannosides (fractions a, b, *and* c.)

Fraction b (12·0 g.) which consisted mainly of trimethyl-methylmannoside was distilled *in vacuo* from a Claisen flask and gave the following sub-fractions:

Sub-fraction	Pressure (mm. Hg)	Bath temperature	Yield (g.)	n_D^{17}
b_1	0·12	120–125°	2·0	1·4595
b_2	0·12	125–135°	6·0	1·4620
b_3	0·12	135–160°	2·6	1·4650
b_4	0·12	160–170°	0·8	1·4735

Sub-fraction b_1 was now mixed with fraction a (total weight, 5·1 g.) and distilled from a Claisen flask with a Widmer flask as a receiver for the first fraction, and gave the following sub-fractions:

Sub-fraction	Pressure (mm. Hg)	Bath temperature	Yield (g.)	n_D^{17}
a_1	0·09	115–125°	4·0	1·4585
a_1	0·09	125–135°	0·5	1·4610
a_3 (Still residue)	0·09	—	0·5	1·4690

Sub-fraction a_1 (4 g.) was now re-distilled very slowly through the Widmer column and gave the following sub-fractions:

Sub-fraction	Pressure (mm. Hg)	Bath temperature	Yield (g.)	n_D
First drop	0·09	115–118°	—	1·4535
a_4	0·09	115–120°	1·1	1·4560
a_5	0·09	120–125°	0·68	1·4560
a_6	0·09	125–128°	0·41	1·4560
a_7	0·09	128–135°	0·20	1·4565
a_8	0·09	135–150°	1·30	1·4620
a_9 (Still residue)	—	—	0·30	1·4620

The methoxyl content of sub-fraction a_4 was 58·08 %, and sub-fractions a_4 to a_7 had distilled without effective separation of constituents. Accordingly a thin spiral fractionating column was now used, leaving a space of 2 cm. between the top of the column and the side arm. The outside of the column was surrounded by a thick layer of asbestos paper. Sub-fractions a_4 to a_7 were combined (2·3 g.) and distilled as follows:

Sub-fraction	Pressure (mm. Hg)	Bath temperature	Yield (g.)	$n_D^{21°}$	% OMe
A_1	0·06	118–120°	1·71	1·4512	60·7
A_2	0·06	120–125°	0·30	1·4560	58·1
A_3 (Residue)	—	—	0·30	1·4610	51·5

The amount of tetramethyl-methylmannoside in sub-fraction A_2 was 0·15 g. Thus the total yield of tetramethyl-methylmannoside from sub-fractions A_1 and A_2 was 1·86 g. To this amount must be added a predetermined 10 % correction for losses so that the total yield of tetramethyl-methylmannoside was 2·046 g. from 15·3 g. of methylated mannocarolose, corresponding to 13·4 % of tetramethyl-methylmannoside and to a chain length of 8–9 units.

Analysis and identification of the 2:3:4:6-tetramethyl-methylmannoside.

The tetramethyl-methylmannoside from sub-fraction A_1 showed $[\alpha]_{5780}^{20°}+71°$ in methyl alcohol (c, 0·84), $[\alpha]_{5780}^{20°}+46°$ in water (c. 1·0). (Found: C, 52·9; H, 8·4; OMe, 60·7 %. $C_{11}H_{22}O_6$ requires C, 52·8; H, 8·9; OMe, 62·0 %.)

On treatment with $2N$ H_2SO_4 at 100° the tetramethyl-methylmannoside (1 g.) hydrolysed completely in 4 hours, the equilibrium rotation being $[\alpha]_{5780}^{17°}+4°$. The H_2SO_4 in the hydrolysate was removed by the addition of barium carbonate, the solution filtered, concentrated *in vacuo* and the products of hydrolysis isolated by extraction with chloroform: 0·9 g. of a syrup was obtained which was strongly reducing to Fehling's solution and had $n_D^{15°}$, 1·4631. This was treated with aniline in boiling alcohol in the usual manner and gave 2:3:4:6-tetramethylmannopyranose anilide in 85 % yield. It crystallised in long needles from a mixture of alcohol and light petroleum and had M.P. 142° alone or in admixture with an authentic specimen.

Analysis and identification of 2:3:4-trimethyl-methylmannoside.

Sub-fractions b_2, a_2, a_8, a_9, A_3, having B.P. at bath temperatures of 125–150° at 0·06–0·12 mm. and n_D, 1·4610–1·4620, were combined and re-distilled from a Claisen flask. The product distilled completely at 130–135°/0·08 mm. as a colourless mobile syrup, $n_D^{17°}$, 1·4620; $[\alpha]_{5780}^{20°}+58°$ in water (c, 1·25). (Found: C, 50·9; H, 8·8; OMe, 51·02 %. Trimethyl-methylmannoside $C_6H_8O_2\,(OMe)_4$ requires C, 50·9; H, 8·5; OMe, 52·5 %.)

Further methylation of 2:3:4-trimethyl-methylmannoside.

1 g. of re-distilled trimethyl-methylmannoside was methylated twice with silver oxide and methyl iodide in the usual manner and the product (1 g.), distilled at 0·08 mm. at a bath temperature of 115–118°, showed $n_D^{21°}$, 1·4515, and $[\alpha]_{5780}^{20°}$ $+42·5°$ (*c*, 0·83). This syrup was hydrolysed at 100° with 2*N* H_2SO_4, the rotation changing from $+42·5°$ to $+3·3°$ in 3 hours. 2:3:4:6-Tetramethylmannopyranose was isolated from the hydrolysis solution in the usual manner and gave 2:3:4:6-tetramethylmannopyranose anilide in 95 % yield, M.P. 142°, and identical with an authentic specimen.

Hydrolysis of 2:3:4-trimethyl-methylmannoside.

4 g. of trimethyl-methylmannoside were hydrolysed with 2*N* H_2SO_4 at 100 giving an equilibrium value of $[\alpha]_{5780}^{21°}$ $+6°$ after 3 hours. The hydrolysis product, 2:3:4-trimethylmannose, was extracted in the usual manner giving 3·8 g. of a colourless syrup having $n_D^{17°}$, 1·4735, $[\alpha]_{5780}^{21°}$ in water $+9°$ (*c*, 1·25) and OMe, 40·2 %. (Theoretical for $C_6H_9O_3(OCH_3)_3$, 41·9 %.) This syrup failed to give a crystalline anilide and gave an oily product on treatment in the usual manner with phenylhydrazine at 70° for 3 hours. The syrup crystallised on keeping in a desiccator for 3 months and was recrystallised from ether-light petroleum (B.P. 40–50°) in the form of triangular prisms, M.P. 94–96°, $[\alpha]_{5780}$ $+7°$ (equilibrium value) in water (*c*, 2·0). The M.P. 102–103° was higher when the substance was freshly crystallised as is the case with tetramethylglucose. (Found: C, 48·4; H, 8·3; OMe, 40·8 %. $C_6H_9O_3(OCH_3)_3$ requires C, 48·6; H, 8·1; OMe, 41·9.) Mutarotation in water (*c*, 20·4) zero hours $[\alpha]_{5780}^{20°}$ $+18·2°$; 5 min. $+15·3°$; 8 min. $+13·2°$; 17 min. $+9·1°$; 65 min. $+8·1°$; equilibrium value $+7·0°$.

Oxidation of 2:3:4-trimethylmannose.

2 g. of 2:3:4-trimethylmannose were warmed at 40° with bromine in aqueous solution for 48 hours and the lactone so formed was isolated in the usual manner. It was non-reducing to Fehling's solution and distilled at bath temperature 138–140° at 0·04 mm. Yield, 1·85 g. n_D^{21}, 1·4750, OMe, 41·7 %. (Theoretical for $C_9H_{16}O_6$, 42·3 % OMe.) Its hydrolysis curve in aqueous solution at room temperature was followed polarimetrically and was typical for the δ-lactone of the mannose series. Zero hours $[\alpha]_{5780}$ 158°; 17 hours, 122°; 22 hours, 110°; 38 hours, 105°; 48 hours, 103° (constant value). This behaviour is similar to that of a trimethylmannopyranolactone.

Further methylation of 2:3:4-trimethylmannopyranolactone.

0·5 g. of 2:3:4-trimethylmannopyranolactone was methylated with silver oxide and methyl iodide. The product was isolated by extraction with chloroform and had $[\alpha]_{5780}^{20°}$ $+154°$, changing to $+77°$ in 24 hours. This lactone was shown conclusively to be 2:3:4:6-tetramethylmannonolactone by the formation from it in quantitative yield of the characteristic crystalline phenylhydrazide, M.P. 184–185°, alone or in admixture with an authentic specimen.

Rate of lactonisation of 2:3:4-trimethylmannonic acid at room temperature.

Initial $[\alpha]_{5780}$ $+22°$; 18 hours, $+61°$; 42 hours, $+77°$; 66 hours, $+93°$; 80 hours, $+98°$ (constant value). The amounts of lactone and acid at equilibrium were approximately 43 % and 57 % respectively.

Oxidation of 2:3:4-trimethylmannopyranolactone.

2:3:4-Trimethylmannopyranolactone (1 g.) was oxidised by heating with nitric acid (sp. gr. 1·42) for 8 hours at 90°. The excess nitric acid was removed by distillation *in vacuo* with water for 6 hours and the product esterified with methyl alcoholic HCl. The esters (0·55 g.) were distilled as follows:

Fraction	Bath temperature	Pressure (mm. Hg)	Yield (g.)	$n_D^{16°}$	$[\alpha]_{5780}^{21°}$ in methyl alcohol
I	120–125°	0·06	0·31	1·4400	−9°
II	125–135°	0·06	0·13	1·4440	−22°
III	135–150°	0·06	0·10	1·4500	—

On nucleation with methyl *i*-dimethoxysuccinate, fraction I crystallised almost completely. The crystals after being drained on a tile and recrystallised from ether-light petroleum (B.P. 40–50°) had M.P. 68° alone or mixed with an authentic specimen of inactive methyl dimethoxysuccinate. Yield 0·1 g.

The non-crystalline portions of fractions I and II were treated with methylamine in dry methyl alcohol to form the methylamides. After keeping overnight, crystals in the form of long needles (0·07 g.) separated and were recrystallised from a mixture of ethyl acetate and ether; M.P. 210° alone or in admixture with an authentic specimen of inactive dimethoxysuccinomethylamide. The mother-liquors from the preparation of the methylamide were concentrated and crystallised completely (0·15 g.), M.P. 160–165°. Fractional crystallisation from ethyl acetate-ether gave 0·07 g. pure crystals, M.P. 171°, $[\alpha]_{5780}+58°$ in water (*c*, 0·56). This compound was shown to be *d*-arabotrimethoxyglutaromethylamide. It was found that an effective and less tedious separation of inactive dimethoxysuccinomethylamide from *d*-arabotrimethoxyglutaromethylamide could be effected by fractional sublimation of a mixture of the two substances either at ordinary pressures or *in vacuo*, the latter substance subliming at a much lower temperature than the former.

Analysis and identification of 2:3-dimethyl-methylmannoside.

Fraction *c* and sub-fractions a_3, b_3 and b_4 were combined and redistilled at a pressure of 0·08 mm. The fraction distilling with a bath temperature of 155–160° and weighing 1·5 g. had $n_D^{17°}$, 1·4735; $[\alpha]_{5780}^{21°}+64°$ (*c*, 1·25 in water). (Found: C, 49·4; H, 8·5; OMe, 41·1 %. Dimethyl-methylmannoside $(C_6H_9O_3(OCH_3)_3$ requires C, 48·6; H, 8·1; OMe, 41·9 %.) It was found by the procedure given below that the fraction consists mainly of 2:3-dimethyl-methylmannoside. On further methylation with methyl iodide and silver oxide, 2:3:4:6-tetramethyl-methylmannopyranoside was obtained, B.P. 120°/0·09 mm., $n_D^{21°}$, 1·4515. It gave 2:3:4:6-tetramethylmannopyranose anilide, M.P. and mixed M.P. 142° in 95 % yield. The 2:3-dimethyl-methylmannopyranoside gave, after hydrolysis with $2N$ H_2SO_4 at 100° for 3 hours, 2:3-dimethylmannose, $[\alpha]_{5780}^{21°}+16°$ in water (*c*, 1·2). (Found: OMe, 29·4 %. Theoretical for $C_6H_{10}O_4(OCH_3)_2$, 29·8 %.) It gave an oily osazone on treatment with phenylhydrazine. On oxidation of 0·8 g. of the 2:3-dimethylmannose with bromine at 40° for 24 hours it gave mainly 2:3-dimethylmannofuranolactone (0·6 g.), $[\alpha]_{5780}^{18°}+106° \rightarrow +66°$ in 14 days. This lactone on further oxidation with nitric acid (sp. gr. 1·42) yielded only *i*-dimethoxysuccinic acid, M.P. 68° (0·15 g.) characterised by the formation of its methylamide, M.P. 210°.

SUMMARY.

The molecular structure of mannocarolose, a polysaccharide produced from glucose by *Penicillium Charlesii* G. Smith, has been investigated. On acid hydrolysis mannocarolose gives *d*-mannose as the sole hydrolytic product.

Mannocarolose gives a methyl derivative which, on subsequent hydrolysis followed by glycoside formation, gives a mixture of 13·4 % of 2:3:4:6-tetramethyl-methylmannopyranoside, 75 % 2:3:4-trimethyl-methylmannopyranoside and 10 % of 2:3-dimethyl-methylmannopyranoside. Molecular weight determinations on mannocarolose and on its acetyl and methyl derivatives indicate that the chain length of mannocarolose is represented by 8–9 units of *d*-mannopyranose linked through the 1:6 positions. This is a unique molecular structure for a polymannose. Mannan A occurring in vegetable ivory has on the other hand the same structural linking as cellulose where the hexose units are joined at positions 1:4 [Klages, 1934]. Few of the naturally occurring mannans have been investigated and it is of interest that one form is present in the polysaccharide of the tubercle bacillus [Laidlaw and Dudley, 1925].

LXXIII. HISTAMINASE.

IV. FURTHER STUDIES IN PURIFICATION.

V. SOURCE OF THE AMMONIA FORMED IN THE HISTAMINE-HISTAMINASE REACTION.

By EARL WILLARD McHENRY and GERTRUDE GAVIN.

From the School of Hygiene, University of Toronto.

(*Received January 24th, 1935.*)

In a previous communication in which attempts to purify histaminase were discussed, the authors [1932] showed that when this enzyme causes the destruction of histamine, ammonia is liberated stoichiometrically. In this paper the results of further studies on methods of purification of histaminase and on the histamine-histaminase reaction are presented.

As in previous studies [Best and McHenry, 1930; McHenry and Gavin, 1932] kidney powder was used as a source of histaminase. The amount of enzymic activity was determined by measuring the amount of histamine remaining after incubation for 24 hours at 38° in a mixture which originally contained a known amount of histamine and enzyme preparation. All determinations of histamine have been made by the blood-pressure method in etherised cats [Best and McHenry, 1930].

IV. FURTHER STUDIES IN PURIFICATION.

As a basis for these investigations histaminase solutions were prepared by extracting 1 part of kidney powder with 25 parts of Sørensen phosphate buffer, p_H 7·2 for one hour at 38°. A single extraction yields 60 % of the enzyme contained in the powder, and the yield is increased to 80 % by a second extraction. Longer extraction periods (2–24 hours) gave no greater yields.

The authors [1932] reported that the presence of phosphate ions augmented the activity of histaminase. If this were due to the precipitation of traces of calcium, which have been shown by Best and McHenry to be inhibitory, one might expect that oxalate ions would have the same effect. Extraction of kidney powder with 1 % sodium oxalate was as satisfactory as extraction with phosphate solution. Varying the concentration of oxalate (0–0·53 g. per 100 ml.) during the incubation of histamine with histaminase gave the same type of curve as was found for the effect of the concentration of phosphate on the enzyme. It is likely that the similar effects shown by the oxalate and phosphate ions are due to the removal of calcium presumably contained in the crude histaminase.

The effects on histaminase of a number of substances known to activate or inhibit enzymes have been tested. Preservatives such as 0·3 % tricresol and 0·1 % sodium benzoate completely inhibited the enzyme. Methylene blue (0·2 %) gave 60 % inhibition at p_H 7·2 and the effect was not changed by the presence of 0·005 *M* potassium cyanide. Glutathione 0·1 %, cystine 0·01 %, cysteine 0·015 %, ergothioneine 0·005 % and phenolindophenol 0·008 % had no apparent effect on histaminase.

Several protein precipitants, in addition to those previously employed, have been used in an effort to fractionate histaminase solution. 40 % of the potency was recovered in the precipitate when just sufficient picric acid to cause a precipitate was added. Precipitation from a mixture containing 0·1 % flavianic acid destroyed all activity. Precipitation from a mixture containing 0·5 % tannic acid and extraction of the precipitate with cold aldehyde-free acetone to remove the tannic acid, gave complete recovery of the enzyme. This process increases the activity twenty-fold on a dry-weight basis.

Earlier work had shown that an ammonium sulphate precipitate of the enzyme could be dried to give a stable powder. As a basis for subsequent experiments in purification a large quantity of this precipitate was prepared as follows. 30 g. of kidney powder were extracted, first with 750 ml. and then with 600 ml. of phosphate solution. The combined filtrates were stirred for one-half hour with 4 g. carbex E (Pfanstiehl) per 100 ml. of solution and filtered. This removes about 10 % of the impurities and causes very little loss of potency. Ammonium sulphate to give 90 % saturation was added to the filtrate, the precipitate filtered off by suction and dried in a vacuum-oven at a temperature under 50°. A phosphate buffer solution of this dried precipitate was used in the following experiments. Ice-cold alcohol may be used to precipitate the enzyme. When the concentration of alcohol was varied between 30–90 % the amount of enzyme precipitated varied directly with the concentration of alcohol, a maximum recovery of 65 % being obtained with 90 % alcohol. On a basis of unit activity per g. this method gave little purification. From an ice-cold mixture of 10 parts enzyme solution, 10 parts alcohol, 6 parts ether, the precipitate contained 75 % of the original activity. Ice-cold aldehyde-free acetone also precipitated the enzyme. The percentage potency recovered increased in proportion to the acetone concentration with a maximum of 65 % activity with 90 % acetone. When the acetone, prior to admixture, was neutralised with sodium hydroxide, 95 % of the activity was recovered in the precipitate if the concentration of acetone was between 60–80 %. On a dry weight basis this procedure gave no apparent purification as phosphate was precipitated by concentrations of acetone above 50 %. By dissolving the ammonium sulphate powder in distilled water neutralised with sodium hydroxide and by treating this solution with acetone, a four-fold increase in activity on a dry-weight basis was obtained. A phosphate solution of this precipitate was stable for one month at refrigerator temperature.

Experiments were made on adsorption of the enzyme from a phosphate solution of the kidney powder. Histaminase was not adsorbed by Eastman's norite, darco, special carbon, Pfanstiehl's carbex E, or Lloyd's reagent. Kaolin in water, water and alcohol, phosphate buffer, phosphate buffer and alcohol showed no adsorption of the enzyme. The most useful method was the aluminium hydroxide procedure developed by Sherman *et al.* [1930], for pancreatic amylase. The gel was prepared as described by these authors. It was found advantageous to have both phosphate and alcohol present during the adsorption phase. The best proportions were found to be 6 parts gel, 5 parts alcohol, 4 parts phosphate buffer, 15 parts histaminase solution. This mixture was stirred for 15 minutes, centrifuged, and the supernatant fluid, which contained no potency, was discarded. Very little enzyme was eluted with 1 % ammonium hydroxide or with 1 % diammonium hydrogen phosphate. Elution with phosphate buffer p_H 7·2 and 8·8 gave 75 % recovery, while at p_H 5·9 there was a 50 % recovery. Increasing the concentration of phosphate three times or decreasing it to one-third normal gave lower yields. The most successful method of elution was to use a mixture of phosphate buffers p_H 6·0 to 7·2 and glycerol. Yields of 85–90 % of the original activity were obtained when the glycerol concentration was between 40–60 %. If a phosphate solution of an ammonium sulphate powder was used in the above procedure only a 50 % yield was obtained. A still lower yield was secured if a solution of the acetone precipitate of the ammonium sulphate powder was used. Attempts to precipitate the enzyme after elution by tannic acid were unsuccessful.

V. SOURCE OF THE AMMONIA FORMED IN THE HISTAMINE-HISTAMINASE REACTION.

We have previously found that during the histamine-histaminase reaction the iminazole nucleus of histamine is ruptured and also that at p_H 7·2 one mol. of ammonia per mol. of destroyed histamine is liberated. If this ammonia were formed from the side chain, a change in the amino-nitrogen content during the reaction would be expected. In preliminary experiments to ascertain the source of the ammonia it was found that, owing to the presence of interfering substances in the solution, colorimetric methods of determining amino-nitrogen could not be used. Measurements with the Van Slyke gas analysis apparatus were more successful. With this method it was essential first to remove the proteins from the solution to be tested. The routine procedure of precipitation with sodium tungstate carried down a portion of the histamine present. Other protein precipitants, *e.g.* molybdic acid, tungstomolybdic acid, tannic acid, alcohol, zinc sulphate, magnesium sulphate, lead acetate, precipitated all or a part of the histamine. With Schenk's reagent and with copper sulphate no histamine was precipitated but the resulting solutions were unsuitable for use in the Van Slyke apparatus. The method finally adopted was precipitating with 1 volume of 10 % trichloroacetic acid to 1 volume of kidney solution and washing the precipitate with 5 % trichloracetic acid solution. For each experiment 3 flasks were used: *A*, histamine + a phosphate solution of histaminase p_H 7·2 + toluene; *B* and *C*, a similar histaminase solution + toluene. These were incubated for 48 hours at 38° to destroy the histamine in flask *A*. After incubation histamine equivalent to that originally present in flask *A* was added to flask *C*. Flask *B* served as a control for the amino-nitrogen value of the enzyme solution. The proteins in each flask were then precipitated with trichloroacetic acid. Immediately before the gas analysis the trichloroacetic acid filtrates were neutralised and histamine

Changes in amino-nitrogen during enzymic destruction of histamine.

		Before incubation		After incubation		
		Mg. histamine initially present	Mg. amino-nitrogen theoretical	Mg. residual histamine (cat assay)	Mg. amino-nitrogen theoretical	Mg. amino-nitrogen as found
Histamine inactivated (flask A)	(*a*)	109	14	0	0	1·1
	(*b*)	109	14	1	0·1	0·8
	(*c*)	109	14	4	0·5	3·1
	(*d*)	87	12	11	1·4	2·0
	(*e*)	109	14	20	2·6	2·9
Control (flask C). *Note.* Histamine added after incubation	(*a*)	109	14	56	7·3	6·6
	(*b*)	109	14	98	12·8	12·4
	(*c*)	109	14	102	13·2	13·1
	(*d*)	87	12	71	9·2	8·1
	(*e*)	109	14	92	11·9	10·9

assays were made by the blood pressure method in etherised cats. It will be seen in the following tables that when large amounts of histamine were inactivated there frequently remained a small amount of amino-nitrogen in excess of that due to the kidney solution and any remaining histamine. Some inactivation of histamine took place in the control flasks probably owing to the high temperature in the laboratory during the experiments.

From these results it is evident that there is a very marked fall in amino-nitrogen value during the destruction of histamine. This would indicate that the ammonia formed during the reaction is derived from the amino-nitrogen of the side chain and that the rupture of the iminazole nucleus yields no amino-compounds.

SUMMARY.

A number of procedures for the concentration of histaminase have been described. During the histamine-histaminase reaction the amino-nitrogen value falls almost to zero indicating that the ammonia liberated is derived from the side chain of the histamine molecule.

Grateful appreciation is expressed to Miss Neta Thompson for valuable assistance and to Dr C. H. Best and Dr J. G. FitzGerald for their continued interest in the investigation.

LXXIV. A NEW TYPE OF MICROBURETTE.

BY NORMAN GEORGE HEATLEY.

From the Biochemical Laboratory, Cambridge.

(*Received January 25th, 1935.*)

DURING the last decade several microburettes have been described, notably those of Benedetti-Pichler [1926], Kirk [1933], Linderström-Lang and Holter [1931; 1933], Rehberg [1925], Schilow [1927], Schwartz [1933] and Widmark and Orskov [1928]. Till a year ago, none of them, with the possible exception of that of Pincussen [1927], was specially designed for serial titrations. Two different types have been described during the last year, which are specially designed for this purpose.

That of Conway [1934] is simple, easy and cheap to make, and accurate. Though entirely suitable for the purpose for which it was designed, it can only be used with one solution.

The tapless microburette of Links [1934] is more complicated but it can be used with different solutions; it is not difficult to clean and has most of the advantages of the screw-controlled type. It can be used with any solution as the latter does not come into contact with the mercury.

The burette described below was designed before the description of either Links's or Conway's apparatus came to the attention of the author and had been, in fact, partly constructed. It is not as accurate as some other types, but as it has been in use for several months with satisfactory results, and as it can be made from the material usually available in the laboratory, its description may be of some interest.

Some of its main advantages are as follows:

1. The readings are taken at a mercury-air surface.
2. The titrating reagent only comes into contact with pyrex glass, paraffin wax and paraffin oil, and once prepared is never exposed to the air.
3. A large number of titrations can be carried out without refilling.
4. The titrating reagent can be changed almost instantaneously.
5. No cleaning is necessary when changing reagents.
6. Calibration is simple and direct.
7. The burette can be used for small quantities.

PRINCIPLE.

The apparatus is similar in principle to the measuring device of Hahn [1929]. The various titrating fluids are contained in small bottles, each of which is fitted with two tubes, a delivery tube (with a titrating point) and a second tube which connects the bottle to the burette proper. An exactly measured volume of liquid paraffin is displaced from the burette into the bottle, from which in turn an equal volume of titrating fluid is delivered.

CONSTRUCTION.

1. *Stock bottles.* For stock bottles, 2 oz. "Kali" bottles are chosen and coated inside with paraffin wax. An ordinary cork is bored to carry a 5 mm. tube, *H* which ends flush with the bottom of the cork, and a delivery tube of pyrex

glass bent twice at right angles and passing to the bottom of the bottle. The cork is boiled in paraffin wax for a time, then the tubes are fitted, and the cork is forced as tightly as possible into the neck of the bottle while the wax is still hot. The solution with which the bottle is to be filled is sucked up the delivery tube (by applying suction to *H*), and when it is nearly full, pure paraffin oil is poured down the tube *H* in such a way as to exclude all air.

2. *Burette proper.* The general scheme of the apparatus will be seen from Fig. 1. *B* is a length of graduated thermometer tubing, calibrated by weighing a thread of mercury of known length. It is connected at one end with the pressure-regulating mechanism *C*, and at the other, through the bulb *D*, with an ordinary three-way stopcock *E*. The second tube of the stopcock expands into the reservoir *F*, and the third is connected with a shallow U-shaped piece of capillary tubing *M*; to this is attached the tube *H* of the stock bottle. The reservoir *F*, tube *M*, tap *E*, and the upper half of the bulb *D* all contain paraffin oil. The lower half of *D* and the burette stem *B* contain mercury, as does the pressure-regulating mechanism *C*. When *C* is lowered, and *F* is connected to *D*, the mercury column in *B* will flow towards the zero mark; when *C* is raised, and the tap is turned through 180 degrees, the mercury will travel along the scale in the opposite direction and expel an equivalent volume of titrating fluid from the titrating point.

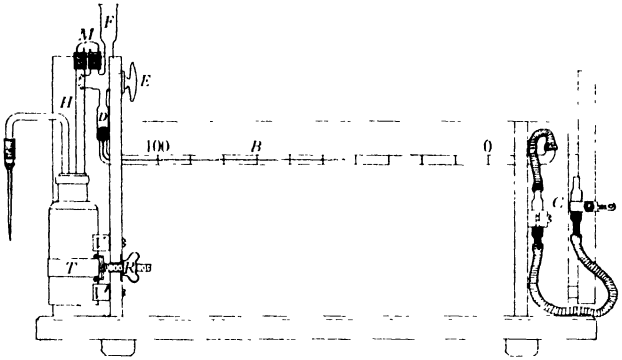

Fig. 1.

3. *Stand.* Absolute rigidity is essential for the proper functioning of the burette. This is obtained by clamping the stock bottle against the two V-shaped wooden chocks *V* and *V'*, by means of the flexible copper strip *T*, which is tightened by the butterfly nut *R*. (The blocks are allowed a certain amount of horizontal play to allow proper alignment of *H* with *M*, before tightening *R*.) The slide track, *etc.*, for the pressure-regulating mechanism was constructed from curtain rail fittings obtained from a sixpenny store.

4. *Titrating point.* This can be drawn from the delivery tube itself, though such an arrangement is extremely inconvenient if the tip gets damaged. A separate tip can, of course, be fitted with a properly ground joint, but after a certain amount of experiment, the joint described below has been found to be entirely satisfactory. The delivery tube of the stock bottle is first drawn out so that it will fit snugly into some pyrex tubing (Fig. 2, *a*). This latter tubing is then drawn out to a capillary from 4 to 6 inches long and is cut close above the drawn out part (Fig. 2, *b*); *a* is then moistened with water and dipped into carborundum powder, and the tip is roughly ground on. (It is not necessary to do more grinding than will prevent the sharp edges from splintering.) What grinding there is should be at the tip of *a* and not at the shoulder. Both parts are then thoroughly

cleaned and dried, and the titrating tip is drawn down to the requisite fineness. A blob of vaseline is placed on *a*, and *b* is gently warmed, so that on fitting it on to *a*, the vaseline will flow into the annular space between the two tubes. Finally a piece of rubber tubing which has been moistened inside with paraffin is pushed over the joint; it is easy to arrange that the rubber is in a state of tension, thus holding the tip firmly in position (Fig. 2, c).

The tip must be protected when not in use, and the titrating fluid must be prevented from syphoning over. This can be done in the following way. A piece of thin rubber tubing is placed over the shoulder of the titrating point so as to act as a cushion. The mouth of the pyrex tube (Fig. 2, *d*) is held against this, so as to make an airtight joint, by an elastic band which passes over the horizontal part of the delivery tube (this and the copper stirrup by which it is attached to the pyrex tube are not shown on the diagram). The protecting tube contains a small amount of titrating fluid covered by a layer of paraffin oil.

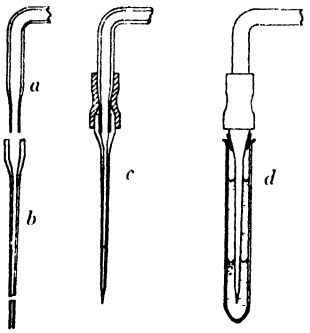

Fig. 2.

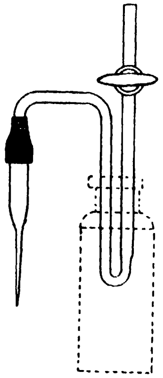

Fig. 3.

MANIPULATION.

The stock bottle is loosely clamped in position by the strip *T*, and the tube *H* and its rubber connection are filled with paraffin. (A small wash-bottle containing paraffin is convenient for this purpose.) Whilst the tube *M* is being pushed home, the tap *E* is momentarily opened. The butterfly nut is then tightened, and the protecting tube is removed from the titrating point. A small amount of the reagent is run out of the titrating point, and the mercury in *B* is brought back towards the zero mark by lowering *C* and connecting *D* to *F*.

The titration is carried out by raising *C* and turning the tap through 180 degrees. As there are no drainage errors, it does not matter how fast the first part of the titration is carried out; towards the end-point, however, *C* is lowered so that there is only a slight positive pressure, sufficient to expel the fluid from the titrating point only when the latter is immersed in the liquid being titrated. The fluid is prevented by surface tension from escaping when the tip is withdrawn. This principle has been used by Schilow, Schwartz, Linderström-Lang and others, and by its means the end-point can be very carefully controlled.

Use of burette for small samples.

Fig. 3 shows an arrangement which is used for solutions of which only a small quantity is available. In this case the bottle merely acts as a stand, the tube *H* being continuous with the delivery tube. It is used as follows: a short piece of pyrex tubing wide enough to fit over the delivery tube is drawn out to a titrating point. It is then filled with paraffin and attached to the delivery tube as shown by a rubber sleeve. The tube *H* is attached to the burette as usual, and the tap *P* is opened. The required fluid is then sucked up the titrating point by lowering *C*, the tap *E* being in the appropriate position. The titration is then carried out in the usual way and the titrating tip is discarded when finished with.

This attachment has been found useful when dealing with enzyme solutions *etc.*, for not only can the whole of the solution be used, but the exact volume of it is known before measuring it out. The ability to use all the available solution is not often an advantage, but as far as the author knows, such a property has not been claimed for any other microburette, though a number could easily be adapted for this purpose.

ACCURACY.

The burette in use has a scale approximately 25 cm. long and a capacity of 0·1 ml. It is divided into a hundred parts, each division representing 1·0 μl. To test the accuracy of the apparatus, twelve samples of approximately decinormal sulphuric acid were accurately measured out and titrated against decinormal NaOH from the burette, using methyl red as indicator. The following results were obtained:

Tube no.	Volume of *N* NaOH required (μl.)	Deviation from mean	% error
1	51·6	0·2	0·4
2	51·7	0·1	0·2
3	51·8	0	0
4	51·9	0·1	0·2
5	52·1	0·3	0·6
6	51·7	0·1	0·2
7	52·1	0·3	0·6
8	51·8	0	0
9	51·8	0	0
10	52·2	0·4	0·8
11	51·6	0·2	0·4
12	51·4	0·4	0·8

These results leave much to be desired, but it must be remembered that the scale is comparatively short, and in the above titrations, which were selected at random, only half of it was being used.

At first the tap *E* was lubricated with a paraffin-rubber composition, but it was found that this soon became softened and dissolved by contact with the liquid paraffin, and a certain amount of creep was liable to occur. This difficulty was got over by using an aqueous starch-glycerol lubricant, prepared as follows: 0·5 g. of Kahlbaum soluble starch is stirred up with 0·2 ml. of 5 % mercuric chloride solution and 0·7 ml. of water and heated in a boiling water-bath for 10 minutes; 0·5 ml. of glycerol is then added and stirred in whilst the mixture is still hot. It thickens considerably on standing and should not be used till 3 or 4 hours after preparation.

The rubber joints at each end of the tube *M* slowly swell and absorb paraffin. The actual rate of absorption has no disturbing effect on the titration, but the tubing, which of course is thick-walled, must be renewed when it becomes too loose fitting.

Note. A second burette has been constructed which is similar in all respects to the above, except that two calibrated tubes are incorporated instead of one. They are of 0·5 and 0·05 ml. capacity respectively and are connected to bulb *D* through a two-way tap, so that either can be used.

LXXV. UNSATURATED ACIDS OF NATURAL OILS.

I. HIGHLY UNSATURATED ACIDS FROM OITICICA OIL (*LICANIA RIGIDA*).

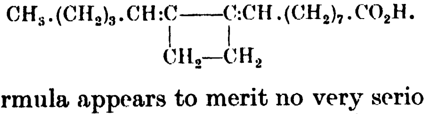
By WILLIAM BERNARD BROWN
AND ERNEST HAROLD FARMER.

From the Organic Chemistry Department, Imperial College of Science and Technology, South Kensington, London.

(*Received January 30th, 1935.*)

Oiticica oil comes into the market from Brazil in two forms, (1) as a fat of melting-point about 20° and (2) as a permanent oil. The botanical source of the oil has been for some years in doubt, being variously ascribed to the fruits of *Couepia grandiflora* (or *grandifolia*), *Licania rigida*, *Moquilea tomentosa*, *Pleragina umbrosissima*, *Arruda camara* and several other trees. The most recent opinion, however, ascribes the oil to the kernels of *Licania rigida*.

The authors' experiments were begun with the intention of investigating the constitution of the most highly unsaturated acid present (as a glyceride) in the oil of *Couepia grandiflora*, which according to the work of Van Loon and Steger [1931] is a conjugated triene acid, $CH_3.(CH_2)_3.(CH{:}CH)_3.(CH_2)_7.CO_2H$, isomeric with elaeostearic acid. If the constitution thus assigned were correct the new acid would add a third conjugated isomeride (supposedly of *cis-trans* type) to the two well-known forms (α- and β-) of elaeostearic acid.[1] The new acid, a substance very prone to atmospheric oxidation, has been designated by Van Loon and Steger couepic acid, and its constitution depends on its reputed conversion into stearic acid by catalytic hydrogenation (three double bonds) and its oxidation by ozone to yield valeric acid and azelaic acid. The physical characteristics of the acid are represented as being considerably different from those of α-elaeostearic acid: the optical exaltation, in particular, is low (2·3) in comparison with that of α-elaeostearic acid (8), a circumstance on which Rossmann [1932] subsequently bases a criticism of the triene constitution assigned by Van Loon and Steger, suggesting in place of the latter the non-conjugated semi-cyclic constitution



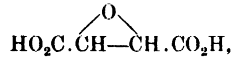
$$CH_3.(CH_2)_3.CH{:}\underset{CH_2-\!\!-\!\!-CH_2}{C-\!\!-\!\!-C}{:}CH.(CH_2)_7.CO_2H.$$

This semi-cyclic formula appears to merit no very serious consideration, but the multiplication of the isomerides of the economically important α-elaeostearic acid as reported by Van Loon and Steger—especially in view of certain recent experimental observations of Rossmann [1933] to the effect that elaeostearic acid passes on heating to 220° in an atmosphere of carbon dioxide into both a semi-cyclic isomeride and a dimeride—is of very great interest.

---

[1] Van Loon and Steger [1931] recognise five elaeostearic acids of which three (α-, β- and γ-) are stated to occur in chinawood oil, one (δ-) is obtained synthetically, and the fifth (ε-) is couepic acid.

The authors' attempts to obtain the authenticated fruits or oil of *Couepia grandiflora* proved unsuccessful and attention was turned to oiticica oil which appeared probably, although not certainly, to be the material actually employed by Van Loon and Steger. Two varieties of commercial oiticica oil and an adequate supply of oiticica kernels were obtained, the latter being definitely identified as kernels of *Licania rigida*. One of the commercial samples of oil was a semi-solid fat at room temperature, and this resembled the fat extracted by light petroleum from the disintegrated kernels (a faintly yellow oil until cooled); the other sample was permanently an oil and doubtless represented a "polymerised" oiticica oil which is obtained by heating the solvent-extracted or hot-pressed oil at 225° for about an hour. The permanently liquid oil, the heat-modified nature of which was not at first suspected by the authors, yielded on saponification a mixture of unsaturated and saturated acids from which the highly unsaturated component could readily be separated by crystallisation from petroleum. This acid, amounting to about 2 % of the total mixed acids (much of the original highly unsaturated acid having apparently undergone conversion into a petroleum-insoluble material), melted at 96·5° and rapidly absorbed oxygen from the atmosphere: it corresponded in all described characteristics with an acid, M.P. 94°, reported by Wilborn and Löwa [1929] to be isolable from *Couepia grandiflora*, but was apparently different from Van Loon and Steger's couepic acid (highest recorded M.P. 74–75°) in that it yielded on oxidation with permanganate not valeric acid and azelaic acid as principal products, as should a geometrical isomeride of elaeostearic acid, and as was indeed reported by Van Loon and Steger for their acid, but valeric acid and γ-ketoazelaic acid, $HO_2C.(CH_2)_4.CO.(CH_2)_2.CO_2H$. There was formed, however, in addition to the above-mentioned major products, a very small proportion of a dicarboxylic acid of M.P. 205°, doubtless fumarylglycidic acid



$$HO_2C.\overset{\diagup O \diagdown}{CH{-}CH}.CO_2H,$$

apparently derived by the dehydration of racemic acid.

Saponification of the two semi-solid fats yielded in each case a mixture of acids from which the highly unsaturated component could readily be isolated by crystallisation from petroleum. This substance was in each case the same, *viz.* an acid of M.P. 74–75°, which, although similar in general characteristics to the one from permanently liquid oiticica oil, showed a marked depression of melting-point on mixing therewith; furthermore in each case the acid was obtained in not less than 25 % (maximum isolated 33 %) yield, and in each case was unaccompanied by any considerable quantity of petroleum-insoluble acid. There was thus every indication that the semi-solid commercial oiticica oil was in reality licania oil in a state not seriously changed by the processes involved in its preparation. The subsequent observations are mainly concerned with the structure of what must now be regarded as the characteristic highly unsaturated acid of *Licania rigida*, and this acid is henceforth referred to as *licanic acid*. It is to be noted that the saturated and the less highly unsaturated acids of licania or oiticica oil have not been examined.

Licanic acid yielded on oxidation with permanganate valeric acid and a ketoazelaic acid identical with that obtained from the highly unsaturated acid of "polymerised" oiticica oil. These were the major products, but when oxidation was pushed well beyond the stage at which rapid decoloration of permanganate at 0° ceased, there were also obtained some oxalic acid (about $\frac{1}{3}$ mol.) and a quantity of syrupy and gummy acidic material which was susceptible of further slow oxidation with permanganate at room temperature. It is to be observed, however, that none of the dicarboxylic acid (M.P. 205°) referred to above was formed.

The ketoazelaic acid, which readily yielded a semicarbazone (M.P. 197°) and passed smoothly into azelaic acid on reduction by the method of Clemmensen, must necessarily be either the α- or γ-keto-derivative of the normal-chained dibasic acid, since it neither gave a colour with ferric chloride, as would a β-keto-acid, nor resembled the already-known δ-ketoazelaic acid (M.P. 108–109°; semicarbazone, M.P. 176–177°) synthesised by von Pechmann and Sidgwick [1904]. Its formulation as the γ-acid was confirmed by its degradation in the expected manner with Beckmann's chromic acid mixture; with this reagent it yielded as principal products adipic and succinic acids:

$$HO_2C.(CH_2)_4.\,\vdots\,CO\,\vdots\,.(CH_2)_2.CO_2H \rightarrow HO_2C.(CH_2)_4.CO_2H + HO_2C.(CH_2)_2.CO_2H.$$

In the presence of platinum licanic acid absorbed three molecular proportions of hydrogen yielding thereby hexahydrolicanic acid—an acid characterised by great stability towards permanganate but capable of forming a semicarbazone and possessing the empirical composition of a ketostearic acid. Thus, since both the two principal oxidation fragments are normal-chained acids, only two formulae offer themselves for the representation of licanic acid, *viz.* (I) and (II), which embody the two ways in which the ketoazelaic acid skeleton can be attached to the valeric acid skeleton whilst retaining triene unsaturation:

$$\text{(I)}\quad CH_3.(CH_2)_3.(CH{:}CH)_3.(CH_2)_4.CO.(CH_2)_2.CO_2H;$$
$$\text{(II)}\quad CH_3.(CH_2)_3.(CH{:}CH)_3.(CH_2)_2.CO.(CH_2)_4.CO_2H.$$

The correctness of the normal chain here depicted follows from the smooth conversion of the hexahydrolicanic acid into stearic acid by the method of Clemmensen:

$$\left.\begin{array}{ll}\text{(III)} & CH_3.(CH_2)_{13}.CO.(CH_2)_2.CO_2H \\ & \qquad\qquad\text{or} \\ \text{(IV)} & CH_3.(CH_2)_{11}.CO.(CH_2)_4.CO_2H\end{array}\right\} \rightarrow CH_3.(CH_2)_{16}.CO_2H.$$

Choice between the two formulae (III) and (IV) for hexahydrolicanic acid was made by oxidising the latter acid with chromic acid in acetic acid. The hexahydro-acid possessed a much higher degree of resistance towards chromic acid than did γ-ketoazelaic acid, but it broke down slowly on boiling with the oxidising mixture into a low-melting mixture of fatty acids and succinic acid; no adipic acid or glutaric acid was formed. The fatty acid product resembled myristic acid, but obviously was not homogeneous: doubtless it consisted of a mixture of myristic acid, $CH_3.(CH_2)_{12}.CO_2H$, and pentadecanoic acid, $CH_3.(CH_2)_{13}.CO_2H$, but, owing to the great difficulty of separating these acids, the isolation of the pure fatty acid components was not attempted with the amount of material at disposal. The dibasic acid complementary to pentadecanoic acid, *viz.* malonic acid would not survive under the conditions of oxidation. Of the two formulae (III) and (IV), III must therefore represent hexahydrolicanic acid; that is to say, hexahydrolicanic acid, M.P. 96·5°, is γ-ketostearic acid. Confirmation of this conclusion is supplied by the experimental establishment of identity between hexahydrolicanic acid and synthetic γ-ketostearic acid, M.P. 97°, the latter first obtained by Clutterbuck and Raper [1925] as an oxidation product of stearic acid and now obtained by repeating their preparation.

Licanic acid is accordingly γ-keto-$\Delta^{\theta,\kappa,\mu}$-octadecatrienoic acid (4-keto-$\Delta^{9:11:13}$-octadecatrienoic acid), represented by formula (I), and it is, so far as the authors are aware, the first ketonic polyene-acid outside the group of carotenoids to be described.

A point of interest arises in connection with the nature of the difference between the two triene acids described above. Both licanic acid and the acid from permanently liquid oiticica oil (*iso*licanic acid) are forms of γ-keto-$\Delta^{\theta\kappa\mu}$-octadecatrienoic acid, and the difference between the two would appear to be one of geometrical configuration about one or more of the double bonds. It is to be noted that only about half the quantity of acid taken readily undergoes degradation to valeric acid and γ-ketoazelaic acid, the remainder doubtless persisting as hexahydroxy-derivatives, which by reason of superior resistance to oxidative attack survive where their stereoisomerides undergo fission. The nature of these and of similar resistant polyhydroxy-acids obtained by oxidation of highly unsaturated acids is at present being investigated, but it is perhaps significant to find that although neither licanic nor *iso*licanic acid yields any appreciable quantity of racemic or mesotartaric acid, *iso*licanic acid gives a very small yield of fumarylglycidic acid (see p. 632).

Although there is nothing to show whether the oxide ring is formed during the oxidation process or subsequently by the dehydration of racemic acid, the appearance of the fumarylglycidic acid suggests that the middle double bond of *iso*licanic acid possesses a *trans*-configuration, in which respect it probably differs from licanic acid, which on further investigation may be found to yield the less-readily isolable maleylglycidic acid corresponding to mesotartaric acid.

It would seem likely that licanic acid is identical with Van Loon and Steger's couepic acid and that the latter authors' constitution for this acid is erroneous. There remains a possibility, however, that the botanical source of their *Couepia grandiflora* oil is a tree distinct from *Licania rigida*.

EXPERIMENTAL.

The triene acid from commercial oiticica oil (*liquid*). The liquid variety of oiticica oil as imported from Brazil was a dark golden yellow viscous liquid which from its permanent liquidity, comparatively high specific gravity (0·9898) and low iodine value (108·2) doubtless represented the so-called "polymerised" variety of oiticica oil, obtained by heating commercially expressed (or solvent-extracted) oil at 225°. The "polymerised" nature of the oil was not, however, known to the authors at the beginning of the work. The oil was saponified in the following way:

100 g. of oil were boiled under reflux for 5 hours with a solution made by dissolving 50 g. of caustic potash in the minimum quantity of water and diluting the product with 200 ml. of rectified spirit. The alcoholic solution of the potassium salts was made up to 500 ml. with cold water and then cooled in ice, cautiously acidified with 100 ml. of 45 % sulphuric acid (by weight) and finally shaken with 150 ml. of ether. The ethereal solution of fatty acids thus obtained was washed with water, dried with anhydrous sodium sulphate and gently warmed to remove the bulk of solvent; the free fatty acids were obtained by removing the residual solvent at reduced pressure without further heating.

The saponification product was immediately mixed with petroleum (B.P. 40–60°): at first a homogeneous solution was obtained, but on further addition of the solvent two layers separated, the lower layer consisting apparently of the partially oxidised or "polymerised" components of the commercial oil. This portion was twice extracted with petroleum but not further utilised. The combined upper layer and petroleum extracts were concentrated to a bulk of

300–400 ml. and allowed to cool to room temperature: a highly unsaturated acid crystallised out which was only sparingly soluble in petroleum. This acid was collected and twice extracted with 150 ml. of boiling petroleum (B.P. 40–60°), the extracts being rapidly filtered, united and allowed to cool. The crystals which then separated were collected, washed with petroleum and stored under petroleum to prevent atmospheric oxidation, which rendered them somewhat sticky in the course of several hours and ultimately converted them into a liquid material. One further recrystallisation was always carried out before the acid was used: in this way colourless flaky crystals of M.P. 96·5° were obtained. The maximum yield of acid was 1·3 g. from 100 g. of oil. Owing to the rather rapid absorption of oxygen the acid was troublesome to analyse but gave figures showing it to be an octadecatrienoic acid (C, 73·8, 73·4; H, 9·6, 9·65 %. $C_{18}H_{28}O_3$ requires C, 73·7; H, 9·65 %). On exhaustive hydrogenation at room temperature and atmospheric pressure, in an alcoholic medium and using a platinum catalyst, the acid took up three molecules of hydrogen and yielded a saturated acid which did not decolorise permanganate even on boiling. This saturated acid which crystallised from rectified spirit in colourless flakes of M.P. 96° (C, 72·95; H, 11·5 %. $C_{18}H_{34}O_3$ requires C, 72·75; H, 11·8 %) proved to be identical with the hexahydrolicanic acid described below; moreover the semicarbazone of the acid (M.P. 126°) and its methyl ester (M.P. 49·5°) proved on direct comparison to be identical with the corresponding derivatives of hexahydrolicanic acid described below.

On oxidation with approximately 3 % permanganate at 0° the unsaturated acid took up readily 7·3 atoms of oxygen. At this stage of oxidation the principal products were a volatile fatty acid recognised as valeric acid (B.P. 180–185°; *p*-bromophenacyl ester, M.P. 64°, mixed M.P. 64°) and a solid acid which after several recrystallisations from chloroform melted at 108–109°; there were also obtained some oxalic acid and a quantity of partly oxidised material. The acid of M.P. 108–109° had the composition and basicity of a ketoazelaic acid, subsequently identified as *γ-ketoazelaic acid* (C, 53·35; H, 6·9 %; mol. wt. (dibasic), 204. $C_9H_{14}O_5$ requires C, 53·4; H, 6·9 %; mol. wt., 202), and yielded a *semicarbazone* of M.P. 197° (C, 46·0; H, 6·6 %. $C_{10}H_{17}O_5N_3$ requires C, 46·3; H, 6·6 %). All the above-named oxidation products were also obtained from commercial oiticica fat and from the fat from *Licania rigida* kernels and are more fully described below; another oxidation product, however, was isolated from the crude ketoazelaic acid in very small yield, and this has been obtained from neither of the other varieties of oil studied. This substance, which differed greatly from ketoazelaic acid in respect of its sparing solubility in ether, its high M.P. (205° with decomp.), and high oxygen content, appears from its composition, basicity and general properties to be the fumarylglycidic acid described by Lossen [1906] (C, 36·75, 36·65; H, 3·25, 3·2 %; equiv., 65·9. $C_4H_4O_5$ requires C, 36·35; H, 3·05 %; mol. wt., 132). The further study of the liquid form of oiticica oil has been postponed.

The triene acid from commercial oiticica fat. The commercial fat was a cream-coloured solid consisting of a mixture of glycerides. Like the liquid variety of oil it was readily saponifiable by boiling for 5 hours with strong alcoholic potash, the resulting potassium soap yielding on cautious acidification with dilute sulphuric acid and extraction as described above a partly solidifiable mixture of fatty acids. From this mixture, which set on cooling to a pale yellow waxy solid, the highly unsaturated component was isolated by dissolving the former in boiling petroleum (B.P. 60–80°) and filtering off the crystals which separated on cooling. These crystals melted at once at 73–74°, the highest M.P. attainable even after numerous recrystallisations from petroleum being 74–75°. The crystals absorbed oxygen on exposure to the air yielding a sticky liquid; consequently it was convenient to preserve the once-crystallised acid under petroleum and crystallise it still once more immediately before use. The yield of this acid, which is henceforth designated *licanic acid*, amounted to 33 %.

On analysis licanic acid gave figures indicating that it possessed the empirical composition $C_{18}H_{28}O_3$ (C, 72·85; H, 9·65 %; mol. wt., ebullioscopic, in alcohol, 277; equiv., 291·5. $C_{18}H_{28}O_3$ requires C, 72·9; H, 9·65 %; mol. wt., 292) and on hydrogenation at room temperature and atmospheric pressure (platinum catalyst) in an alcoholic medium took up 3 mols. (experimental figure, 3·05 mols.) of hydrogen to yield a saturated acid of M.P. 96°. This *hexahydrolicanic acid* crystallised in colourless flakes from alcohol, the purest specimens obtainable melting at 96·5°; it possessed ketonic properties, yielding a well-defined *semicarbazone* which crystallised from aqueous alcohol in colourless flattened needles, M.P. 126° (C, 64·1; H, 10·25 %. $C_{19}H_{37}O_3N_3$ requires C, 64·15; H, 10·5 %); moreover its analytical figures pointed to the empirical formula $C_{18}H_{34}O_3$ (C, 72·70; H, 11·55 %; equiv., 295. $C_{18}H_{34}O_3$ requires C, 72·75; H, 11·8 %; mol. wt., 298). On esterification with methyl alcoholic hydrogen chloride, the hexahydro-acid yielded the corresponding *methyl ester* which crystallised from alcohol in colourless plates, M.P. 49–50° (C, 73·1; H, 11·6 %. $C_{19}H_{36}O_3$ requires C, 73·1; H, 11·6 %).

Thus licanic acid is a keto-octadecatrienoic acid, and direct comparison of this acid with the isomeric acid of M.P. 96·5° obtained from the permanently liquid variety of oiticica oil showed the two substances to be quite different: on the other hand the hexahydro-acids derived from the two triene acids proved to be identical in M.P. and in the characteristics of their derivatives; moreover there was no depression of M.P. on mixing the two hexahydro-acids, their semicarbazones or their esters, and both acids yielded identical products on oxidation with chromic acid (see below).

Reduction of hexahydrolicanic acid by Clemmensen's method. 0·7 g. of the hexahydro-acid, dissolved in 15 ml. of concentrated hydrochloric acid, was boiled for 4 hours with 6 g. of zinc amalgam, during which operation hydrogen chloride was passed into the boiling solution. The product, on precipitation with water and filtration, yielded a mixture of two acids, the components of which were readily separable by fractional crystallisation from petroleum (B.P. 60–80°) into unchanged hexahydrolicanic acid (M.P. 96°; mixed M.P. 96°) and stearic acid; the latter was identified by comparison with an authentic specimen (M.P. 69·5–70°; mixed M.P. 69·5–70°) and by conversion into its methyl ester (M.P. 36°; mixed M.P. 38°). Thus hexahydrolicanic acid is a ketostearic acid.

Oxidation of licanic acid. 19·5 g. of the acid dissolved in a solution of 10 g. of sodium carbonate in 100 ml. of water were oxidised at 0° with 1320 ml. of 4·85 % permanganate (9·1 atoms of oxygen). The manganese mud was filtered off and extracted three times with boiling water, the filtrate and aqueous extracts so obtained being united, concentrated to a bulk of 200 ml. and then acidified with slight excess of concentrated hydrochloric acid. The acidic product was extracted four times with 125 ml. portions of ether and the aqueous liquor first freed from ether and then from oxalic acid by precipitation with calcium chloride in presence of free ammonia; finally the ammoniacal filtrate was evaporated to dryness, the residue taken up in a little water and the filtered solution cautiously acidified and re-evaporated to dryness. From the final residue 3·2 g. of syrupy and viscous acidic material were extracted by ether and acetone used successively; a portion of this material esterified with methyl alcoholic hydrogen chloride yielded an oil which decomposed on distillation. On removal of the solvent the ethereal extract yielded a partly crystalline residue: the liquid portion of this yielded 4·6 g. of pure valeric acid of B.P. 184° (86–88°/15 mm.), the identity of which was confirmed by the preparation of the corresponding *p*-bromophenacyl ester of M.P. 64° (mixed M.P. with an authentic specimen, 64°); the rather sticky solid residue yielded on crystallisation from chloroform 6·1 g. of the γ-ketoazelaic acid (M.P. 108–109°; semicarbazone, M.P. 197°) previously obtained by the oxidation of permanently liquid oiticica oil and 2·9 g. of a syrupy acidic residue. It was remarkable that the crude calcium oxalate obtained from the oxidation product (about 3 g.) contained no considerable quantity of the salts of mesotartaric or racemic acid, although the restriction of the quantity of permanganate to that actually employed might have been expected to lead to their formation.

A similar oxidation carried out with 37·5 g. of licanic acid yielded 12·6 g. of ketoazelaic acid, 5·9 g. of valeric acid, 3·6 g. of calcium oxalate and 4 g. of brown syrupy acid; a portion of the last on re-oxidation with permanganate yielded a further small quantity of ketoazelaic acid.

Constitution of ketoazelaic acid. 1 g. of ketoazelaic acid was boiled for 4 hours with 10 g. of amalgamated zinc and 15 ml. of concentrated hydrochloric acid through which hydrogen chloride was bubbled continuously. On extraction with ether the cooled product yielded an acid which on crystallisation from water formed colourless prisms, M.P. 105–106°. This acid was different from the original acid, depressing the melting-point thereof and yielding no semicarbazone: it was identified as azelaic acid (mixed M.P. 105–106°).

3·5 g. of ketoazelaic acid were boiled gently with 45 ml. of Beckmann's chromic acid mixture until the latter was completely reduced. On exhaustive extraction of the cooled product with ether 4·2 g. of dry acids were obtained. Preliminary examination of this mixture by fractional crystallisation showed it to contain succinic acid, probably adipic acid and a substance melting below 100°. The mixture was therefore dissolved in water, rendered alkaline with ammonia and the boiling solution treated with calcium chloride; from the calcium succinate precipitated 0·2 g. of pure succinic acid, M.P. 185° (mixed M.P., 185°), was obtained. The dry mixed acids (3·2 g.) recovered from the ammoniacal liquor consisted mainly of adipic acid and yielded on crystallisation from ether-chloroform slightly impure adipic acid which on one further recrystallisation from the same medium attained the M.P. of 148° and gave no depression of M.P. with an authentic specimen of adipic acid. The small acidic residue (M.P. 95–100°) recovered from the solvent yielded no glutaric anhydride on treatment with acetic anhydride and appeared to be somewhat impure ketoazelaic acid.

From the above evidence it follows that the ketoazelaic acid obtained from licanic acid is the γ-keto-compound, a conclusion which is in agreement (*a*) with the observation that this ketoazelaic acid gave no colour with ferric chloride in aqueous or alcoholic solution, and (*b*) with the fact that this acid differed in melting-point and in the melting-point of its semicarbazone from the δ-ketoazelaic acid described by von Pechmann and Sidgwick [1904].

Oxidation of hexahydrolicanic acid. 2·8 g. of the hexahydro-acid were dissolved in 25 ml. of glacial acetic acid and thereto 5·12 g. of chromic oxide (twice the calculated quantity) were added. The mixture was boiled for 3 hours on a sand-bath and then cooled. After diluting somewhat and filtering off unchanged acid the filtrate was saturated with sulphur dioxide, boiled to expel excess of this reagent, diluted and treated with excess of ammonia. The chromium hydroxide precipitated on boiling the alkaline liquor was filtered off and the filtrate evaporated to dryness. The residue was acidified with slight excess of concentrated hydrochloric acid and the product extracted several times with ether; the aqueous liquor was evaporated to dryness and the residue extracted first with ether and then with acetone. From the first ethereal extract, after evaporation of the solvent and the acetic acid contained therein, there was obtained a semi-solid mass, from which light petroleum removed a low-melting solid acid, leaving a small quantity of unchanged hexahydrolicanic acid; the low-melting acid (M.P. 25–30°), doubtless largely myristic acid contaminated with some proportion of pentadecanoic acid, was not further examined owing to the improbability of its complete purification being effected with the amount of material at disposal. The second ethereal extract and the acetone extract both yielded nearly pure succinic acid, melting at 185° on recrystallisation (mixed M.P. 185°). Since no trace of adipic acid was isolated the ketone group of hexahydrolicanic acid must be in the γ-position, the hexahydro-acid being accordingly γ-ketostearic acid.

The triene acid from the oil of Licania rigida *kernels.* The disintegrated kernels on extraction with petroleum (B.P. 60–80°) in a Soxhlet apparatus gave a 26·3 % yield of a clear golden yellow oil; when extracted with ether a 35·8 % yield of a rather turbid pale yellow oil was obtained. Both products when cooled in ice set to a faintly yellow-coloured fat which retained its solidity at room temperature. On saponification of the oil with alcoholic potash licanic acid, M.P. 74–75°, was obtained in a yield rather less than that from commercial oiticica fat. The identity of this acid with the acid from the commercial oil was fully confirmed by its behaviour on oxidation and hydrogenation and also by the identity of the corresponding derivatives of the two acids.

Preparation of hexahydrolicanic acid from stearic acid. By repetition of the oxidative procedure described by Clutterbuck and Raper [1925] γ-ketostearic acid was obtained in the form of colourless flakes, M.P. 96°; this acid yielded a semicarbazone of M.P. 126°. The acid and its semicarbazone were found by direct comparison to be identical respectively with the hexahydro-acid derived from each of the above-mentioned specimens of oiticica oil and its semicarbazone.

SUMMARY.

Two specimens of commercial oiticica oil have been examined in respect of the most highly unsaturated acid contained therein. Oiticica fat yields by saponification a solid triene acid (M.P. 74–75°), the constitution of which has been shown by degradative and synthetic methods to be γ-keto-$\Delta^{\theta\kappa\mu}$-octadecatrienoic acid, $CH_3.(CH_2)_3.(CH:CH)_3.(CH_2)_4.CO.(CH_2)_2.CO_2H$. This acid is found to be identical with that obtainable by saponification of the freshly extracted oil from the kernels of *Licania rigida*. Thus the source of oiticica oil, which has long been in doubt, is almost certainly *Licania rigida*, and the name licanic acid is now applied to the above-mentioned acid.

From the second or permanently liquid variety of oiticica oil another form of γ-keto-$\Delta^{\theta\kappa\mu}$-octadecatrienoic acid (M.P. 96·5°) has been obtained in small yield. This appears to differ from its isomeride in geometrical configuration only and is designated *iso*licanic acid. Since the permanently liquid oil appears to have been heat-altered during its commercial preparation, the *iso*-acid is probably all that remains of the original licanic acid, the remainder having been oxidised, cyclised or polymerised.

Licanic acid appears to be the first naturally-occurring ketonic unsaturated

acid to be described. It is in all probability the same compound as the "couepic acid" of van Loon and Steger.

The authors desire to thank the Government Grant Committee of the Royal Society for a grant to one of them, and also the Director of the Imperial Institute for valuable assistance in the identification of botanical specimens.

LXXVI. INDOLE FORMATION BY *BACTERIUM COLI.*

I. THE BREAKDOWN OF TRYPTOPHAN BY WASHED SUSPENSIONS OF *BACTERIUM COLI.*

By DONALD DEVEREUX WOODS.

From the Biochemical Laboratory, Cambridge.

(*Received January 31st, 1935.*)

Kuhne [1875] recognised indole as one of the products of the bacterial decomposition of proteins. The discovery of tryptophan by Hopkins and Cole [1901] was followed by the proof by these authors that tryptophan was the parent substance of bacterially formed indole [Hopkins and Cole, 1903]. They succeeded in isolating indole and indoleacetic acid from the products of the aerobic growth of bacteria (including *Bact. coli*) on a medium consisting of pure tryptophan and gelatin. Under anaerobic conditions they were able to isolate indolepropionic acid.

Hertzfeldt and Klinger [1915] studied, in roughly quantitative manner, the relationship between the disappearance of tryptophan and the production of indole with both indole-positive and indole-negative organisms. They used peptone medium and also a medium of pure tryptophan and salts, in which tryptophan was the sole source of nitrogen. In the latter case it is noteworthy that a form of bacterial suspension was used. Raistrick and Clarke [1921] investigated the bacterial decomposition of both the side chain and ring of tryptophan, but *Bact. coli* was not used. Fellers and Clough [1925] made a careful survey of the tests available for the detection of indole and skatole in bacterial cultures and applied them to a large number of bacterial species, but peptone and similar complex media were employed.

Bact. coli was chosen for the following work since it is a strongly indole-positive organism. An additional advantage is that *Bact. coli* does not decompose indole [Hertzfeldt and Klinger, 1915].

Experimental.

Most of the previous work on indole production has been done by means of growth experiments; it was decided here to employ washed bacterial suspensions for the following reasons. (*a*) The reaction occurs much more rapidly—about 36 hours instead of 3–4 days. (*b*) Pure tryptophan may be used as substrate and the reaction carried out in phosphate buffer, thus avoiding the complications incident to the use of bacterial media, such as the production of volatile phenolic substances. (*c*) Possible use of the tryptophan for bacterial growth is avoided. (*d*) Indole is the only volatile product.

In order to determine whether the indole produced could be recovered and estimated quantitatively from the bacterial suspension the following trial experiment was carried out. Distillation *in vacuo* of the cultures was tried in place of the steam-distillation, direct distillation or extraction with organic solvents previously used in this class of work. 2 ml. of stock *Bact. coli* suspension were added to 10 ml. of indole solution (containing 0·01–0·1 mg. indole per ml.). 10 ml. of this mixture were adjusted to p_H 9·2 [Zoller, 1920], using phenolphthalein as internal indicator, and washed into a small Claisen flask with 10 ml. water. This was distilled *in vacuo* almost to dryness, the tip of the condenser dipping below 10 ml. of water in an ice-cooled receiver. Two further amounts of 10 ml. of water were run into the flask and treated similarly. The temperature of the bath was not allowed to exceed 40°. The distillate and washings were made up to 100 ml. and were kept at 0° till estimated.

The distillation method of indole recovery has been criticised [Berthelot, 1914] on the grounds that some indole derivatives, *e.g.* β-indolecarboxylic acid decompose to indole on boiling. A number of indole derivatives (β-indolecarboxylic acid, β-indoleacetic acid, β-indolepropionic acid, β-indolepyruvic acid, β-indoleacrylic acid) have been submitted to distillation *in vacuo*, but no indole was detected, the lower temperature of distillation preventing any possible decomposition.

From a number of colorimetric methods available for the quantitative estimation of indole, that of Herter and Foster [1905], modified by Bergeim [1917] was chosen after trial. It has the advantage that the coloured compound formed is stable, and that the reaction is specific, no colour being given with skatole. Ammonia gives a green colour, but blank experiments in which culture distillates were shaken with synthetic permutit before estimation proved that sufficient ammonia to interfere was never present.

50 ml. of the distillate and 50 ml. of standard indole solution were run into separating funnels and to each were added 0·5 ml. of freshly prepared 1 % sodium β-naphthoquinonemonosulphonate and 1 ml. of 10 % potassium hydroxide. After standing for 15 minutes the blue solution was extracted successively with 5 ml. and 3 ml. of chloroform. The orange-red chloroform solution was run into 10 ml. volumetric flasks and made up to volume. The unknown and standard solutions were compared in a colorimeter with micro-plungers and cups (1 ml.). With concentrations of indole above 5 ml. of stock standard in 100 ml. the solutions were diluted with their own volume of water before estimation.

Stock standard. About 10 mg. of indole were weighed accurately, dissolved in a minimum volume of ethyl alcohol and diluted to 100 ml. with water. The solution remained constant in strength for 4–5 days if kept at 0°. Standard solutions of required strength were prepared from this stock standard.

Table I gives the percentage recovery of added indole from *Bact. coli* suspensions using the above method.

Table I.

Indole added (mg.)	Indole recovered (mg.)	% recovered	Indole added (mg.)	Indole recovered (mg.)	% recovered
0·927	0·901	97·2	0·515	0·500	97·1
0·927	0·888	95·8	0·515	0·492	95·6
0·927	0·895	96·5	0·206	0·199	96·4
0·721	0·684	94·9	0·206	0·197	95·7
0·721	0·695	96·4	0·103	0·100	97·3
0·515	0·499	96·9	0·103	0·097	94·5
				Mean	96·2

Preparation of bacterial suspensions. Bact. coli was grown on Roux bottles containing tryptic caseinogen broth agar. After 18 hours' incubation the growth of six bottles was washed off in the usual way with sterile precautions, washed and centrifuged twice with sterile Ringer's solution and finally suspended in 60 ml. of Ringer's solution and stored at 0°. The dry weight of 1 ml. suspension was 0·024 ± 0·003 g.

Tryptophan. The tryptophan used in this work was prepared from caseinogen according to Hopkins and Cole [1901], as modified by Dakin [1918]. It gave the following analytical figure:

Nitrogen % (micro-Dumas) 13·6 % Theoretical 13·7 %.

Indole formation from tryptophan.

In the following experiments small quantities of tryptophan were used since:

(*a*) the reaction is slow and if larger amounts are used a much longer time is needed for the completion of the reaction;

(*b*) it has been reported [Kilborn *et al.*, 1928] that 0·1 % of indole is toxic to *Bact. coli*. The concentration of indole formed in the experiments to be described did not exceed 0·01 %.

In view of the differing products obtained by Hopkins and Cole from the action of *Bact. coli* on tryptophan according to the degree of aeration, it was desirable to maintain good aerobic conditions. Air was bubbled through the suspensions at a steady rate. For each experiment the following quantities were used: 100 ml. tryptophan solution in phosphate buffer p_H 7·2 containing 20 mg. of tryptophan; 20 ml. stock *Bact. coli* suspension. The tryptophan solution was sterilised by filtration through a Seitz filter, and the apparatus was also sterilised. The solutions were run in with sterile precautions. The air current was turned on and the apparatus incubated at 37°. 10 ml. samples were removed aseptically at intervals and the indole formed was estimated by the method described. The p_H was checked with each sample and was found to remain constant.

In Fig. 1, curves *a*, *b* and *c* show some typical results obtained. Curve *d* shows the negligible autolytic production of indole when *Bact. coli* suspensions are incubated with water instead of tryptophan solution. Between 85 and 90 % of the theoretical yield of indole was obtained, though the time taken to reach this maximum varied between 16 and 36 hours. The yield of indole began to fall after reaching the maximum owing to volatilisation and the continuous aeration. 100 ml. of a solution of indole (of strength chemically equivalent to the

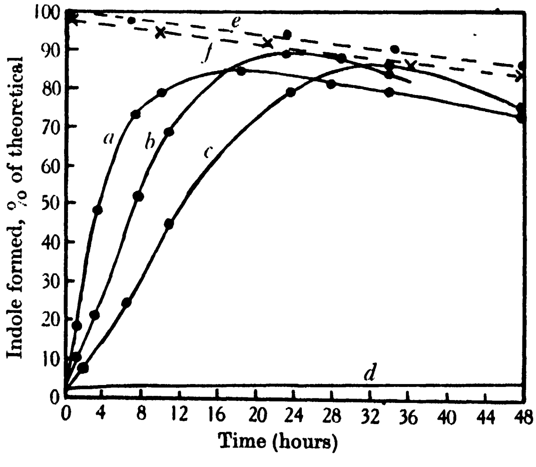

Fig. 1.

tryptophan solutions) was aerated together with 20 ml. of *Bact. coli* suspension (Fig. 1*e*). This curve gives the rate of loss of indole due to aeration. An experiment in which indole was aerated with a killed suspension of *Bact. coli* (Fig. 1*f*) proves that this loss is due to aeration and not to breakdown of tryptophan by *Bact. coli*, for the rate of loss of indole is identical in the two cases.

In Fig. 2 the curves *b* and *c* of Fig. 1 have been corrected for the steady loss of indole shown above and further for the average 4 % loss occurring in the distillation process. In each case the indole formed is shown to be 100 % of that theoretically obtainable from the tryptophan added. Four other experiments gave similar results.

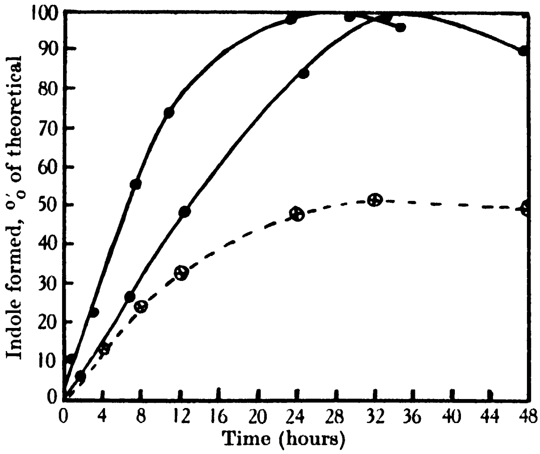

Fig. 2. ——— *l*-Tryptophan; - - - - *dl*-tryptophan.

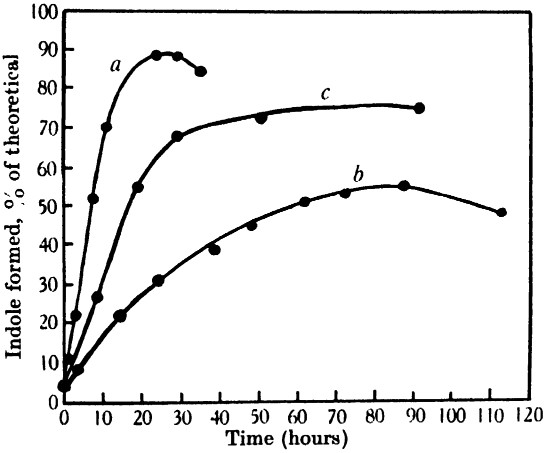

Fig. 3.

Hopkins and Cole [1903] isolated indoleacetic acid, as well as indole, from the products of the aerobic growth of *Bact. coli* on a medium of tryptophan, salts and gelatin; it will be seen that in the experiments described above there was no formation of this acid. This distinction is probably due to the different conditions under which the experiments were performed, for the present work using washed suspension differed from that of Hopkins and Cole in that: (*a*) the cultures were aerated, (*b*) a small amount of tryptophan and a large quantity of *Bact. coli* were used and (*c*) there were no other substrates present. It is possible that the presence of alternative sources of carbon and nitrogen modifies the course of the reaction. The course of breakdown of tryptophan by *Bact. coli* has been shown to be modified considerably by the addition of glucose and other sugars [Hertzfeldt and Klinger, 1915].

Effect of aeration. The degree of aeration was found to have a marked effect on the course and completeness of the reaction. In Fig. 3, curve *a* represents the (uncorrected) production of indole when air was continuously passed through the apparatus; curve *b* is from a non-aerated experiment; and curve *c* is from an experiment in which the culture was contained in a 500 ml. Ehlenmeyer flask. Attempts to detect indoleacetic acid in the culture filtrates at the end of the experiments were unsuccessful.

Rate of breakdown of tryptophan.

It was hoped that by studying the disappearance of tryptophan concurrently with the formation of indole further light might be thrown on the course of the reaction. In the previous work of Hertzfeldt and Klinger [1915] these had been shown to be roughly in agreement.

Two methods of estimating tryptophan were used and estimations of indole were carried out at the same time in the usual way.

(1) A colorimetric method making use of the condensation reaction between tryptophan and *p*-dimethylaminobenzaldehyde in the presence of hydrochloric acid. (Details as to quantities are from a private communication from Dr R. S. Alcock.) An aeration experiment with tryptophan solution and *Bact. coli* suspension was performed as described above and 10 ml. samples were removed for the estimation of indole and 15 ml. samples for the tryptophan determinations. The latter were filtered through kieselguhr and 12 ml. of the filtrate precipitated with 2 ml. of 30 % trichloroacetic acid and filtered with kieselguhr to remove proteins. 10 ml. of the filtrate were extracted three times with ether to remove indole and freed from ether by aeration. 4 ml. or less (according to the concentration of tryptophan, which should be 0·2–0·5 mg. in not more than 4 ml.) were taken for estimation. The tryptophan standard was diluted to the same volume as the test solution. To each were added 4 drops of 4 % *p*-dimethylaminobenzaldehyde (in alcohol) and 15 ml. of concentrated hydrochloric acid. After standing 2–3 days in the dark to develop the maximum blue colour, the solutions were diluted to 25 ml. and compared colorimetrically with a standard prepared in a similar way. In the later stages when the concentration of tryptophan had become very low, 6 and 8 ml. of the indole-free solution were taken for estimation and fuming hydrochloric acid was used instead of concentrated.

A typical result is shown in Fig. 4 (*a* and *b*). The broken curve (*a*) represents the percentage of tryptophan oxidised, the full line (*b*) the percentage of indole formed (corrected). It will be seen that there is complete correspondence.

(2) As tryptophan was the only amino-acid present it was possible to estimate it by determinations of amino-nitrogen. The manometric method of Van Slyke [Peters and Van Slyke, 1932] was chosen.

15 ml. samples from a tryptophan-*Bact. coli* aeration experiment were deproteinised by the addition of 4 ml. of 30 % trichloroacetic acid and filtered with kieselguhr. To 10 ml. of the filtrate were added 4–5 drops excess of Phillips's "milk of magnesia" and the solution was boiled down to half-volume in order to remove ammonia. After the addition of a slight excess of glacial acetic acid, the

clear solution was diluted to 10 ml. and 4 or 5 ml. samples were taken for estimation. A blank experiment was performed without tryptophan in order to determine the endogenous production of amino-N by *Bact. coli* from its own protein. The blank values were subtracted from the values obtained in the tryptophan experiment and the difference gives the amount of amino-N due to the tryptophan.

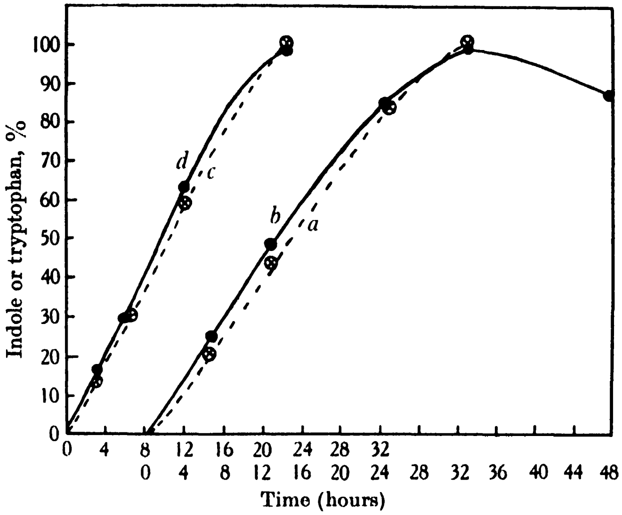

Fig. 4. ——— Indole formed, %; - - - - tryptophan broken down, %.

Table II gives the results of such an experiment.

Table II.

Time hrs.	Tryptophan exp. amino-N mg./100 ml.	Blank exp. amino-N mg./100 ml.	Amino-N due to tryptophan mg./100 ml.	% tryptophan remaining	% indole formed (corrected)
0	1·146	0·387	0·776	100	0
3·0	1·310	0·637	0·673	86·7	17·1
6·3	1·280	0·743	0·537	69·2	30·8
12·0	1·170	0·840	0·330	41·0	64·0
22·5	0·914	0·933	—	0	99·3

The results are given in graphical form in Fig. 4, curves *c* and *d*. It will be seen that identical results are obtained by the two methods; the rate of formation of indole is equal to the rate of disappearance of tryptophan and these experiments do not indicate any accumulation of intermediate products. The second method also measures the rate of deamination of tryptophan and the results lead to the conclusion that if more than one step is involved in the breakdown of tryptophan to indole, then the whole process is limited by the rate of deamination, since this is identical with the rate of formation of indole.

Oxygen uptake of the reaction.

The oxygen uptake of the oxidation of tryptophan to indole was measured in Barcroft manometers. 1 ml. *Bact. coli* suspension was placed in both cups; the left cup also contained 1 ml. buffer p_H 7·2 and 1 ml. water, and the right cup 1 ml. buffer and 1 ml. tryptophan solution (containing 1–5 mg. of tryptophan). The centre tubes of both cups contained 40 % KOH for the absorption of carbon dioxide. The reaction proceeded very slowly, however, and after 12 hours' shaking only 40 % of the theoretical amount of indole had been formed. Attempts were made to accelerate the reaction by adjustment of the concentration of the reactants, and also by the addition of oxygen carriers such as methylene blue, but with no success.

It was decided to put up a series of experiments and to compare the oxygen uptake with the indole formed at different periods. The contents of the Barcroft cups were washed out and diluted to a suitable volume and the indole was estimated in the usual way (see Fig. 5). The straight line relationship was more marked than was expected, for the high endogenous oxygen uptake of the thick *Bact. coli* suspensions necessary to bring about the reaction at a reasonable rate render small errors in the volume of suspension added very serious. The period of shaking (up to 12 hours) was also much longer than that normally used in accurate manometer work. The straight line relationship between oxygen uptake and indole formation renders justifiable a calculation of the oxygen uptake for the complete reaction. A series of eight experiments gave an average oxygen uptake of 472 μl. of O_2 per mg. of indole formed (Table III).

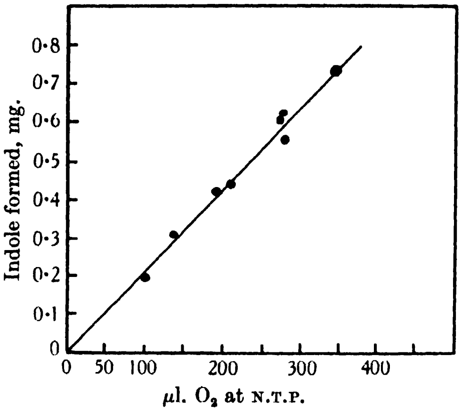

Fig. 5.

Table III.

O_2 uptake (μl. of O_2 at N.T.P.)	Indole formed mg.	μl. O_2 per mg. of indole	O_2 uptake (μl. of O_2 at N.T.P.)	Indole formed mg.	μl. O_2 per mg. of indole
101	0·191	528	278	0·608	457
134	0·312	428	279	0·628	444
190	0·418	455	281	0·543	517
207	0·432	479	345	0·735	469
				Mean	472

Theoretically, if the oxidation of 1 molecule of tryptophan is brought about by:

(*a*) 6 atoms of oxygen, then 570 μl. of O_2 per mg. of indole are required;
(*b*) 5 ,, ,, 475 ,, ,, ,,
(*c*) 4 ,, ,, 380 ,, ,, ,,

The conclusion seems unavoidable that 5 atoms of oxygen are involved in the oxidation of each tryptophan molecule. This agrees with an equation postulating the final complete oxidation of the tryptophan side chain to carbon dioxide and water, together with the elimination of nitrogen as ammonia:

$$C_8H_6N.CH_2CHNH_2COOH + 5O \rightarrow C_8H_7N + 3CO_2 + NH_3 + H_2O.$$

Experiments with inhibitors.

The effect of enzymic inhibitors on the course of the oxidation of tryptophan was studied. Barcroft manometric experiments were used for this purpose, since any change or stoppage of the reaction would be reflected by a change in the oxygen uptake. The following treatments were used:

(1) *Toluene.* The bacterial suspension was shaken with toluene, incubated for 10 min. at 37° and freed from toluene by aeration. The normal oxygen uptake was completely inhibited.

(2) *Chloroform.* The treatment was the same as with toluene, and in Barcroft experiments there was again no oxygen uptake.

(3) *Acetone. Bact. coli* suspension was centrifuged down, rubbed up with acetone, washed twice by centrifuging and finally suspended in the original volume of Ringer's solution. There was no oxygen uptake after this treatment.

(4) *Cyclohexanol.* The bacterial suspension was made 2 % with respect to cyclohexanol, incubated at 37° for 8–9 hours and washed as in (3). Oxygen uptake was again totally inhibited.

These results show the reaction to be very sensitive to inhibitors, and no information was obtained from them as to the course of the breakdown of tryptophan.

Anaerobic experiments.

A series of 75 ml. Thunberg tubes each containing 20 ml. of tryptophan solution of the usual strength and 4 ml. of *Bact. coli* suspension was set up. The tubes were evacuated, filled with nitrogen and incubated at 37°. At intervals during 48 hours tubes were taken out and indole was estimated. A regular formation of a small amount of indole, amounting in 48 hours to only 5·8 % of that theoretically possible, was noted. This is probably due to the presence of endogenous hydrogen acceptors in the bacterial suspension.

Hopkins and Cole [1903] have isolated β-indolepropionic acid from the products of the anaerobic growth of the Rauschbrand bacillus on tryptophan-gelatin medium. It was found impossible to devise a satisfactory method for the quantitative estimation of indolepropionic acid, but its anaerobic formation by *Bact. coli* suspensions from tryptophan was confirmed in the following way. After 48 hours' incubation the culture was filtered through kieselguhr, proteins were precipitated by warming at p_H 3·8 and the liquid was again filtered through kieselguhr. The filtrate was adjusted to p_H 1 and extracted with ether. The aqueous layer gave negative tests for tryptophan with bromine water and with the formaldehyde test. The ether solution, after concentration, was extracted twice with 1 % sodium carbonate solution and the extracts were diluted to the original volume of the tryptophan solution. Tests for β-indolepropionic acid were made on this solution by colour reactions given in detail in Table I of the following paper [Woods, 1935, p. 651]. A solution of β-indolepropionic acid of strength equivalent to the original tryptophan solution gave identical reactions of approximately the same intensity. No trace of any other indole derivative could be detected.

These results show that tryptophan is completely broken down by suspensions of *Bact. coli* under anaerobic conditions, and that the production of indolepropionic acid is almost quantitative.

Experiments with racemic tryptophan.

A sample of racemic tryptophan was prepared from *l*-tryptophan by the method given by du Vigneaud and Sealock [1932]. The production of indole from racemic tryptophan was studied by aeration experiments with *Bact. coli* suspension, similar to those already described for *l*-tryptophan.

A maximum production of 45·2 % of the theoretical quantity of indole was found. Correction for indole losses (see p. 643) brought this figure up to 51·0 %. The result of an experiment is shown in the broken curve of Fig. 2. The rate of fall of indole after the maximum was slower than usual, suggesting that there is a very slight and slow breakdown of the *d*-tryptophan. These experiments show that if *Bact. coli* is able to bring about the formation of indole from *d*-tryptophan at all, then it does so at a rate incomparably slower than from *l*-tryptophan.

SUMMARY.

1. The formation of indole from *l*-tryptophan by thick washed suspensions of *Bact. coli* has been studied. Under conditions of continuous aeration there is quantitative production of indole.

2. The degree of aeration has a marked effect on the rate and completeness of the reaction.

3. The rate of disappearance of tryptophan is identical with the rate of formation of indole.

4. The oxidation of one molecule of tryptophan to indole by *Bact. coli* requires five atoms of oxygen.

5. *d*-Tryptophan is broken down, if at all, at a very slow rate.

6. Under anaerobic conditions β-indolepropionic acid is formed.

My thanks are due to Miss M. Stephenson for constant advice and criticism, and to Sir F. G. Hopkins for his interest and encouragement.

LXXVII. INDOLE FORMATION BY *BACTERIUM COLI.*

II. THE ACTION OF WASHED SUSPENSIONS OF *BACTERIUM COLI* ON INDOLE DERIVATIVES.

By DONALD DEVEREUX WOODS.

From the Biochemical Laboratory, Cambridge.

(*Received January 31st, 1935.*)

A convenient technique for the quantitative investigation of indole formation having been described in the preceding paper [Woods, 1935], it was decided to study the action of thick washed suspensions of *Bact. coli* on various indole derivatives. Such derivatives, if intermediate stages in the breakdown of tryptophan by *Bact. coli*, should give rise to indole at least to the same extent and as rapidly as tryptophan itself under the same conditions.

Frieber [1922], in a series of growth experiments with *Bact. coli*, substituted a number of indole derivatives for tryptophan in his growth medium. He found no production of indole from the following compounds: α-indolecarboxylic acid, αβ-indoledicarboxylic acid, skatole, β-indolealdehyde, β-indoleacetic acid, β-indolepyruvic acid, β-indole-ethylamine. Saito [1933] found that, in growth experiments, *dl*-β-indolelactic acid (but not *l*-indolelactic acid) gave rise to indole when incubated in a suitable medium with *Bact. coli*. This formation of indole took place only in the presence of an alternative source of nitrogen—a mixture of ammonium lactate and asparagine was used. Unfortunately the tests for indole were qualitative only, and no data as to concentration of either indolelactic acid or indole are given, so that it is difficult to assess the importance of this result. Saito also finds that with β-indolepyruvic acid there is formation of indole if fresh cultures of *Bact. coli* are used. This was presumably in the presence of alternative sources of nitrogen, though this is not definitely stated; results were again qualitative. Saito's result with indolepyruvic acid does not agree with that of Frieber, whose medium also contained ammonium lactate, though not asparagine.

Preparation of the indole derivatives.

β-Indolepropionic acid was prepared from adipic acid by a series of reactions quoted by Berg *et al.* [1929]. The final colourless crystalline product melted at 133° (uncorrected). N (micro-Dumas), 7·35 %. Theoretical, 7·41 %. Equivalent (by titration in alcoholic solution), 188. Theoretical, 189.

β-Indolealdehyde was prepared as described by Majima and Kotaki [1922, 1], modified by Putochin [1926]. It was found more expedient to start the Grignard reaction in ether solution and to add the benzene solutions gradually. A considerable loss occurs during the steam-distillation of the crude product owing to resinification. This was avoided in the following way. The crude aldehyde formed on hydrolysis of the Grignard compound was centrifuged down, sucked dry on a Büchner funnel and washed on the funnel with a small amount of pure benzene. After drying at 37° it was ground up twice with light petroleum, filtered and dried. This treatment removes *N*-formylindole, indole and other unchanged reactants. The product was finally recrystallised twice from boiling water. From 10 g. of indole 3 g. of faint gold-coloured crystals M.P. 194° were obtained. N (micro-Dumas), 9·60 %. Theoretical, 9·66 %.

β-Indoleacetic acid was made from indole according to Majima and Hoshino [1925]. The chloroacetonitrile used was prepared from chloroacetamide [Steinkopf, 1908]. The product decomposed at 160–165° to skatole and carbon dioxide. N (micro-Dumas), 8·05 %. Theoretical, 8·00 %. Equivalent (by titration in alcoholic solution), 173. Theoretical, 175.

β-Indolecarboxylic acid. The method of Majima and Kotake [1922, 2] was used. The final product was faintly pink and melted at 215° (uncorrected). N (micro-Dumas), 8·64 %. Theoretical, 8·70 %.

β-Indoleacrylic acid was synthesised from β-indolealdehyde by the procedure described by Bauguess and Berg [1934]. The yellow crystals obtained melted with decomposition at 194° (uncorrected). N (micro-Dumas), 7·56 %. Theoretical, 7·49 %. Equivalent (by titration in alcoholic solution), 186. Theoretical, 187.

β-Indolepyruvic acid was prepared according to Ellinger and Matsuoka [1920] from β-indolealdehyde. The product, after removal of acetic acid of crystallisation, was buff-coloured. It darkened at 200°, softened at 206° and melted at 211° (all uncorrected). Berg *et al.* [1929] give these figures as 198°, 204° and 212°. N (micro-Dumas), 9·56 %. Theoretical, 9·66 %.

Experiments with indole derivatives.

In the work to be described the conditions were identical with those described in the preceding paper [Woods, 1935] in studying the breakdown of tryptophan. The following quantities were used: 100 ml. of a solution of the indole derivative in phosphate buffer p_H 7·2 (containing the chemical equivalent of 20 mg. of tryptophan). 20 ml. of *Bact. coli* suspension (prepared as described in the last paper). It was necessary to dissolve the derivatives in a small amount of dilute alkali as they are all soluble with difficulty in cold water. The p_H was adjusted to 7·2, buffer was added and the solutions were diluted to the required volume. They were sterilised by filtration and all experiments were conducted at 37°.

The culture filtrates used for testing for the derivatives were prepared in the following way. The suspension was filtered through kieselguhr and proteins were precipitated by warming at p_H 3·8. After filtering through kieselguhr the clear solution was adjusted to p_H 1–2 and extracted well with ether. The ether solutions were concentrated, extracted twice with 2 % sodium carbonate solution and the extracts diluted to the original volume of the suspension.

The colour reactions used for the detection of the various indole derivatives are given in detail in Table I.

Anaerobic experiments were conducted in Thunberg tubes, which were evacuated and filled with nitrogen.

β-Indolealdehyde. An aeration experiment with *Bact. coli* suspension was performed as described in the last paper. In 48 hours there was only the normal 1–2 % autolytic production of indole from the suspension itself.

β-Indolecarboxylic acid. There was no formation of indole from this derivative when aerated together with *Bact. coli* suspension.

β-Indoleacetic acid. This is a particularly interesting compound, since Hopkins and Cole [1903] have isolated it from the products of the aerobic growth of *Bact. coli* on tryptophan, whilst the washed suspension technique has been shown [Woods, 1935] to give only indole (in theoretical yield) and no trace of β-indole-

Table I.

All tests are on solutions containing 10 mg. of indole (or their equivalent) in 100 ml.

Test (3 ml. solution)	β-Indolepyruvic acid	β-Indoleacrylic acid	β-Indoleacetic acid	β-Indolepropionic acid	Skatole	Indole
1 ml. 50 % H_2SO_4 and 1–2 drops 2 % KNO_2	Purplish red colour insoluble in $CHCl_3$, soluble in amyl alcohol, giving cherry-red solution with absorption band at 550 $m\mu$ (1)	Yellow, then light pink colour, soluble in amyl alcohol to a pink solution	Cherry-red colour soluble in amyl alcohol	Golden yellow intensifying on warming. With higher concentrations crystalline needles on cooling. Soluble in amyl alcohol	Yellow in the cold, more orange on boiling. Soluble in amyl alcohol and in $CHCl_3$	Cherry-red colour, soluble in amyl alcohol, insoluble in $CHCl_3$
3 drops 2 % *p*-dimethylaminobenzaldehyde (in alcohol) and 1 ml. conc. HCl	No colour even on heating	No colour is given	Violet on boiling, deeper violet on adding 1 drop 2 % KNO_2. Insoluble in $CHCl_3$, soluble in amyl alcohol	Light rose, deepening on adding 1 drop 2 % KNO_2. Colour quickly goes orange and fades	Blue-violet colour on boiling, soluble in amyl alcohol and $CHCl_3$ to a pure blue solution. Addition of 1 drop 2 % KNO_2 gives intense blue colour, soluble in amyl alcohol and in $CHCl_3$	Red-violet colour soluble in amyl alcohol and $CHCl_3$ to a red-violet solution. Addition of 1 drop 2 % KNO_2 gives a more orange tint, soluble as before
3 drops 2 % *p*-dimethylaminobenzaldehyde (in alcohol) and 3 ml. fuming HCl	Orange on boiling. On adding 1 drop 2 % KNO_2 colour goes greenish yellow (soluble in amyl alcohol)	Orange on boiling. On adding 1 drop 2 % KNO_2 colour goes orange-red (soluble in amyl alcohol)	Similar to preceding test (above)	Red-violet colour on warming. Addition of 1 drop 2 % KNO_2 gives a deep blue-violet colour soluble in $CHCl_3$ to a deep blue-violet solution	Similar to preceding test (above)	Similar to preceding test (above)
1 drop conc. HCl and a few drops of very dilute $FeCl_3$	On warming first violet-red, then orange at higher temperatures	Orange-brown on boiling	Red-violet on boiling. Soluble in amyl alcohol	Orange solution on warming	Orange-red on boiling, intensified by 1 drop 2 % KNO_2	Very pale yellow on boiling. 1 drop 2 % KNO_2 gives a cherry-red colour
2 drops 1 % vanillin (in alcohol) and 3 ml. conc. HCl	Orange colour on boiling. Addition of 1 drop 2 % KNO_2 gives colour as in (1)	Orange on boiling. Addition of 1 drop 2% KNO_2 gives a deeper colour	Pale pink on boiling, soluble in amyl alcohol. Colour intensifies on adding 1 drop 2 % KNO_2, soluble in amyl alcohol to a pink-violet solution	Light purplish pink on boiling, insoluble in $CHCl_3$. Addition of 1 drop 2 % KNO_2 gives a deep violet colour soluble in $CHCl_3$	Permanganate colour on boiling, soluble in amyl alcohol and $CHCl_3$ to a violet solution. 1 drop 2 % KNO_2 gives a deep violet colour soluble as before	Deep orange colour soluble in amyl alcohol, almost insoluble in $CHCl_3$. Addition of 1 drop 2 % KNO_2 causes colour to fade
Shaken with 1 drop dimethylaniline and 3 ml. conc. HCl added	Orange on boiling	Orange on boiling	Pink on boiling, insoluble in $CHCl_3$, soluble in amyl alcohol	Blue-violet colour on heating, soluble in $CHCl_3$ giving a purple-red extract	Violet colour on boiling, soluble in amyl alcohol and in $CHCl_3$	Pale orange pink on boiling, partly soluble in $CHCl_3$, soluble in amyl alcohol
50 ml. solution, 0·5 ml. 1 % Na β-naphthoquinonemonosulphonate and 1 ml. 10 % KOH					No colour is formed	Blue colour develops in 15 mins. (or precipitate with strong solutions), soluble in $CHCl_3$ to an orange-red solution

acetic acid. However, aeration experiments showed that, in 48 hours, this acid gave rise to no indole, beyond the normal 1–2 % blank, when incubated with *Bact. coli* suspensions. No trace of skatole was observed. A culture filtrate at the end of the experiment gave reactions identical with the original indoleacetic acid solution, and there was no trace of any other derivative.

Equal quantities of β-indoleacetic acid and tryptophan were mixed and an aeration experiment performed; a normal curve for the production of indole from tryptophan was obtained, showing that indoleacetic acid is neither toxic to *Bact. coli* nor inhibitory of the production of indole.

Anaerobic experiments were also done with β-indoleacetic acid and *Bact. coli* suspension in order to determine if skatole could be formed under these conditions. After 50 hours' incubation the culture distillates showed no trace of indole or skatole. Salkowski E. and H. [1885] have shown that the sodium salt of indoleacetic acid when sown with a mixed putrefactive culture gave no indole or skatole.

β-Indolepropionic acid. This is the end-product of the anaerobic action of *Bact. coli* on tryptophan. Aeration experiments showed that it was not broken down to indole under aerobic conditions, as in 48 hours only the usual small blank was obtained. When mixed with tryptophan it did not inhibit the normal production of indole from this amino-acid. A culture filtrate was prepared at the end of the experiment; it gave tests identical with a solution of pure indolepropionic acid and there was no trace of indoleacetic acid or of any other derivative. These experiments show that the product of the anaerobic breakdown of tryptophan is quite unchanged when incubated with *Bact. coli* aerobically.

β-Indolepyruvic acid. In view of the oxidative nature of the breakdown of tryptophan to indole, it was thought possible that an initial stage might be an oxidative deamination to β-indolepyruvic acid. Some results by other workers with this derivative have already been mentioned. Aeration experiments were performed using freshly made suspensions of *Bact. coli*, but only the normal blank of 2 % indole was obtained in duplicate experiments (Fig. 1, curve *a*). Tests of the culture filtrate indicated that the acid was unchanged, and in addition identical derivatives with 2:4-dinitrophenylhydrazine were obtained from the culture filtrate and from a solution of pure indolepyruvic acid.

The usual experiment to test the possibility of the derivative itself inhibiting the formation of indole led to a surprising result. When a solution containing both indolepyruvic acid and tryptophan was aerated in the presence of *Bact. coli* suspension, 10–15 % more indole was formed than could have been derived from the tryptophan present. This is shown in curve *b* of Fig. 1. Curve *c* shows the formation of indole from the same weight of tryptophan as was used for *b*. The excess formation of indole is outside the limits of experimental error (see previous communication, Table I). Bearing in mind that Saito's [1933] experiments—in which indole was obtained from β-indolepyruvic acid—were conducted in the presence of an alternative source of nitrogen, it seemed of interest to try the effect of replacing tryptophan by other nitrogen compounds. Ammonia was chosen as the simplest possible.

In one experiment 30 mg. of ammonium sulphate were added to 20 mg. of indolepyruvic acid in 100 ml. of solution; in another the indolepyruvic acid was dissolved in dilute aqueous ammonia and the p_H adjusted to 7·4 (the ammonia present was equivalent to 300 mg. of ammonium sulphate). The results of aeration experiments with these solutions are shown in Fig. 1, curves *d* and *e*. It is seen that indole was formed in appreciable quantity (8–10 %) in the first 8–10 hours and then remained steady for 20 hours, after which there was a slight fall.

Since indole is continually lost by aeration (see previous paper, p. 650), the constant period is really a period of slightly increasing indole concentration reaching 1–2 % above the maximum recorded. The experiments are good duplicates, showing that increasing the concentration of ammonia has no effect. Further, the addition of more ammonium sulphate during the steady period did not increase the yield of indole.

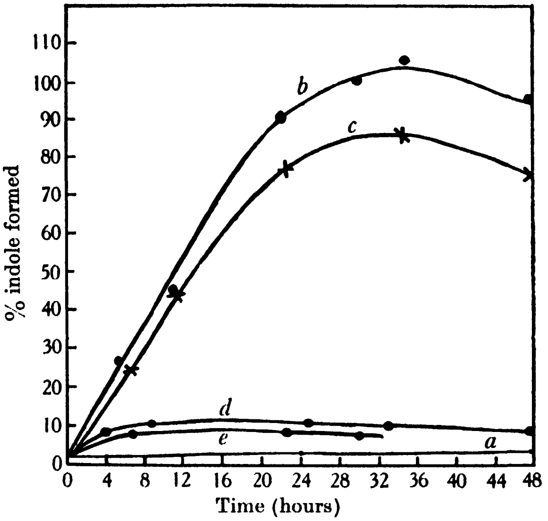

Fig. 1.

The effect of tryptophan in the experiment shown in curve *b* is probably due, therefore, to ammonia formed from the deamination of tryptophan during its breakdown to indole, for the amount of extra indole is approximately equal to the indole obtained in the presence of ammonia. The possible significance of these results will be discussed later.

The action of *Bact. coli* on β-indolepyruvic acid under anaerobic conditions was also tried. The usual proportions of substrate and suspension were incubated anaerobically for 48 hours and a protein-free filtrate prepared. On testing the filtrate there was no trace of β-indolepropionic acid and the indolepyruvic acid was unchanged.

β-Indoleacrylic acid. When an aeration experiment with *Bact. coli* was carried out there was no formation of indole beyond the normal 2 % blank. The possible inhibitory action of β-indoleacrylic acid on indole production was tested and a normal formation of indole from tryptophan was found. The addition of ammonium sulphate did not bring about any formation of indole, and in all cases tests on the culture filtrate showed the acid to be unchanged, no trace of any other indole compound being detectable.

Anaerobic experiments were also done:

(*a*) With indoleacrylic acid and *Bact. coli* suspension alone.

(*b*) With indoleacrylic acid and suspension in the presence of formate as a hydrogen donator (10 mg. sodium formate to 20 ml. of solution).

(*c*) With indoleacrylic acid and suspension in the presence of both formate and ammonium sulphate (10 mg. of each to 20 ml. of solution).

The culture filtrate after 50 hours' incubation showed no formation of indolepropionic acid in any of the experiments, and the indoleacrylic acid was unchanged.

DISCUSSION.

The growth experiments of Frieber [1922] were repeated in a number of cases (β-indolealdehyde, β-indoleacetic acid and β-indolepyruvic acid) by the washed suspension technique and his results were confirmed. It seems probable, therefore, that his other experiments, of which β-indole-ethylamine is of most physiological importance, would also be confirmed. This duplication of results provides support for the validity of the use of washed suspensions. Work described in the previous paper shows that a theoretical yield of indole can be obtained from tryptophan by the action of washed suspensions of *Bact. coli*; there seems little reason to doubt that, if any of the indole compounds used had been intermediates in the breakdown of tryptophan to indole, then they would have given rise to indole in something like quantitative yield, especially as in all the cases tried the derivatives themselves were not inhibitory of the normal production of indole from tryptophan.

The only case in which some indole was obtained—that of β-indolepyruvic acid—is of peculiar interest. In growth experiments, such as those of Saito [1933], it is reasonable that an alternative source of nitrogen should be necessary, since nitrogen is essential for growth of the organism and *Bact. coli* is not able to split the indole ring to obtain this nitrogen. But that an alternative source of nitrogen should be necessary for the formation of indole from indolepyruvic acid in washed suspension experiments must cast doubt on any suggestion that β-indolepyruvic acid is an intermediate, quite apart from the fact that only 8 % of the indole theoretically possible is obtained, compared with 100 % from tryptophan. A possible explanation of this formation, and also of the formation of indole from *dl*-β-indolelactic acid noted by Saito [1933], is that there is some synthesis of tryptophan from indolepyruvic acid and ammonia, and that this tryptophan is then oxidised in the usual way to indole.

It has been suggested, Harden [1930], that the bacterial decomposition of tryptophan occurs by the following route: tryptophan → β-indolepropionic acid → β-indoleacetic acid → indole. The work here reported gives no support to this hypothesis.

In the breakdown of tryptophan to indole, decarboxylation may either precede or follow deamination. In the former case β-indole-ethylamine should result, but Frieber's [1922] work showing that this amine does not give rise to indole with *Bact. coli* is evidence that this does not occur. In the latter case an oxidative deamination to β-indolepyruvic acid seems probable in view of the aerobic nature of the reaction, but, as has been already pointed out, experiment does not support this theory.

Raistrick [quoted by Cole, 1933] has suggested that the primary reaction in both aerobic and anaerobic breakdown of amino-acids by bacteria is a deamination to the unsaturated acrylic acid. This suggestion is based on the isolation of unsaturated acids from the corresponding amino-acids (histidine, tyrosine and aspartic acid) after bacterial action. Indoleacrylic acid has not, so far as the author knows, been reported as having been obtained in this way. The experiments which have been described show that β-indoleacrylic acid does not give rise either to indole aerobically or to indolepropionic acid anaerobically. Raistrick further suggests that the breakdown may proceed as follows:

$$R.CH_2.CH(NH_2).COOH \rightarrow R.CH{:}CH.COOH \rightarrow R.C(OH){:}CH.COOH \rightleftarrows$$
$$R.CO.CH_2COOH \rightarrow R.COOH \rightarrow RH.$$

This avoids β-indolepyruvic acid, but postulates instead a β-keto-acid as an intermediate product. This β-substituted compound would be very unstable and difficult to prepare in a free form, so it was not possible to test this experimentally. Since indole was produced from neither β-indoleacrylic acid nor β-indolecarboxylic acid, it seems unlikely that this series of reactions actually occurs. Indolecarboxylic acid has been detected by Berthelot [1914] in 15-day cultures of *B. proteus* on tryptophan-gelatin medium, but there is no justification for generalising from one bacterial species to another, and in any event the acid is probably a stable end-product formed under the given conditions.

It has been shown in the preceding paper that 5 atoms of oxygen are involved in the oxidation of the tryptophan molecule to indole, and that the side chain is completely oxidised to carbon dioxide, water and ammonia. It was also demonstrated that the rate of indole formation is limited by the rate of deamination of the tryptophan, but the results given in the present paper do not suggest any scheme for the course of the reaction. It is possible, as in all metabolic work, that the intermediate compounds are highly unstable substances of short lifetime which are passed on immediately from one enzyme to the next. The formation of indoleacetic acid as well as indole when the conditions are different [Hopkins and Cole, 1903] suggests that a series of reactions does occur, β-indoleacetic acid being the stable end-product of a branch from the main course of the action; it is improbable that indole is formed by a direct splitting off of the side chain of tryptophan from the indole nucleus.

SUMMARY.

1. The action of washed suspensions of *Bact. coli* on certain indole derivatives has been investigated.

2. There was no formation of indole from the following compounds: β-indolealdehyde, β-indolecarboxylic acid, β-indoleacetic acid, β-indolepropionic acid and β-indoleacrylic acid.

3. β-Indolepyruvic acid, but only in the presence of ammonia, gives rise to a 10 % production of indole.

It is a pleasure to record my thanks to Miss M. Stephenson for much advice and criticism and to Sir F. G. Hopkins for his interest in this work.

LXXVIII. THE PREPARATION OF SEMI-PERMEABLE SAC-MEMBRANES.

By JOHN DUCKWORTH.

Rowett Research Institute, Bucksburn, Aberdeen.

(*Received January 31st, 1935.*)

Prior to a series of studies on the partition of serum-calcium in the case of the lactating cow it was felt that a study of methods of preparing membranes and of their use in ultrafiltration would be advisable. A survey of the literature revealed a number of methods for the preparation of membranes but the time required for the manufacture and the manipulation of somewhat elaborate apparatus were definite obstacles. It was consequently felt that the introduction of a method which would give membranes capable of duplication by different workers and easy of preparation and manipulation would be advantageous.

Two contributions to membrane preparation which appear to have received little consideration are:

(1) Trendelenburg's method [1923] of casting membranes on the outside of test-tubes.

(2) Pierce's method [1927] of limiting the porosity of flat membranes by the use of ethylene glycol.

By combining these two methods the objective has been attained.

Reagents and apparatus.

7 °/₀ Collodion solution. B.D.H. collodion is analysed for nitrocellulose content and diluted with an alcohol-ether solution (1:1 by weight) until it contains 7 % by weight of nitrocellulose.

Membrane solution. To the 7 % nitrocellulose solution is added the requisite amount of ethylene glycol found to be satisfactory by experimental trial.

15 °/₀ gelatin solution in water.

Gies reagent [*1910*]. To 1 litre of 10 % KOH solution add 25 ml. of 3 % $CuSO_4$ solution.

Test-tubes. A small hole is blown in the tip of each test-tube. The size of test-tube required depends on the amount of serum available for analysis.

The ultrafiltration apparatus. It was felt that the elimination of automatic valves and compressed air cylinders would be advisable. Ultrafiltration is carried out at a positive pressure of 175–185 mm. of Hg. and the maintenance of this pressure for one hour, without attention, can be achieved by the use of the pressure unit herein described (Fig. 1).

A. Manometer to register 175–220 mm. Hg.

B. A tube containing a Bunsen valve. This valve is necessary since it is difficult to obtain a pressure bulb which does not allow some air-leakage.

C. A tube containing normal saline.

D. A Winchester bottle as a reservoir of compressed air.

E. A wide-mouthed bottle which connects the pressure unit with the individual ultrafiltration units. In our investigations four ultrafiltration units are connected to this bottle.

F. Serum reservoir.

G. Membrane.

H. Ultrafiltrate tube.

I. A wide-mouthed bottle containing physiological saline. Since the vapour pressures of normal saline and ultrafiltrates are practically identical the losses by evaporation are minimised.

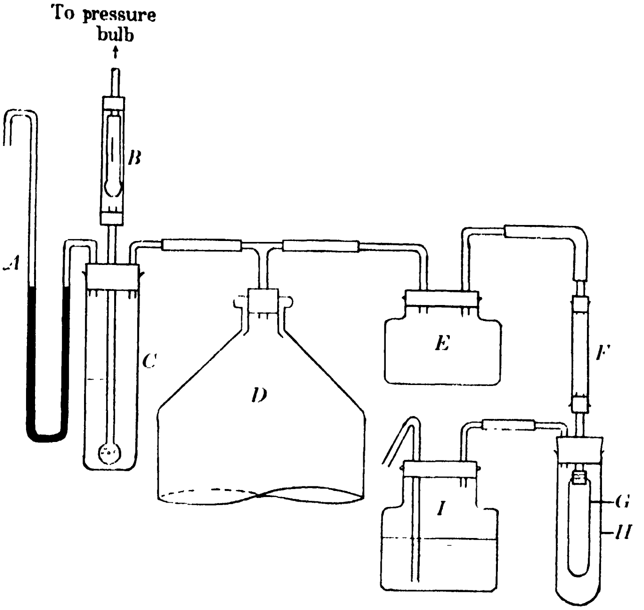

Fig. 1. Ultrafiltration apparatus.

Preparation of membranes. The test-tubes are coated with gelatin by dipping the stoppered tube into warm gelatin solution. The tubes are immersed to within 1 cm. of the lip, withdrawn and suspended in a special rack to drain and dry for several hours. The small hole in the tip should be sealed by a film of gelatin. Once dry these tubes can be stored until required.

To prepare the membrane the gelatined tube is dipped into the collodion-ethylene glycol solution to the required depth and slowly withdrawn. The tip of the tube is left in contact with the surface of the solution for a few seconds to facilitate draining and the tube is then rapidly transferred to the special rack and suspended. When removing the tube it is advisable to guard against drops of collodion falling into the solution, since this causes air-bubbles which will be picked up by subsequent tubes and cause faults in the membranes. The strand of nitrocellulose which forms at the tip of the tube as a result of draining is cut off as it forms, since the weight of it draws off too much nitrocellulose and results in fragile membranes. The entire preparation of the membrane should take about 20 seconds.

After the membranes have been drying in the rack for 20 minutes (exactly) the tube is filled with water and placed in a beaker of distilled water. The membrane should be entirely below the surface. After 1 hour or so the tubes are filled with warm water and shaken vigorously to dissolve the gelatin sealing the small hole at the tip of the tube and also to melt the gelatin film between the membrane and the glass. When the membrane slides free it is removed and filled with distilled water.

Instead of tying the membranes on to rubber stoppers it has been found more convenient to tie them on to pieces of rubber pressure tubing 1·5 cm. in length. When used in the ultrafiltration unit the glass tube connecting the membrane to the serum reservoir is somewhat larger than is generally used with this size of rubber tubing. The extra distension of the rubber is enough to cause the membrane to grip the tubing quite securely. This method was found to be so satisfactory that the connections of the serum reservoir are also made from rubber tubing instead of stoppers.

After being tied on to the rubber tubing the membrane is washed free from gelatin by shaking several times with distilled water. Finally the membrane is filled with distilled water and connected to the serum reservoir, which is then filled with distilled water, and 5 ml. of water are forced through the membrane at a pressure of 220 mm. of Hg. This removes the ethylene glycol and detects faulty membranes. It is advisable not to let the level of the water fall as low as the sac since the drying of any portion of the membrane will result in fragility at that point. When the membrane is removed it is filled to the top with distilled water and closed with a short glass rod. The membranes are stored in chloroform water until required.

Determination of ethylene glycol-nitrocellulose ratio. The proportion of ethylene glycol to nitrocellulose necessary to give a sac-membrane impermeable to serum proteins is slightly variable, depending on the sample of collodion.

To a series of tubes each containing a known amount of the 7 % nitrocellulose solution are added increasing amounts of ethylene glycol. The range employed is 1·5–2·0 ml. of ethylene glycol to 1 g. of nitrocellulose. Membranes are cast by the method described above and tested by ultrafiltering a sample of serum. Such membranes as show a negative biuret test when Gies reagent is added correspond to the maximum dilution permissible. It is advisable to keep somewhat below this.

So far it has been found that a proportion of 1·8 ml. of ethylene glycol to 1·0 g. nitrocellulose (*i.e.* 12·6 ml. of ethylene glycol to 100 ml. of the diluted collodion) gives uniformly biuret-negative filtrates.

Ultrafiltration method. When required for analytical purposes the membrane is rinsed out three times with serum, the washings being removed by means of a pipette, and filled with serum. The sac is then connected to the reservoir and the reservoir filled with serum. The pressure is raised to 180 mm. of Hg. and the outside of the sac dried with filter-paper. The ultrafiltrate appears almost immediately. After about 10 minutes the pressure is reduced to about 50 mm. (sufficient to keep the sac distended to facilitate handling) and the sac dried. The ultrafiltrate tube is then connected over the sac and the pressure raised to 185 mm. The pressure falls very gradually, usually to about 175 mm. in 1 hour.

RESULTS.

It is unnecessary to quote results regarding permeability. Sac-membranes made by this method were found to be completely permeable to aqueous solutions of $CaCl_2$ with a calcium content of 10 mg. per 100 ml.

The main point under investigation was that of duplication. Consequently three membranes each were made by four members of this Institute and used to prepare ultrafiltrates from a sample of serum obtained from slaughter-house blood. Each ultrafiltrate was analysed in triplicate. The results are shown in full in Table I.

Table I.

Results in mg. Ca per 100 ml. of ultrafiltrate.

Made by	Membrane number	Analysis 1	Analysis 2	Analysis 3	Average
A	1	6·0	6·0	6·1	6·0
	2	6·1	6·0	6·0	6·0
	3	5·9	6·1	6·0	6·0
B	1	5·8	5·9	5·8	5·8
	2	5·9	—	5·9	5·9
	3	5·9	6·0	5·9	5·9
C	1	5·8	5·9	5·9	5·9
	2	5·9	6·0	5·8	5·9
	3	6·0	5·9	—	6·0
D	1	6·0	5·9	6·0	6·0
	2	5·7	5·9	5·8	5·8
	3	5·8	5·9	6·0	5·9

The calcium estimations were by the method of Clark and Collip [1925]. The experimental error of this method is ± 2 %. A study of the results in Table I indicates that the variation in the calcium contents of the various ultrafiltrates was of this order. It would appear, therefore, that membranes made by the proposed method, and by different investigators, will yield identical results.

It is a point of interest that the membranes used in this experiment were two days old, with the exception of those prepared by D, which were over a week old. The results do not appear to be affected by the age of the membrane, at least within this limit. Also the membranes used were those prepared for the first time by all workers except D.

SUMMARY.

A method of preparing sac-membranes is described which will yield practically identical ultrafiltrates, at least in so far as the calcium is concerned, at the hands of different investigators.

LXXIX. THE ULTRACENTRIFUGAL PROTEIN SEDIMENTATION DIAGRAM OF NORMAL HUMAN, COW AND HORSE SERUM.

By ARTHUR SPROUL McFARLANE.[1]

From the Institute of Physical Chemistry, Upsala, Sweden.

(*Received February 1st, 1935.*)

It has been shown in a previous paper [McFarlane, 1935] that the diagrams which are obtained in the refractive index method of following protein sedimentation in the ultracentrifuge are capable of yielding a great deal of valuable qualitative and quantitative information relating to the composition of the protein solution in the centrifuge cell. In particular, they are capable of giving the concentration of each molecular fraction which separates in the centrifugal field and an estimate of the relative degree of dimensional homogeneity of the constituent molecules of each fraction. In the work to be reported here we have obtained the sedimentation diagrams for various sera and have attempted to establish the following general points: (1) the extent to which the ultracentrifugal sedimentation diagram is a strictly reproducible characteristic of a serum; (2) the nature and extent of any changes in the diagram caused by treating the serum in various ways; (3) whether the serum from a series of members of the same species gives the same sedimentation diagram; and (4) to what extent the serum diagram of normal members of different species is the same.

It is to be emphasised at the outset that the work which will be reported is essentially of the nature of a general survey of this new field of investigation, the object being more to discover the possibilities of the field as a whole than to establish any particular points in great detail.

Since each complete ultracentrifugal experiment takes some considerable time it has been necessary throughout to minimise the number of experiments. The evidence in regard to (1) is, therefore, largely obtained incidentally in the experiments designed to investigate (2) and (3). We have used cow serum in investigating the effect of treatment on the same sample of a serum because a large quantity was readily available to cover all the experiments. It was more convenient, and also of greater interest, to use human serum in investigating (3), and for the species comparison in (4) we have used human, cow and horse sera.

It is necessary to refer the reader to the previous paper [1935] for a full description of the theory and technique of an ultracentrifuge experiment and for the details of the methods of calculating the results. We shall require in the present communication to refer frequently to that paper.

SECTION 1. THE SEDIMENTATION DIAGRAM OF NORMAL COW SERUM.

In this section we shall describe a series of experiments all performed on the same sample of cow serum and designed to investigate the effect of treatment of various kinds on the sedimentation diagram of the serum.

---

[1] Beit Memorial Research Fellow.

A large sample of blood was obtained from a cow which had no signs or history of disease.[1] The blood was allowed to clot spontaneously and the serum was separated after 12 hours. Portions of this serum were used in the following experiments. During the period of these experiments (10 weeks) the serum was kept at 4° under sterile conditions, and no signs of decomposition could be detected.

A portion of the serum was placed in a collodion dialysis bag arranged as for an osmotic pressure measurement. The bag was placed in 10 times its volume of 1 % sodium chloride solution and the level of serum in the capillary kept constant by externally applied pressure from a water manometer. When equilibrium had been reached, as indicated by constant manometer pressure, the apparatus was dismantled and the refractive index of solution and dialysate measured by means of the Pulfrich refractometer and using the sodium D line. The dialysate gave a negative protein reaction with salicyclsulphonic acid. By subtracting the two values we obtained the total protein refraction increment of the serum, subject to the assumptions regarding the effect of the diffusible ion concentrations discussed in the previous paper.

In calculating protein concentrations from our refractometric data we have used the following specific refraction increment values throughout this work:

Protein	Specific refraction increment	Author
Horse serum albumin	0·00183	Adair and Robinson [1930, 1]
Horse serum globulin	0·00186	Adair and Robinson [1930, 1]
Total horse serum	0·00184	—
Human serum albumin	0·00200	Schretter [1926]
Human serum globulin	0·00219	Schretter [1926]
Total human serum	0·00202	Schretter [1926]
Cow serum albumin Cow serum globulin Total cow serum	0·00185	—

The value for total horse serum protein is a mean of Adair and Robinson's values for horse serum albumin and globulin, and the cow serum values are assumed to be the same as the horse and sheep serum values which Adair and Robinson have given. The use of these values can only give approximate concentrations because of these assumptions, and because there is a good deal of difference of opinion in the literature as to the exact values of the specific refraction increment of the serum proteins, and particularly of human serum protein [*cf.* Linder *et al.*, 1924; Starlinger and Hartl, 1925; Schretter, 1926]. In this work we are primarily concerned to measure and compare differences in refractive index (n_1-n_0), concentration measurements being of secondary importance. We have, therefore, not made any more accurate determinations of concentrations than are given by the refractometric data, and we have avoided basing any important conclusions on the concentration values given.

In order to be able to compare the measured refractivity of the protein with the value calculated from the sedimentation diagram we have applied to the measured values the wave-length correction factor which Pedersen and Andersson, as described in our previous paper [1935], have obtained for horse serum proteins, *viz.* 1·08.

Exp. 1. Untreated cow serum. A portion of the serum was examined in a centrifuge cell 2·0 mm. thick. The centrifuge reached 58,000 r.p.m. (equivalent to a mean centrifugal force of 240,000 times gravity) after 40 mins. and was kept at this speed to within ± 300 r.p.m. throughout the run which lasted a further 3 hours and 3 mins. up to the time of the last exposure.

---

[1] I am indebted to Med. Kand. O. Mellander for the supply of this serum.

It was found on viewing the scale from the camera when regular sedimentation had been established that an optical scale distance of 1·54 cm. gave satisfactory results, *i.e.* a large line displacement with good definition of the displaced lines, and this was used in all exposures. The temperature of the cell at the time of the first exposure (which we will call T_f) was 33·4°, and at the time of the last exposure (T_l) was 35·2°. The photographs were taken on Cramer plates using the mercury line at 366$m\mu$, which was isolated by means of a Corning nickel oxide glass filter. The exposure time was 25 secs., and the photographic enlargement factor 0·996.

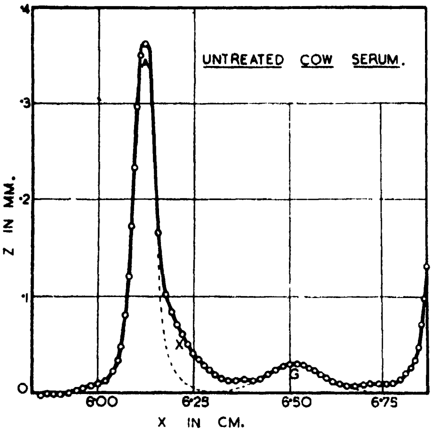

Fig. 1.

The curve shown in Fig. 1 was obtained from a photograph taken 108 mins. after reaching full speed. The position of the meniscus (not shown in the figure) is 5·64 cm. from the centre of rotation. It will be seen that three molecular fractions are present. $S_{W,20}$ for the lightest fraction is 2·67 and for the heaviest fraction is 4·60. These $S_{W,20}$ values are corrected for the density and viscosity of the electrolyte medium in which the protein is dissolved (*cf.* equation (5) of previous paper) but take no account of the concentration of the protein. The value of $S_{W,20}$ at infinite dilution (or the true sedimentation constant) of the *A* fraction may be obtained by extrapolating to infinite dilution a series of values of $S_{W,20}$ at various concentrations. It is not so easy to obtain the true sedimentation constant of the *X* or *G* fractions because it is necessary to take into account the effect of the concentration of the lighter fraction or fractions, as the case may be. In this work we are mainly concerned to identify a particular fraction, and for this purpose it is not necessary to obtain the extrapolated sedimentation constant. It is to be emphasised, however, that the $S_{W,20}$ values in this paper may not be compared with the true sedimentation constants published for other proteins, since these latter are all extrapolated and represent natural constants characteristic of the proteins and independent of the concentration. $S_{W,20}$ for the intermediate fraction cannot be obtained with any degree of accuracy because a clear separation of this curve from that of the lightest fraction was not obtained. We shall in future label the three fractions, in order of increasing sedimentation velocity, as *A* fraction (presuming a relationship with serum albumin); X fraction (of unknown nature); and G fraction (presuming a relationship with serum globulin).

It is impossible to produce here more than one curve from each experiment. This is a disadvantage because to obtain a complete picture of the sedimentation process it is necessary to consider all the curves.

We may discuss here in some detail a point of importance which arises in connection with the A and X fractions. We find in the case of cow serum the phenomenon of two boundaries which, in the process of sedimentation, reach the bottom of the cell without completely separating. The question arises whether under these conditions of incomplete separation we may attempt to resolve the composite curve graphically on the assumption that it consists of two symmetrical component curves. The problem is more comprehensible if we consider the boundaries in terms of protein concentration instead of refraction gradient. We have represented in Fig. 2A the refraction diagram of a hypothetical composite $A+X$ boundary with the corresponding protein concentration diagram shown in association with it (Fig. 2B). In both diagrams the component curves are represented by thin lines and the composite curve by a heavy line. Above the level "a" in the cell (*i.e.* to the left of the line "a" in the diagram) only A molecules are present, and we may therefore assume that the shape of this part of the curve will correspond to that of the sedimenting boundary curve of a pure solution of A molecules. As we have discussed in the previous paper, the concentration distribution of these molecules is determined by the forces of natural diffusion and an opposing force due to the variation of sedimentation velocity with concentration. Below the level "c" the shape of the curve should correspond to that of the boundary curve of a solution of X molecules sedimenting in a homogeneous medium of A molecules. Between

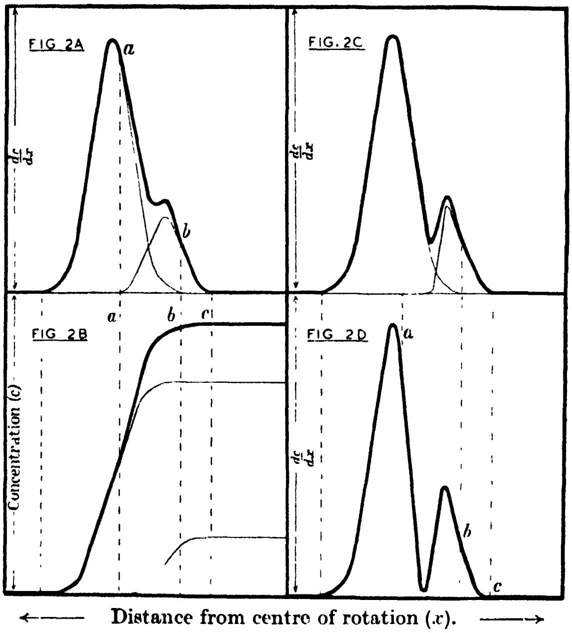

Fig. 2. Illustrating the type of curve-distortion caused by the overlapping boundaries in undiluted serum.

the levels "a" and "b' both molecular types are present in continuously varying concentration and it is difficult to visualise clearly the forces which will determine the ultimate shape of the composite concentration curve. It seems at least definite that in this region the X boundary gradient will be increased by the effect on the sedimentation velocity of the X molecules of the increasing concentration of A molecules as we proceed from "a" to "b". If this were the only factor present we should expect a composite curve of the type shown in Fig. 2c. Actually, however, we obtain curves of the general asymmetrical shape shown in Fig. 2D. The degree of distortion is not marked in the case of cow and horse sera but is characteristically pronounced in the case of untreated normal human sera. To explain the shape of this curve it is necessary to assume that in addition to the increase of the X concentration gradient there has also occurred an apparent "sharpening" of that part of the A boundary which lies between the levels "a" and "b", so that the limb of the curve nearer to the bottom of the cell comes to lie more vertically. It seems unlikely that this sharpening can be attributed to any effect of the concentration of X molecules on the sedimentation velocity of A molecules because the X molecules are sedimenting faster than the A molecules. It is possible, however,, that the diffusion of A molecules in this region will be influenced by the changing viscous effect of the solution of X molecules. The question of the influence of the charge on the molecules also arises, but a significant charge effect is regarded as unlikely in the presence of approximately 1 % neutral electrolyte. The possibility may not be excluded, however. It is not possible to obtain a more exact idea of the phenomenon until we have more data regarding the behaviour of the individual components of a mixture under the conditions of a simple diffusion experiment. We may note, however, that since the asymmetry shown in Fig. 2D is probably due to an external mechanical influence it should not affect the total area enclosed by the curve and the base-line.

When such an asymmetrical curve is obtained it may be questioned whether we know that the boundary is really composite and that the asymmetry is not due to some obscure mechanical factor acting on a homogeneous boundary. The evidence against this is (1) that the base of the curve is much too broad for a homogeneous boundary of the same sedimentation constant; (2) that in several experiments with human serum we have found an asymmetrical $A+X$ curve in the early exposures which separated later into two symmetrical curves; (3) in experiments with certain concentrated globulin solutions the depression of the boundary diffusion is much greater than in the case of undiluted serum and no apparent asymmetry of the curve is present.

The only method we know of attempting to resolve graphically such a composite curve as that shown in Fig. 2c is to locate the points "a" and "c", delete the portion of curve between these points and try to reconstruct the ideal component curves by consideration of symmetry. The procedure is only possible when the portion of curve to the left of "a" is substantially more than half the whole A curve, and even then the accuracy must be very limited. In the case of undiluted cow serum we have usually found that it is possible to reconstruct the A curve in an apparently reproducible way, but the X curve cannot be satisfactorily drawn. We have, therefore, obtained a very approximate value for the area of the X component curve by subtracting the area of the symmetrical A curve from the total boundary area.

The general results of the first experiment are collected in Table I.

As in the previous paper we have obtained a comparative value for the discrepancy between measured and calculated protein concentration (entitled

Table I. *Results obtained with undiluted cow serum.*

	Average $(n_1 - n_0)$ calculated* $\lambda = 366 m\mu$	Calculated protein concentration g./100 ml.	Average $S_{w,20} \cdot 10^{13}$
A fraction	0·00952	4·76	2·67
X fraction	0·00253	1·27	3·2 ± 0·3

Total protein	0·01454	7·28	—

Total $(n_1 - n_0)$, by refractometric measurement on the serum and its dialysate, and correction of the result to $\lambda = 366 m\mu$ ... ... 0·0153

Total protein concentration, measured... ... ... 7·64 g./100 ml.

* These values are obtained from the area of the component curves on the sedimentation diagram by means of equation (3) of the previous paper [1935]. They represent the refraction increments of the individual fractions. The value for the total protein is the sum of the calculated individual values and represents, therefore, the calculated refractive equivalent of the total area of the sedimentation curve.

"'% diff.' total protein") by subtracting the value for the total protein refraction increment calculated from the area of the sedimentation diagram from that obtained by measurement on the serum and its dialysate, and expressing the difference as a percentage of the latter.

"% diff." in total protein values ... ... −5·2 %.

The individual values for the *A* and *X* fractions are only to be regarded as approximate for the reasons already discussed, but the combined value is exact to the limits of the experimental accuracy of the method. The calculated proportion of the total protein which is represented by the *G* fraction is 17·1 %. The *A* boundary sediments to the bottom of the cell with a steady, but very slight, diminution in the breadth of the boundary, thus giving rise to a negative spreading coefficient.[1] We regard this as evidence in favour of the dimensional homogeneity of the molecules of the *A* fraction. The *G* boundary spreading coefficient can only be determined with a very low degree of accuracy and since, in any case, the values are bound to vary with the concentration of *A* molecules, and, therefore, have little significance, we shall ignore them.

Exp. 2. Undiluted cow serum heated to 56° for 2½ hours. The object of this experiment was to find if any change in the molecular dimensions of the serum proteins accompanies the destruction of the complementary substance in immunological reactions.

A different 2·0 mm. cell from that used in Exp. 1 was employed in this case, and an optical scale distance of 1·38 cm. was found suitable. Mean centrifugal

The curves are all so closely similar in shape to those in Exp. 1 that we have not reproduced a specimen here. The results are shown in Table II.

---

[1] The spreading coefficient is defined in the previous paper and is calculated according to equation (8) of that paper.

The only change which might be a possible accompaniment of the heat-inactivation process is an increase in the concentration of the *G* fraction with a compensatory decrease in the concentration of the *X* fraction. The change, however, is not great enough to enable this conclusion to be definitely drawn. In all other respects the data for the normal and heat-inactivated sera are identical.

Exp. 3. The effect of simple dilution on the sedimentation diagram of cow serum. In the first experiment 1 volume of cow serum was diluted with 4 volumes of 1 % sodium chloride and the solution was examined in a 2·0 mm. cell. Mean centrifugal force = 235,000 times gravity. Optical scale distance = 10·14 cm. $T_f = 32{\cdot}2°$. $T_l = 33{\cdot}6°$. Photographic enlargement factor = 0·993. The diagram shown in Fig. 3 was obtained from an exposure taken 84 mins. after reaching full speed, and Table III gives the results.

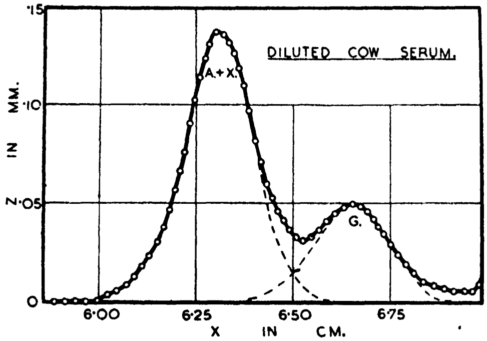

Fig. 3.

Spreading coefficient of *A* boundary	$6{\cdot}1 \times 10^{-7}$

Owing to the increased spreading of the boundaries it is impossible to say whether the *A* fraction is homogeneous or consists of *A* + *X* fractions. It will be noted that there has been a substantial relative increase in the concentration of the *G* fraction and that the percentage discrepancy between measured and calculated $(n_1 - n_0)$ has increased considerably as compared with the previous two experiments.

In a second experiment the serum was examined after dilution with 7 volumes of 1 % sodium chloride. A 4·0 mm. cell was used. Optical scale distance = 8·14 cm. Mean centrifugal force = 235,000 times gravity. $T_f = 31{\cdot}7°$. $T_l = 34{\cdot}5°$. Photographic enlargement factor = 0·996.

Spreading coefficient of *A* boundary ... ... $7{\cdot}7 \times 10^{-7}$

The relative concentration of the *G* fraction has not been increased by this further dilution and it appears probable, therefore, that the maximum "globulin" content of the serum obtainable by ultracentrifugal analysis is approximately 28 %. This will be referred to in a later paper where we shall have occasion to discuss the albumin and globulin concentrations in this serum obtained by precipitation methods. It is also of interest that the percentage discrepancy between measured and calculated $(n_1 - n_0)$ should again be so large in comparison with the case of undiluted serum. It suggests either that simple dilution of cow serum leads to the production of polydisperse protein or that in some way our technique is not exactly the same in the examination of concentrated and dilute solutions.

Exp. 4. Cow serum dialysed against 1 °/₀ sodium chloride. A sample of the cow serum was dialysed against several changes of 1 % sodium chloride until ionic equilibrium was obtained. During the process a slight dilution of the serum occurred. Cell thickness = 2·0 mm. Optical scale distance = 1·69 cm. Mean centrifugal force = 255,000 times gravity. $T_f = 32{\cdot}7°$. $T_l = 36{\cdot}9°$.

Table V. *Results obtained for cow serum dialysed against 1 °/₀ sodium chloride.*

Calculated proportion of *G* fraction ... ... 18·5 %
The spreading coefficient of the *A* boundary in this case is significantly zero.

We may note here the slightly increased sedimentation constants and boundary spreading coefficients as compared with the untreated serum in Exp. 1. These increases may be due to the dilution which occurred inadvertently during the dialysis.

It is also possible that the rather low value of $(n_1 - n_0)$ for the X fraction is due to the slightly increased spreading at the A and X boundaries which makes the graphical separation of the two curves more uncertain than usual. In general, however, we conclude from this experiment that dialysis against 1 % sodium chloride does not affect significantly the protein sedimentation diagram of undiluted cow serum.

Exp. 5. Cow serum dialysed against 0·1 °/₀ sodium chloride. The dialysed serum was examined in a 2·0 mm. cell with an optical scale distance of 2·28 cm. The fact that we were able to use this greater scale distance indicated early in the experiment that a significant change had occurred in the sedimentation diagram. Mean centrifugal force = 255,000 times gravity. $T_f = 32{\cdot}9°$. $T_l = 25{\cdot}2°$.

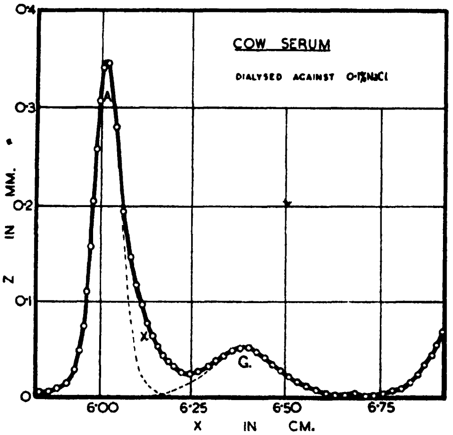

Fig. 4.

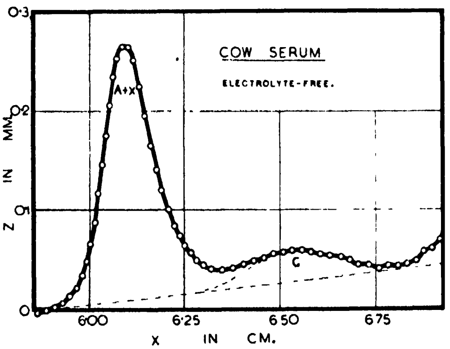

Fig. 5.

We reproduce in Fig. 4 the curve of an exposure taken 56½ mins. after reaching full speed. It will be seen on comparison with the curve for untreated serum in Fig. 1 that the two curves have the same general shape, but as the calculations show, the G curve in Exp. 4 has a definitely greater area than the G curve in Exp. 1, and the A curve in Exp. 4 has a smaller area than the A curve in Exp. 1. The sedimentation velocity of the G fraction appears to be abnormally high. The increase in the boundary spreading coefficient of the A fraction was expected since charged proteins tend to diffuse more rapidly in the presence of lower concentrations of diffusible electrolytes. In order to find if further reduction in the concentration of diffusible electrolytes would give rise to a further increase in the G fraction we examined next electrolyte-free cow serum.

Exp. 6. Electrolyte-free cow serum. The cow serum was dialysed for several days in a collodion bag against distilled water during which procedure a rather scanty flocculum of euglobulin collected at the bottom of the bag. The supernatant solution was then centrifuged in a 2·0 mm. cell. Mean centrifugal force = 255,000 times gravity. Optical scale distance = 3·78 cm. $T_f = 33{\cdot}8°$. $T_l = 35{\cdot}8°$.

Total $(n_1 - n_0)$, measured and corrected to $\lambda = 366 m\mu$ ...	0·011
Total protein concentration, measured	5·51 g./100 ml.

Fig. 5 shows the curve of an exposure taken 52½ mins. after reaching full speed. The base-line is sloping probably because of the high potential gradient set up in the solution by the movement of charged protein in an electrolyte-free medium. It is, therefore, not possible to make calculations of $(n_1 - n_0)$ from this curve which will have any precise significance, but we may obtain approximate values for the sedimentation constants of the A and G fractions. The values are:

$S_{W,20}$ for the A fraction	$3{\cdot}4 . 10^{-13}$
,, G ,, ...	$7{\cdot}4 . 10^{-13}$

It is impossible to say whether any X fraction is present or not.

The high value of $S_{W,20}$ for the G fraction conforms with the high value of the previous experiment. It may be due to charge effects or to an increase in the size of the G molecules. We may also notice in Fig. 5 the marked increase in the degree of spreading at both boundaries. In connection with certain arguments discussed in the previous paper concerning the charge on the proteins in untreated serum, this phenomenon certainly suggests that both fractions in electrolyte-free serum are charged. It may not be inferred, however, that the same is true of untreated serum until we have more evidence that the constitution of the soluble protein in serum is not affected by the removal of electrolytes.

Exp. 7. Cow serum dialysed against M/*20 acetate buffer.* p_H *4·6.* Cell thickness = 2·0 mm. Mean centrifugal force = 250,000 times gravity. Optical scale distance = 1·24 cm. $T_f = 33{\cdot}4°$. $T_l = 35{\cdot}9°$. The results are shown in Table VII.

Table VII. *Results with cow serum dialysed against* M/*20 acetate buffer.*

Calculated proportion of G fraction	19·4 %
Spreading coefficient of A boundary	$0{\cdot}3 \times 10^{-7}$

Owing to a certain amount of leakage from the cell at the beginning of this run the sedimentation path available was shorter than usual, with the result that the presumably merged A and X boundaries reached the bottom of the cell before any detectable separation of the two had time to occur. It was therefore only possible to calculate combined values for $(n_1 - n_0)$ and $S_{W,20}$, for this boundary. In all other respects, and taking into account the slight dilution during dialysis, we regard the curve as showing no significant points of difference from the curve of untreated cow serum.

Exp. 8. Cow serum dried and redissolved. A portion of the serum was rapidly dried under reduced pressure in a desiccator containing phosphorus pentoxide and then mixed with the same volume of water as there was serum originally. In spite of stirring the mixture gently at intervals for 24 hours a rather bulky greyish-brown residue remained. The clear solution after centrifuging off the insoluble material was then dialysed under pressure against 1 % sodium chloride until equilibrium was reached and the total protein concentration was approximately the same as that of the original serum. The solution was examined in a 2·0 mm. cell. Mean centrifugal force = 240,000 times gravity. Optical scale distance = 1·54 cm. $T_f = 33{\cdot}3°$. $T_l = 34{\cdot}4°$.

Fig. 6 shows the curve of an exposure taken 66 mins. after reaching full speed, and Table VIII shows the general results of the run.

Table VIII. *Results for cow serum which had been dried and redissolved.*

"% diff." in total protein values	−15·5 %
Calculated proportion of *G* fraction	17·3 %

The spreading coefficient of the *A* boundary has a negative value.

It will be seen from Table VIII and from Fig. 6 that the results generally are in rather close agreement with those for untreated cow serum, except that there is a greater disrepancy in the total protein values. The values of the sedimentation constant and spreading coefficient are in keeping with the slightly higher total protein concentration in this experiment than in Exp. 1, but the calculated value for $(n_1 - n_0)$ is definitely less. It appears, therefore, that, compared with the untreated serum, some 8–10 % more of the total protein in the redissolved serum is completely heterodisperse in the centrifugal field and does not show on the apparent base-line. It is of interest that, if we disregard this polydisperse protein and the insoluble protein left on redissolving the dried serum, the sedimentation characteristics of the remaining soluble protein after concentration and the concentration ratio of its constituent fractions should be so closely similar to those of the untreated parent serum.

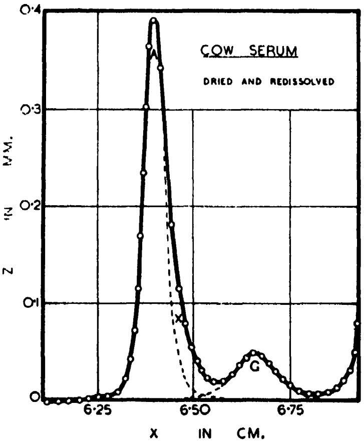

Fig. 6.

Exp. 9. Cow serum, dried, ether-extracted and redissolved. In order to investigate whether the serum lipoids have any influence on the character of the sedimentation diagram we have subjected a portion of the serum powder (prepared as in Exp. 8) to the action of warm ether in a Soxhlet extractor for 3 days. The residue in the extraction thimble was exposed to the laboratory atmosphere for a day to get rid of all traces of ether and then redissolved and dialysed against 1 % sodium chloride. As in the previous experiment there was a bulky residue of insoluble protein. The protein solution after dialysis was examined in a 2·0 mm. cell, using a mean centrifugal force of 255,000 times gravity. Optical scale distance = 2·88 cm. $T_f = 33·7°$. $T_l = 35·7°$.

Table IX. *Results for cow serum which had been dried, ether-extracted and redissolved.*

"% diff." in total protein values	−24·8 %
Calculated proportion of *G* fraction	20·6 %
Spreading coefficient of *A* boundary	$1·0 \times 10^{-7}$

The most notable feature is the fact that almost one-quarter of the total protein present has failed to appear on the diagram. A discrepancy of the same order was found in Exp. 3 using diluted cow serum and there we could not exclude the possibility that an error might arise owing to the different conditions (cell thickness, scale distance, time of experiment *etc.*) under which a dilute and a concentrated solution are examined. In this case we feel justified in drawing the definite conclusion that a considerable amount of polydisperse protein is present because the conditions of the experiment are practically identical with those in Exps. 1, 2, 4, 5, and 7, in which an average loss of only 5·5 % is recorded. It is also interesting to find in this experiment that the refraction equivalent of the total area of the curve of the first exposure, *viz.* 0·0107, is much higher than in the later exposures where it has a constant value of 0·00894. The spreading coefficient of the *A* boundary also appears to be high, but this may be due to the rather low concentration of the homogeneous protein which is present.

It is again interesting to find that in spite of the protein which was lost in the form of the insoluble residue, and of the polydisperse protein which fails to show its presence on the sedimentation diagram, the remaining protein appears to be normal from the sedimentation point of view. We should have expected that the protein loss would fall more heavily on one or other of the fractions. We must conclude from this that the denaturation process affects each fraction in proportion to the concentration in which it is present, or else that the three fractions are in equilibrium and removal of part of one fraction is followed by an internal molecular rearrangement which restores the fractions to their normal relative concentrations. This latter possibility does not seem to us unlikely in view of the equilibrium which exists in mixtures of serum albumin and globulin. We also conclude from this experiment that the serum lipoids which are extractable with ether do not exert an essential influence on the character of the sedimentation diagram.

Exp. 10. Cow serum in the presence of ammonium sulphate. In a preliminary test on a sample of cow serum it was found that globulin precipitation began when 3·9 ml. saturated ammonium sulphate had been added to 10 ml. of serum. We then added to a 1 ml. sample of the serum 0·3 ml. saturated ammonium sulphate and examined the clear solution in the centrifuge. The object of the experiment was to find whether any marked change is induced in the sedimentation diagram by ammonium sulphate in amount insufficient to cause precipitation. Cell thickness = 2·0 mm. Optical scale distance = 3·78 cm. Mean centrifugal force = 255,000 times gravity. $T_f = 33{\cdot}3°$. $T_l = 35{\cdot}4°$.

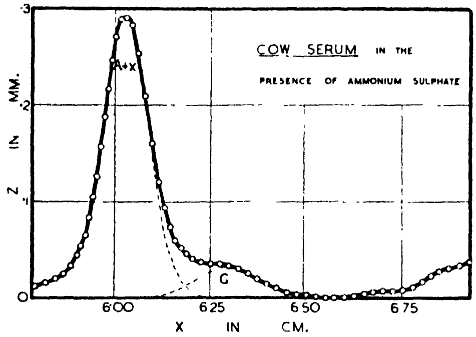

Fig. 7.

The curve shown (Fig. 7) was obtained from a photograph taken 88½ mins. after reaching full speed. This and other exposures show base-line irregularities which are due at least in part to sedimentation of the ammonium sulphate ions. Two fractions are present, and owing to the density and viscosity effects of the ammonium sulphate these sediment very slowly, the complete run requiring 4 hours. More blurring of the boundaries thus has time to occur with the result that no signs of a separation of the lighter fraction into *A* and *X* components can be seen. Also, owing to the abnormal conditions of sedimentation, we cannot say from the spreading coefficient of this boundary whether it is homogeneous or not.

Table X. *Results for cow serum in the presence of ammonium sulphate.*

	Average $(n_1 - n_0)$ calculated $\lambda = 366 m\mu$	Calculated protein concentration g./100 ml.	Average $S_{W,20} \cdot 10^{13}$
A fraction	0·00618	3·09	3·07
G fraction	0·00053	0·27	5·36
Total protein	0·00671	3·36	—

Total $(n_1 - n_0)$, measured and corrected to $\lambda = 366 m\mu$	0·00109
Total protein concentration, measured	5·46 g./100 ml.
"% diff." in total protein values	−38·5 %
Calculated proportion of *G* fraction	7·9 %

The individual values of $(n_1 - n_0)$ for the *A* fraction are interesting, *viz.* 6·64 after 88½ mins., 5·64 after 155 mins. and 5·77 after 204 mins. The spreading coefficients are also uneven—*e.g.* calculated between the exposures at 88½ and 155 mins. = $2{\cdot}46 \,.\, 10^{-7}$, and between the exposures at 155 and 204 mins. = $0{\cdot}86 \,.\, 10^{-7}$. As already pointed out, owing to the slow sedimentation we cannot compare these values with the spreading coefficients which we have determined in other experiments. It is, however, interesting to find a large degree of boundary spreading with falling $(n_1 - n_0)$ in the upper part of the cell and a much smaller degree of spreading with constant $(n_1 - n_0)$ in the lower part of the cell. The whole picture, including the marked discrepancy between measured and calculated total $(n_1 - n_0)$ values, leaves little doubt that a large part of the protein in the solution is polydisperse. Mutzenbecher [1933] has also found that ammonium sulphate causes a dissociation of the serum protein molecules prior to precipitation.

It is also to be noted that the percentage of the total protein refraction increment due to the *G* fraction is very low. It would appear in this case (as distinct from the state of affairs when serum is dried and redissolved) that the loss of protein has fallen more heavily on the *G* fraction. This we would expect since it is only necessary to increase the concentration of ammonium sulphate to the point of precipitation and the globulin fraction practically disappears altogether from the diagram.

Exp. 11. Cow serum treated with ammonium sulphate. In this experiment a collodion dialysis bag filled with cow serum and closed was immersed in a large volume of saturated ammonium sulphate. In a few minutes the serum protein precipitated completely and was left so for 24 hours. The bag was then removed from the ammonium sulphate solution and placed in 1 % sodium chloride solution which was changed frequently until the dialysate was free from sulphate ions. It was verified that no protein leakage had occurred through the bag, the change in the total protein refraction increment of the serum—from 0·00141 to 0·00132—being due to incidental dilution during the dialysis process. The serum was then examined in the same cell as was used in the previous experiment. Mean centrifugal force = 255,000 times gravity. Optical scale distance = 2·28 cm. $T_f = 32{\cdot}3°$. $T_l = 33{\cdot}7°$.

Table XI. *Results for cow serum treated with ammonium sulphate.*

The curve shown in Fig. 8 was obtained from a photograph taken 116½ mins. after reaching full speed. At the apex of the *A* curve there is definite evidence that this fraction is not homogeneous but consists of two molecular species present in approximately equal concentrations. The later exposures from this experiment show the same signs of an early process of resolution of the *A* curve into two curves of approximately equal areas—a process which is, however, still incomplete when the boundary reaches the bottom of the cell. The spreading coefficient of this boundary is $0{\cdot}25 . 10^{-7}$, which is in keeping with a heterogeneous fraction in view of the negative values obtained with the untreated serum.

In Fig. 9 we have shown the curve of a late exposure in Exp. 1 (untreated cow serum), and we have also superimposed on it the curve of the corresponding exposure from this experiment. Owing to the steeper boundary gradient in

Exp. 1 the two experiments were carried out with different scale distances. In order to make the two curves strictly comparable, therefore, we have recalculated each scale line position for the exposure in Exp. 11 to the same scale distance as used in Exp. 1, and these recalculated values are plotted in Fig. 9.

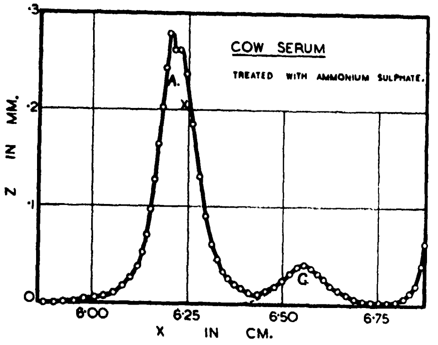

Fig. 8.

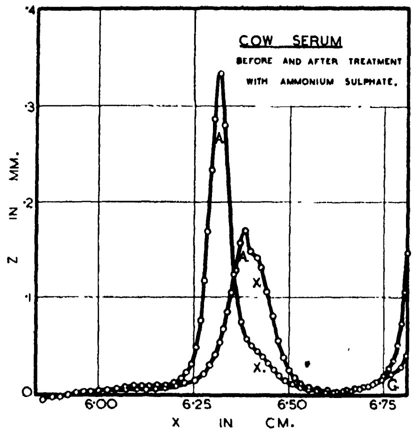

Fig. 9.

There still remains a difference in the total areas of the two curves owing to the slightly lower total protein area in Exp. 11. The difference is too small, however, to affect significantly the shape of the curves. A comparison of the two demonstrates the difference in the relative concentrations of the *A* and *X* molecules in the two cases much more strikingly than the figures which we have been able to give for the spreading coefficient of the *A* boundary in the two experiments.

We have generally preferred to base our conclusions with regard to the homogeneity of a sedimenting fraction on measurements of the actual boundary spreading which occurs between two levels in the cell rather than on measurements of the dimensions of one boundary curve after a given time. We regard this as more reliable because the dimensions of any particular boundary curve are dependent, among other things, on the time required to accelerate the centrifuge to full speed, and, possibly, also on the degree of convectional disturbances at the meniscus during this period. Also, of course, the dimensions are directly dependent on the scale distance, thickness of cell and photographic enlargement factor, which differ between experiments. On the other hand the effect of these latter variables may be eliminated by recalculating the scale line positions for one experiment to the conditions of the other as we have done here. In all our experiments also we have employed, as far as possible, a standard acceleration period for the centrifuge and approximately the same maximum speeds, and it has been our experience that boundary curves with significantly aberrant dimensions do not occur.

With due consideration of the many difficulties in the way of an exact comparison of the dimensions of curves from different experiments, we feel justified in including the evidence in Fig. 9 of gross changes in the dimensions of the curve together with that of the shape of the curve at the apex and the value of the boundary spreading coefficient as support for the view that ammonium sulphate causes an irreversible change in cow serum. The nature of the change may be defined as such that the concentration of the *X* molecular fraction is increased to a value comparable with that of the A fraction, and that the increase is at the expense of the A fraction. It will be shown in the next section that the same appears to be true for horse serum.

SECTION 2. THE SEDIMENTATION DIAGRAM OF NORMAL HORSE SERUM.

In the previous paper [McFarlane, 1935] we have published certain data and a curve from an experiment with fresh untreated horse serum. We pointed out there that the curve was not symmetrical, but to avoid confusing the special issue of that work, which it did not affect in essential principle, we passed over the question of this asymmetry and discussed the serum as a two-component mixture. In the light of the experiments which will now be reported it is necessary to regard horse serum with cow serum as having a heterogeneous lighter molecular fraction consisting of two component fractions which are only imperfectly separable in the centrifugal field. In this section we shall report the results of some experiments on horse serum which were undertaken largely in order to enable a comparison of the results with those obtained for cow serum.

Exp. 12. Untreated horse serum. We are indebted to Prof. Robin Fåhraeus for the supply of this serum from a horse which had not been immunised and had no signs or history of disease. The results of this experiment are taken from the previous paper and given here for purposes of comparison with later experiments. On Fig. 3 (*a*) of the paper referred to there will be found the curve of an exposure taken 117 mins. after reaching full speed. The experimental conditions were: Cell thickness = 2·0 mm. Optical scale distance = 2·14 cm. Mean centrifugal force = 230,000 times gravity. $T_f = 32{\cdot}3°$. $T_l = 34{\cdot}0°$.

Table XII. *Results for untreated horse serum.*

	Average $(n_1 - n_0)$ calculated $\lambda = 366\,m\mu$	Calculated protein concentration g./100 ml.	Average $S_{W,20} \cdot 10^{13}$
A fraction	0·00854	4·32	2·94

Calculated proportion of G fraction	20·2 %
Spreading coefficient of A boundary	$0{\cdot}8 \times 10^{-7}$

Exp. 13. Undiluted horse plasma. A sample of blood from the same horse and taken at the same time as the serum in Exp. 12 was collected in a vessel containing sufficient dry sodium oxalate to make an approximately 0·5 % solution in the plasma. The blood corpuscles were centrifuged off 2 hours later and the clear plasma examined in the same 2·0 mm. cell as was used in the previous experiment. Optical scale distance = 2·14 cm. Mean centrifugal force = 240,000 times gravity. $T_f = 32{\cdot}9°$. $T_l = 34{\cdot}1°$.

Fig. 10 shows the curve of an exposure taken 75 mins. after reaching full speed, and the results are shown in Table XIII.

A comparison of the results in Exps. 12 and 13 and of the curve of Fig. 10 with that of Fig. 3 (*a*) of the previous paper reveals a very close similarity in the characteristics of the serum and plasma of the same animal. The additional protein in the diagram of the plasma, corresponding to the fibrinogen which is removed in the clot, is represented apparently by slight increases in all

the fractions, but the most definite increase is clearly associated with the *G* molecule. We know from previous work that if some globulin were added to the serum used in Exp. 12 it would cause an increase both in the *G* curve and in the composite $A + X$ curve owing to the equilibrium which exists between those fractions. It appears possible then that the fibrinogen of oxalate plasma is present with a molecular weight approximately the same as that of the globulin fraction and that it takes part in the general protein equilibrium reaction of the serum. This would explain the slight increases in the *A* and *X* fractions. Without some such explanation as this we must assume that fibrinogen is not a single substance, but consists of two or three fractions of the same sedimentation constants as the corresponding serum fractions. As a result of this experiment we can say definitely that no new fibrinogen molecule appears in the diagram of the plasma. It is interesting to note in this connection that Verney [1926] found no significant difference in the osmotic pressure per g. of total protein in the case of serum and plasma from the same human subject, indicating that fibrinogen has approximately the same mean molecular weight as the mean molecular weight of the serum proteins.

Exp. 14. Defibrinated horse plasma. We have defibrinated a sample of oxalate plasma from another horse by a usual procedure, *viz.* by adding slightly more solid calcium chloride than is required to precipitate all the oxalate and then stirring vigorously with a glass rod. The shreds of fibrin were centrifuged off and the clear defibrinated plasma examined in the centrifuge in a 2·0 mm. cell. Optical scale distance = 1·54 cm. Mean centrifugal force = 235,000 times gravity. $T_f = 33{\cdot}4°$. $T_l = 34{\cdot}5°$.

Table XIV. *Results for defibrinated horse plasma.*

The preparation again was not dialysed before the experiment so that no measurements of total protein refractivity were made.

Calculated proportion of *G* fraction	20·8 %
Spreading coefficient of *A* boundary	$0{\cdot}3 \times 10^{-7}$

The curve shown in Fig. 11 is from an exposure taken 120½ mins. after reaching full speed.

It is interesting to find that, in spite of the fact that this serum contains considerably more protein than that of Exp. 12, the sedimentation diagram in the two cases is closely similar. The diminished sedimentation constants and spreading coefficient of the *A* boundary in the latter experiment are in keeping with the greater protein concentration.

Exp. 15. Horse serum treated with ammonium sulphate. We have undertaken this experiment in view of the change which had been noticed in the sedimentation diagram of cow serum as a result of treatment with ammonium sulphate. The experimental details were exactly as in Exp. 11 with cow serum. A specimen of the horse serum used in Exp. 12 was dialysed against a saturated solution of ammonium sulphate for 24 hours in a closed collodion bag. Thereafter, the serum was dialysed against changes of 1 % sodium chloride until all sulphate ions had disappeared from the dialysate. Cell thickness = 2·0 mm. Mean centrifugal force = 250,000 times gravity. $T_f = 33{\cdot}6°$. $T_l = 36{\cdot}5°$.

Table XV. *Results for horse serum treated with ammonium sulphate.*

	Average $(n_1 - n_0)$ calculated $\lambda = 366\,m\mu$	Calculated protein concentration g./100 ml.	Average $S_{W,20} \cdot 10^{13}$

G fraction	0·00290	1·44	5·01
Total protein	0·01126	5·67	—

Total $(n_1 - n_0)$, measured and corrected to $\lambda = 366\,m\mu$	0·00130
Total protein concentration, measured	6·54 g./100 ml.
"% diff." in total protein values	−13 %
Calculated proportion of *G* fraction	25 %
Spreading coefficient of *A* boundary	$2{\cdot}2 \times 10^{-7}$

The curve shown in Fig. 12 was obtained from a scale photograph taken 95½ mins. after reaching full speed. It will be seen that this *A* curve shows no signs of dividing into two as was the case with cow serum. It will have been noted, however, in the horse serum experiments that we have never found any negative values for the spreading coefficient of the *A* boundary such as occurred frequently in the cow serum experiments. In general, the degree of *A* boundary spreading is greater in the horse serum experiments and this may be due to the lower total protein concentration in the horse serum and the slightly greater proportion of *G* fraction. We believe this increased boundary spreading to be the reason for the apparent monodispersity of the *A* boundary in this experiment.

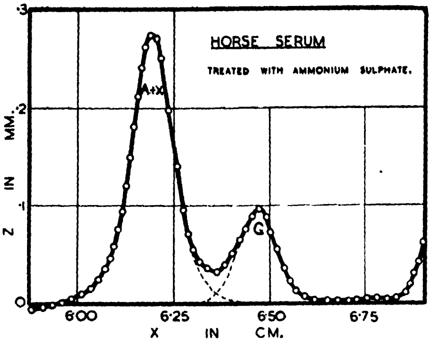

Fig. 12.

On the other hand, the *A* curve in all exposures is perfectly symmetrical, the boundary spreading coefficient appears to be abnormally high, and if the curve in Fig. 12 is replotted to the same scale distance as the curve for the original untreated serum it is seen that there has been a marked change in the general dimensions of the boundary curve similar to the change shown for cow serum in Fig. 9.

In the previous paper we have described an experiment in which albumin and globulin were prepared from this serum by fractionation with ammonium sulphate and then mixed together to form a so-called "synthetic" horse serum. A curve from this experiment is shown in Fig. 3 (*b*) of that paper, and in it, as in all the curves of that experiment, the *A* boundary curve is perfectly symmetrical.

For these reasons we believe that in the treatment of horse serum as well as cow serum with strong solutions of ammonium sulphate a definite change, which the ultracentrifuge is just able to detect and little more, occurs in the composition of the lighter molecular fraction.

We may not attach any particular significance to the high proportion of *G* fraction in this experiment because it will be noted that slight dilution of the serum has occurred during the dialysis. The data of the previous paper, supported by further evidence derived from the next experiment, show that the concentration relationship of the fractions in horse serum is exceedingly sensitive to changes in the total protein concentration—much more so than in the case of cow serum.

Exp. 16. Horse serum diluted with 3 volumes of 1 °/₀ sodium chloride. A sample of the serum used in Exp. 12 was diluted with 3 volumes of a 1 % solution of sodium chloride and examined in a 2·0 mm. cell using an optical scale distance of 8·78 cm. Mean centrifugal force = 250,000 times gravity. $T_f = 32{\cdot}2°$. $T_l = 33{\cdot}2°$. Photographic enlargement factor = 0·996.

The curve in Fig. 13 was obtained from an exposure taken 48 mins. after reaching full speed. In the resolution of this curve into *A* and *G* components
